- (2) Incubate at 35°C to the stationary phase (visual inspection must show very dense turbidity [4.0 McFarland standard] corresponding to 10⁹ CFU/ml).
 - (a) *Enterobacteriaceae*, 2 to 8 h
 - (b) *Pseudomonas*, 4 to 8 h
 - (c) Others, 4 to 8 h

e. Selection of inoculum preparation method

- (1) Direct colony suspension
 - (a) Use for bacteria that grow slowly or unpredictably in broth.
 - (b) Always use for staphylococci.
 - (c) Use for any organism when fresh (18- to 24-h) growth is available.
 - (2) Log-phase or stationary-phase method
 - (a) Use for nonfastidious rapidly growing bacteria when fresh colonies are not available.
 - (b) If desired, use for nonfastidious rapidly growing bacteria when fresh growth is available.
2. For the intermediate dilution, calculate the volume of standardized suspension to be added to 40 ml of water-Tween 80 diluent to obtain a final organism concentration of approximately 5×10^5 CFU/ml in each microdilution well. For prongs that deliver 0.01 ml, use the following.

Inoculum preparation method	Equivalent organism concn (CFU/ml) (McFarland 0.5)	Amt (ml of organism suspension to add to 40-ml water blank)	Dilution	Organism concn/ml in 0.1-ml well
Log-phase growth or direct colony suspension	1.5×10^8 (McFarland 0.5)	2.0	1:20	5×10^5 – 8×10^5
Stationary-phase growth	10 ⁹ (McFarland 4 or higher)	0.2	1:200	5×10^5 – 6×10^5

C. Inoculation

1. Transfer the appropriate volume of well-mixed organism suspension to the water-Tween 80 diluent with a micropipette (or other pipette).
2. Gently mix by inverting five or six times (try to avoid producing air bubbles).
3. Within 1 h (immediately if testing fastidious organisms), inoculate the MIC tray.
4. Inoculation with disposable plastic inoculators that deliver 0.01 ml
 - a. Remove inoculator-reservoir set from its plastic packaging.
 - b. Pour diluted inoculum into inoculum tray reservoir.
 - c. Dip prongs into the inoculum suspension.
 - (1) Orient the sterility well so that it does not get inoculated.
 - (2) Press down on the inoculator firmly to ensure that all prongs have come in contact with the inoculum in the reservoir tray.
 - (3) Carefully remove prongs from inoculum.
 - d. Inoculate the MIC tray by dipping the filled prongs carefully into the MIC tray. Press down on the inoculator firmly to ensure that all prongs have come in contact with the antimicrobial solutions in the tray.
 - e. Discard the prongs as biohazardous waste.

POSTANALYTICAL CONSIDERATIONS

VI. REPORTING RESULTS

A. Interpretation

Interpret MICs based on criteria specified by the NCCLS (1).

B. Reporting

Report the MIC along with its categorical interpretation: susceptible (S), intermediate (I), or resistant (R).

Example: *E. coli*

Drug	MIC (µg/ml)	Interpretation
Ampicillin	>32	R
Cefazolin	1	S
Piperacillin	32	I
Gentamicin	1	S
Trimethoprim-sulfamethoxazole	≤0.5/9.5	S

C. Important reporting rules

- Report methicillin-, oxacillin-, or nafcillin-resistant staphylococci as resistant to all beta-lactam drugs (including beta-lactam–beta-lactamase inhibitor combinations, all cepheems, all penicillins, and carbapenems) regardless of results of in vitro susceptibility testing.
- If test organisms require a nonstandardized method, or if organisms other than the *Enterobacteriaceae*, *P. aeruginosa*, *Acinetobacter* spp., *Stenotrophomonas maltophilia*, *Pseudomonas* spp., *Staphylococcus* spp., *Enterococcus* spp., *Haemophilus* spp., *S. pneumoniae*, and *Streptococcus* spp. are tested by these methods, add a comment to the report stating that susceptibility testing has been performed by a nonstandardized method (e.g., for *Corynebacterium* spp. tested in lysed horse blood MIC panels).
- Misleading results

Specific organism-drug combinations should not be reported, since susceptible results could be *dangerously misleading*:

 - First- and second-generation cephalosporins and aminoglycosides against *Salmonella* spp. and *Shigella* spp.
 - Cephalosporins, trimethoprim-sulfamethoxazole, clindamycin, and aminoglycosides (except for high-level-synergy testing for aminoglycosides) against enterococci
 - Cephalosporins against *Listeria* spp.
 - Beta-lactams against oxacillin-resistant *Staphylococcus* spp.
 - Cephalosporins, penicillins, and aztreonam against ESBL-producing *E. coli* and *Klebsiella* spp.
- For staphylococci and penicillin
 - MIC of 0.03 µg/ml, report penicillin susceptible
 - MIC of 0.25 µg/ml, report penicillin resistant
 - MIC of 0.06 to 0.12 µg/ml and beta-lactamase negative, report penicillin susceptible
 - MIC of 0.06 to 0.12 µg/ml and beta-lactamase positive, report penicillin resistant

VII. PROCEDURE NOTES**A. Oxacillin (methicillin)-resistant staphylococci**

1. Oxacillin is the recommended penicillinase-stable penicillin for testing, and oxacillin results can represent all penicillinase-stable penicillins (oxacillin, methicillin, and nafcillin and also cloxacillin, dicloxacillin, and flucloxacillin). Testing of oxacillin with staphylococci should be performed in CAMHB supplemented with 2% NaCl (other drugs should not be tested in 2% NaCl-supplemented CAMHB).
2. Clues to detection of methicillin (oxacillin)-resistant *S. aureus*
 - a. Multiple resistance to other antimicrobial agents (beta-lactams, aminoglycosides, erythromycin, clindamycin, and tetracycline). Recently, strains of oxacillin-resistant *S. aureus* that are not multiply resistant have been encountered among isolates from patients, primarily with community-acquired infections.
 - b. Subtle growth in wells containing oxacillin, methicillin, or nafcillin

B. Media

1. Thymidine can interfere with performance of sulfonamides and trimethoprim. Monitor media by testing *E. faecalis* ATCC 29212 and trimethoprim-sulfamethoxazole (MIC of $\leq 0.5/9.5$ $\mu\text{g/ml}$ indicates acceptable performance). Blood components (other than horse blood) contain thymidine and should not be used.
2. An increase in the cation content (Ca^{2+} , Mg^{2+}) of the medium results in an increase in the MICs of aminoglycosides for *P. aeruginosa* and an increase in the MICs of tetracycline for all organisms. A decrease in cation content has the opposite effect. Monitor cation content by testing aminoglycosides with *P. aeruginosa* ATCC 27853 and making sure results are within defined QC limits.
3. Increased zinc ions may cause decreased zone sizes with carbapenems.
4. Variation in calcium ions affects the results of daptomycin tests.

C. Materials

1. When supplements (e.g., lysed horse blood) are added to individual wells of antimicrobial broth, the diluting effect need not be considered providing the amount added is less than 10% of the total volume in the well.
2. Although it is preferable to store MIC trays at -70°C , it is often acceptable to store frozen panels without imipenem and combinations with clavulanic acid at -20°C . Imipenem and clavulanic acid are more temperature labile than many other drugs and require -70°C storage. Follow storage recommendations of manufacturer.

D. Inoculum preparation

1. The stationary-phase method of inoculum preparation is not an NCCLS-recommended method; however, this method is suggested as an alternative for several commercial systems. Since the critical factor in inoculum preparation is the final concentration of viable organisms in each microdilution well (approximately 5×10^5 CFU/ml), the stationary-phase method will produce satisfactory results for nonfastidious rapidly growing organisms providing the correct number of organisms is obtained. It is assumed that incubation to stationary phase will produce a suspension containing approximately 10^9 CFU/ml.
2. Alternative inoculating devices, such as semiautomated inoculators, may be used to inoculate MIC trays. Follow the manufacturer's instructions to achieve a final concentration of approximately 5×10^5 CFU/ml.

E. Reading MICs

1. With bacteriostatic antimicrobial agents such as chloramphenicol, erythromycin, and clindamycin, very slight hazes may persist through several di-

VII. PROCEDURE NOTES

(continued)

- lutions. Similarly, very slight hazes and/or pinpoint buttons (≤ 2 mm) may persist through all dilutions of trimethoprim-sulfamethoxazole. These should be ignored. Hazes should not be ignored for resistance that may be subtle, such as that encountered with oxacillin or vancomycin and staphylococci or vancomycin with enterococci.
2. When skipped wells occur, it may be necessary to repeat the MIC test. Skipped wells are indicated by growth at higher concentrations of an antimicrobial agent and no growth at one or more of the lower concentrations. This may occur as a result of the following.
 - a. Contamination at higher dilutions
 - b. Inadequate numbers or organisms inoculated into the wells
 - c. Wells not inoculated properly owing to improper alignment of inoculating pins or prongs
 - d. Peculiarity of the test organism (e.g., it might contain a resistant subpopulation)
 - e. Improper concentrations of antimicrobial agents in the wellsEach skipped well case must be evaluated individually to determine if the test should be repeated.
 3. Contamination may not always be detected using a purity plate since only a very small volume of the inoculum is sampled. The appearance of growth in the microdilution tray wells must be examined closely, and peculiar growth patterns, skipped wells, and/or atypical antibiograms should be investigated.
 4. Reproducibility of broth microdilution MIC testing is generally within ± 1 twofold dilution.

VIII. LIMITATIONS

- A. The basic procedure described here has been standardized for testing commonly isolated bacteria that grow well after overnight incubation in CAMHB. Various modifications have been made for testing some of the more fastidious and special problem pathogens such as *Haemophilus* spp., *S. pneumoniae*, and *Streptococcus* spp. (see appendixes to this procedure).
- B. Because of the small number of organisms tested in each well (approximately 5×10^4 CFU/well), resistance by a small subpopulation may not always be detected with the broth microdilution MIC method.
- C. NCCLS M7-A6 (1) establishes MIC breakpoints based in part on blood levels following standard dosing. For optimal use of MICs, the MIC should be correlated with the presumed antimicrobial agent concentration at the infection site.
- D. Numerous factors can affect results, including inoculum size, rate of growth, formulation and pH of media, incubation environment and length of incubation, drug concentration, and measurement of endpoints. Strict adherence to protocol is required to ensure reliable results.
- E. Emergence of resistance
Some bacteria may become resistant during antimicrobial therapy. Performing susceptibility testing on subsequent isolates after 3 or 4 days is recommended for the following.
 1. *Enterobacter*, *Citrobacter*, and *Serratia* for cephalosporins
 2. *P. aeruginosa* for all antimicrobials
 3. Staphylococci for quinolones
- F. Additional QA measures
Following recommended QC procedures alone does not guarantee prevention of reporting erroneous results for isolates from patient specimens. A mechanism to flag atypical results is an integral component of an effective QA program. A protocol for verification of unusual results should be included in the susceptibility testing procedures (see procedure 5.13).

APPENDIX 5.2–1

Quick reference list for performing broth microdilution MIC tests^a

Organism (s)	Medium	Inoculum method	Incubation length (h)	Incubation atmosphere ^b	Notes
<i>Enterobacteriaceae</i>	CAMHB	DCS/LPG	16–20	Ambient air	
<i>Pseudomonas aeruginosa</i> and <i>Acinetobacter</i> spp.	CAMHB	DCS/LPG	16–20	Ambient air	
Other <i>Pseudomonas</i> spp.	CAMHB	DCS/LPG	16–20	Ambient air	
<i>Haemophilus</i> spp.	HTM broth	DCS	20–24	Ambient air	Perform beta-lactamase test.
<i>Neisseria meningitidis</i> ^c	CAMHB with 2–5% LHB	DCS	24	CO ₂	Presumptive
<i>Staphylococcus</i> spp.	CAMHB; CAMHB with 2% NaCl for oxacillin	DCS	16–20; 24 (oxacillin ^d and vancomycin)	Ambient air	
<i>Enterococcus</i> spp.	CAMHB; BHI for GM 500 and STR 1,000	DCS/LPG	16–20; 24 (vancomycin and GM 500); 48 (STR 1,000)	Ambient air	Perform beta-lactamase and high-level amino-glycoside screen on blood and CSF isolates.
<i>Streptococcus pneumoniae</i>	CAMHB with 2–5% LHB	DCS	20–24	Ambient air (CO ₂ if needed)	Determine penicillin (not oxacillin) and cefotaxime or ceftriaxone MIC when ≤ 19 -mm oxacillin zones appear on the disk diffusion test.
<i>Streptococcus</i> spp.	CAMHB with 2–5% LHB	DCS	20–24	Ambient air (CO ₂ if needed)	Determine penicillin MIC for viridans group streptococci from endocarditis patients.
<i>Listeria</i> ^c	CAMHB with 2–5% LHB	DCS	16–20	Ambient air	Presumptive
Others ^c	CAMHB or CAMHB with 2–5% LHB	DCS	16–24	Ambient air (CO ₂ if needed)	Presumptive

^a DCS, direct colony suspension standardized to a 0.5 McFarland turbidity standard; DCS/LPG, direct colony suspension or log-phase growth standardized to a 0.5 McFarland turbidity standard; HTM, *Haemophilus* test medium; LHB, lysed horse blood; GM, gentamicin; STR, streptomycin.

^b All incubation temperatures are 35°C.

^c Tests for these species not fully addressed by the NCCLS; “presumptive” indicates that at least parts of the procedure are nonstandardized.

^d And other penicillinase-stable penicillins.

APPENDIX 5.2–2

Broth microdilution QC (see p. 5.2.16)

APPENDIX 5.2–3

Haemophilus* spp.*PREANALYTICAL CONSIDERATIONS**

A. SPECIMEN

Isolated colonies of similar colony morphology grown overnight on CHOC

B. SUPPLEMENTAL MATERIALS

1. CHOC

Store at 2 to 8°C.

2. Prepared broth microdilution trays utilizing *Haemophilus* test medium (HTM)

Store at –70°C.

3. Photometric standardizing device (e.g., bench top spectrophotometer) for 0.5 McFarland turbidity and test tubes that will fit this device

ANALYTICAL CONSIDERATIONS

C. QC STRAINS

1. *H. influenzae* ATCC 492472. *H. influenzae* ATCC 497663. *E. coli* ATCC 35218 (for beta-lactam–beta-lactamase inhibitor combinations)4. Refer to NCCLS *Haemophilus* QC table for acceptable QC ranges (1).

D. PROCEDURE

1. Prepare inoculum by using a direct colony suspension in Mueller-Hinton broth or 0.9% NaCl from a fresh (18- to 24-h) CHOC plate.

2. Use a photometric device to adjust turbidity to match a 0.5 McFarland turbidity standard (1×10^8 to 2×10^8 CFU/ml). This step is recommended to avoid erroneous results due to under- or overinoculation.

3. Without delay, prepare intermediate dilution and inoculate the MIC tray and purity plate as previously described.

4. Incubate for 20 to 24 h at 35°C in ambient air.

E. READING RESULTS

Read MICs as described for nonfastidious organisms.

POSTANALYTICAL CONSIDERATIONS

F. REPORTING RESULTS

1. Refer to NCCLS *Haemophilus* interpretive table for MIC interpretation; refer to NCCLS *Haemophilus* QC table for QC ranges (1).

2. Only the susceptible interpretation is defined in NCCLS tables for several cephalosporins, carbapenems, aztreonam, macrolides, and fluoroquinolones because no (or very few) resistant strains have been reported to date. Confirm identification and susceptibility results for all isolates which are not susceptible to these agents, save isolate, and submit to a reference laboratory for testing using an NCCLS dilution reference method.

G. NOTES

1. Beta-lactamase-positive *Haemophilus* spp. are resistant to ampicillin and amoxicillin regardless of the MICs.

2. Occasional isolates are beta-lactamase negative and ampicillin resistant. Consider these resistant to amoxicillin-clavulanic acid, ampicillin-sulbactam, cefaclor, cefamandole, cefetamet, cefonicid, cefprozil, cefuroxime, loracarbef, and piperacillin-tazobactam despite in vitro results.

3. For life-threatening *Haemophilus* infections (e.g., meningitis, bacteremia), report only ampicillin, a third-generation cephalosporin, chloramphenicol, and meropenem.**Reference**

1. NCCLS. 2003. *Methods for Dilution Antimicrobial Susceptibility Tests for Bacteria That Grow Aerobically*, 6th ed. Approved standard M7-A6. NCCLS, Wayne, Pa.

APPENDIX 5.2–4

Streptococcus pneumoniae and *Streptococcus* spp.**PREANALYTICAL CONSIDERATIONS**

A. SPECIMEN

Isolated colonies of similar colony morphology grown overnight on BAP

B. SUPPLEMENTAL MATERIALS

Prepared broth microdilution trays utilizing CAMHB supplemented with 2 to 5% lysed horse blood

Store at -70°C .

ANALYTICAL CONSIDERATIONS

C. QC STRAIN

1. *S. pneumoniae* ATCC 49619

2. Refer to NCCLS *S. pneumoniae* and *Streptococcus* QC table for acceptable QC ranges (1).

D. PROCEDURE

1. Prepare inoculum by using a direct colony suspension in Mueller-Hinton broth or 0.9% NaCl from fresh (16- to 18-h) growth on BAP.

2. Adjust turbidity visually to a 0.5 McFarland turbidity standard or use a photometric device.

3. Without delay, prepare intermediate dilution and inoculate MIC tray and purity plate as previously described.

4. Incubate for 20 to 24 h at 35°C in ambient air (CO_2 only if necessary).

E. READING RESULTS

1. Read MICs as described above for nonfastidious organisms.

2. Only the susceptible interpretation is defined for vancomycin and linezolid for all streptococci and for penicillin, ampicillin, and extended-spectrum cephalosporins for beta-hemolytic streptococci because resistance has not been observed. Confirm identification and susceptibility results for all isolates which are not susceptible to these agents, save isolate, and submit to a reference laboratory for testing using an NCCLS dilution reference method.

POSTANALYTICAL CONSIDERATIONS

F. REPORTING RESULTS

Refer to NCCLS *S. pneumoniae* and *Streptococcus* interpretive tables for MIC interpretation (1).

G. NOTES

1. *S. pneumoniae*

a. Pneumococci may lyse rapidly in liquid (particularly water). Therefore, follow the inoculum preparation procedure described here precisely and inoculate the MIC tray immediately after standardization of the inoculum suspension.

b. Penicillin-resistant *S. pneumoniae* does not produce beta-lactamase; do not use a beta-lactamase test to predict penicillin resistance.

2. Nutritionally variant streptococci (*Abiotrophia adiacens* and *Abiotrophia defectiva*)

a. When supplementing with pyridoxal (for nutritionally variant streptococci), the final concentration should equal 0.001% or 1 $\mu\text{g}/\text{ml}$ (pyridoxal stock, 1,000 $\mu\text{g}/\text{ml}$; add 0.2 ml to 9.8 ml of broth [20 $\mu\text{g}/\text{ml}$]; add 0.005 ml to each well).

b. Wells in a panel with CAMHB can be converted to lysed horse blood wells by adding 0.005 ml of lysed horse blood (50%, vol/vol) to each well containing 0.1 ml of antimicrobial agent (final concentration is 2.5% lysed horse blood).

Reference

1. NCCLS. 2003. *Methods for Dilution Antimicrobial Susceptibility Tests for Bacteria That Grow Aerobically*, 6th ed. Approved standard M7-A6. NCCLS, Wayne, Pa.

APPENDIX 5.2–5

Extended-Spectrum Beta-Lactamase Testing for *E. coli*, *Klebsiella pneumoniae*, and *Klebsiella oxytoca***PREANALYTICAL CONSIDERATIONS**

A. PRINCIPLE

ESBLs are derived from point mutations in the genes that code for common beta-lactamases such as TEM-1, TEM-2, or SHV-1. In contrast to TEM-1, TEM-2, and SHV-1, ESBLs hydrolyze or inactivate extended-spectrum cephalosporins, aztreonam, and expanded-spectrum penicillins. They do not hydrolyze carbapenems and generally do not hydrolyze cephamycins. ESBLs are blocked by beta-lactamase inhibitors such as clavulanic acid, and laboratory tests for detecting ESBL-producing bacteria are based on this property.

The MIC screening test for ESBL production in *E. coli* and *Klebsiella* spp. utilizes MIC interpretive criteria for certain third-generation cephalosporins and aztreonam that are different from those used for routine testing of *Enterobacteriaceae*. Once an isolate is deemed screen positive and therefore suspicious for ESBL production, a phenotypic confirmatory test is performed. The confirmatory test requires four MIC tests: (i) ceftazidime alone, (ii) cefotaxime alone, (iii) ceftazidime plus clavulanic acid, and (iv) cefotaxime plus clavulanic acid. If the MIC of either ceftazidime or cefotaxime (or both) in the presence of clavulanic acid is three or more twofold dilutions lower than the MIC of the respective agent alone, the test is considered positive for ESBL production.

B. SPECIMEN

Colonies as described in item II of procedure 5.2 for routine MIC testing of rapidly growing nonfastidious bacteria

C. SUPPLEMENTAL MATERIALS

MIC tests for the following agents at the concentrations specified

1. Ceftazidime, 0.25 to 128 µg/ml
2. Ceftazidime-clavulanic acid, 0.25/4 to 128/4 µg/ml
3. Cefotaxime, 0.25 to 64 µg/ml
4. Cefotaxime-clavulanic acid, 0.25/4 to 64/4 µg/ml

ANALYTICAL CONSIDERATIONS

D. QC STRAINS

1. *Klebsiella pneumoniae* ATCC 700603 (ESBL-producing strain)
2. *E. coli* ATCC 25922
3. Refer to current NCCLS QC and ESBL tables for acceptable QC ranges (1).

E. PROCEDURE

Follow standard MIC testing recommendations for inoculum preparation, inoculation, and incubation as indicated in item V of procedure 5.2.

1. Initial screen test

- a. Perform MIC tests with one or more of the following agents and include the concentration listed below. If the MIC exceeds that listed (positive screen test), proceed with the ESBL phenotypic confirmatory test.

<u>Antimicrobial agent</u>	<u>MIC (µg/ml)</u>
Cefpodoxime	4
Ceftazidime	1
Cefotaxime	1
Ceftriaxone	1
Aztreonam	1

- b. If the screen test is positive, suppress any susceptible results for penicillins, cephalosporins, or aztreonam from the patient report.
- c. If the screen test is negative, consider the isolate ESBL negative.

APPENDIX 5.2–5 (continued)

2. Phenotypic confirmatory test
 - a. Perform four MIC tests to include the concentrations listed.
 - (1) Ceftazidime, 0.25 to 128 µg/ml
 - (2) Ceftazidime-clavulanic acid, 0.25/4 to 128/4 µg/ml
 - (3) Cefotaxime, 0.25 to 64 µg/ml
 - (4) Cefotaxime-clavulanic acid, 0.25/4 to 64/4 µg/ml
 - b. Read MICs as described above for testing rapidly growing nonfastidious bacteria.

POSTANALYTICAL CONSIDERATIONS

F. REPORTING RESULTS

1. Positive for ESBL production: at least a three-twofold decrease in an MIC for either ceftazidime or cefotaxime tested in combination with clavulanic acid versus its MIC when tested alone
 - a. Demonstration of enhanced activity (at least three-twofold decrease in an MIC) in the presence of clavulanic acid with either one or both pairs of agents is a positive result.
 - b. Report all penicillins, cephalosporins (excluding the cephamycins such as ceftioxin or cefotetan), and aztreonam as resistant, even if the in vitro susceptibility test results are intermediate or susceptible.
2. Negative for ESBL production: less than a three-twofold decrease in an MIC for either antimicrobial agent tested in combination with clavulanic acid versus its MIC when tested alone

G. NOTES

1. At least 130 different types of ESBL enzymes have been described for *E. coli* and *Klebsiella* spp. Among the bacteria that produce these, a wide variety of susceptibility profiles may be noted with extended-spectrum beta-lactam agents, including the ESBL test screening agents. Use of more than one screening agent increases the likelihood of detecting the various types of ESBLs.
2. Extended-spectrum beta-lactam resistance in isolates that are screen test positive but confirmatory test negative is generally due to a mechanism other than ESBL production. ESBL screening tests have high specificity for *K. pneumoniae* but low specificity for *E. coli*. Many ESBL screen positive *E. coli* strains are resistant to extended-spectrum antimicrobial agents due to a resistance mechanism such as hyperproduction of AmpC beta-lactamase. As a screening agent for *E. coli*, cefpodoxime is the most sensitive but the least specific.
3. Generally, the hierarchy of activity of the screening agents in detecting ESBL production is cefpodoxime > ceftazidime > cefotaxime > ceftriaxone > aztreonam.
4. The genes for ESBL production are typically located on plasmids, and genes for resistance to other agents are often found on the same plasmid. Consequently, isolates that produce ESBLs often (but not always) demonstrate multiple resistance to other classes of antimicrobial agents (e.g., aminoglycosides, fluoroquinolones, or trimethoprim-sulfamethoxazole).
5. ESBLs do not hydrolyze carbapenems, and ESBL-producing *E. coli* and *Klebsiella* spp. remain susceptible to these agents. Carbapenems are considered the beta-lactams of choice for treating infections due to ESBL-producing bacteria.

H. LIMITATIONS

1. Some organisms with ESBLs may contain other beta-lactamases or other resistance mechanisms (e.g., porin alterations) that can mask ESBL production in the phenotypic confirmatory test, resulting in a false-negative result.
2. Other members of *Enterobacteriaceae* produce ESBLs. However, practical clinical laboratory methods for screening and detection of these isolates have not been determined as yet.

APPENDIX 5.2–6

Breakpoint MIC Panels

I. PRINCIPLE

The breakpoint MIC test is a variation of the broth microdilution MIC test. Generally, one to three concentrations of each drug are tested, and these represent the categorical breakpoint concentrations specified in NCCLS documents. These selected concentrations allow interpretation of results as susceptible (S), intermediate (I), and resistant (R). When two concentrations are tested, growth at both indicates resistance, growth in the low but not the high concentration indicates intermediate results, and a lack of growth in either well indicates susceptibility. Sometimes a single high concentration is tested for urinary tract agents; growth indicates resistance and a lack of growth indicates susceptibility. Results are reported in qualitative terms; however, the bracketed MIC can also be included in the report.

The major advantage of breakpoint panels is that numerous drugs can be tested on a single panel. The extra wells are often used for biochemical tests so that identification and susceptibility tests can be performed at the same time. The primary disadvantage is that a precise MIC is not obtained.

The information provided in this appendix addresses the unique aspects of performing breakpoint MIC tests. The details that are identical to those described for full-range broth microdilution MIC tests have been omitted.

II. MATERIALS

Broth microdilution MIC trays usually contain 0.1 ml of drug per well. An example of a portion of an MIC breakpoint panel for gram-negative bacilli is shown in Appendix 5.2–7.

III. QUALITY CONTROL

A. Ideally, the QC strains for each drug tested should include the following.

1. An isolate for which the MIC is right below the lowest concentration tested
2. An isolate for which the MIC is right above the highest concentration tested

☑ Although such strains are often utilized by commercial manufacturers of breakpoint panels, this does not represent a practical approach for clinical laboratories.

B. Current recommendations for QC of breakpoint panels are the same as those for full-range MIC panels. Weekly QC is acceptable once a laboratory documents satisfactory daily QC testing.

IV. REPORTING RESULTS

A. Interpretation

Interpret MICs based on criteria specified by the NCCLS (1).

B. Reporting

Report interpretive category result with or without bracketed MIC result. It is inappropriate to report an MIC alone when three or fewer drug concentrations are tested.

Example: *Klebsiella pneumoniae*

Drug	MIC (µg/ml)	Interpretation
Ampicillin	>16.0	R
Cefazolin	≤8.0	S
Gentamicin	≤4.0	S
Piperacillin	32	I

V. LIMITATIONS

A. The QC method used for full-range MIC panels currently represents the only practical approach for clinical laboratories. However, because endpoints of these strains are often off the scale (lower than the lowest concentration tested or higher than the highest concentrations tested), the value of this approach is limited for breakpoint MIC panels.

B. Because the ability of current QC procedures to identify problems with breakpoint testing is limited, use extreme caution when performing breakpoint MIC testing.

C. Because only one to three drug concentrations are tested, skipped wells often go undetected.

5.3

Beta-Lactamase Tests

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Beta-lactamases are enzymes produced by many clinically significant bacteria and are major mediators of bacterial resistance to beta-lactam agents. Routine beta-lactamase tests are based on visual detection of

the end products of beta-lactamase hydrolysis, which is demonstrated with a colorimetric reaction. These tests primarily include the chromogenic cephalosporin method, the acidimetric method, and the

iodometric method and are summarized in Appendix 5.3–1. Not every method is satisfactory for detecting beta-lactamase produced by all of the bacteria for which the test is useful.

II. SPECIMEN

- A. Several colonies of similar colony morphology grown overnight (18 to 24 h) on nonselective medium (e.g., BAP or CHOC)
- B. Some staphylococci may require induction (exposure to a beta-lactam agent) to increase production of enzyme to measurable levels.
 1. Streak isolate onto a nonselective medium such as BAP and drop an oxacillin disk (1 µg) onto the area where the inoculum was streaked (it is not necessary to standardize the inoculum, as the goal is to obtain cells that have come in contact with beta-lactam molecules).
 2. Incubate overnight.
 3. Test growth from the periphery of the zone of inhibition around the disk.
 4. Alternatively, grow the isolate in broth overnight containing a subinhibitory concentration of a beta-lactam agent (e.g., 0.25 µg of cefoxitin per ml), and perform the test on this suspension.

ANALYTICAL CONSIDERATIONS

III. QUALITY CONTROL

- A. QC strains
 1. *Staphylococcus aureus* ATCC 29213—positive
 2. *Haemophilus influenzae* ATCC 10211—negative
- B. Perform QC each day the test is performed and record results on QC form (*see* Appendix 5.3–2).

IV. CHROMOGENIC CEPHALOSPORIN METHOD

Include QC information on reagent container and in QC records.

A. Materials

1. Media and reagents
 - a. Cefinase disks (Becton Dickinson Microbiology Systems, Cockeysville, Md.; other products commercially available; follow manufacturer's instructions)
Store at 2 to 8°C.
 - b. Sterile distilled water
Store at 25°C.
2. Supplies
 - a. Glass slides or empty petri plates
 - b. Sterile Pasteur pipettes
 - c. Sterile wooden applicator sticks or inoculating loops

B. Procedure

1. Dispense the required number of disks onto a clean microscope slide or an empty petri plate.
2. Moisten each disk with 1 drop of sterile distilled water.
3. With a sterile loop or applicator stick, smear several colonies onto the disk surface.
4. Observe disk for color change. Positive results usually appear within 15 s to 5 min. If no color change occurs within 5 min, the test is negative. However, positive reactions for some staphylococci may take up to 1 h.

C. Reading reactions

1. Positive: yellow changes to red.
2. Negative: no change in color occurs.

V. ACIDIMETRIC METHOD

Include QC information on reagent container and in QC records.

A. Disk or strip method

1. Materials
 - a. Media and reagents
 - (1) Acidimetric disk or strip (commercially available from several suppliers; store according to manufacturer's instructions)
 - (2) Sterile distilled water
Store at 25°C.
 - b. Supplies
 - (1) Glass slides or empty petri plates
 - (2) Sterile Pasteur pipettes
 - (3) Sterile wooden applicator sticks or inoculating loops
2. Procedure
 - a. Dispense the required number of disks or strips onto a clean microscope slide or a sterile petri plate.
 - b. Moisten with 1 or 2 drops of sterile distilled water.
 - c. With a sterile loop or applicator stick, smear several colonies onto the disk or strip surface.
 - d. Observe for color change. A positive result will occur within 10 min. If no color change occurs within 10 min, the test is negative. However, positive reactions for some staphylococci may take up to 1 h. When dry, the color remains for up to 24 h.
3. Reading reactions
 - a. Positive: violet changes to yellow.
 - b. Negative: no change in color occurs.

V. ACIDIMETRIC METHOD*(continued)*

Include QC information on reagent container and in QC records.

B. Tube test**1. Materials****a. Media and reagents**

- (1) 0.5% Phenol red solution

Add 0.5 g of phenol red to 100 ml of water. Store at 25°C. Shelf life is 6 months. Heat may be needed to dissolve dye.

- (2) Crystalline potassium penicillin G (vial containing 20 million U)

Store as indicated by manufacturer.

- (3) 1 N NaOH

Add 4 g of NaOH crystals to 100 ml of water.

Caution: This will cause heat production.

Store at 25°C. Shelf life is 6 months.

- (4) Substrate preparation

- (a) Add 2 ml of the 5% phenol red solution to 16.6 ml of sterile distilled water. Mix.

- (b) Add the phenol red-water solution (18.6 ml) to the vial of crystalline benzylpenicillin G.

- (c) Remove solution from vial and place in sterile container.

- (d) Add 1 N NaOH dropwise to this acidic solution until it develops a violet color (pH 8.5).

- (e) Dispense in 0.1-ml aliquots into sterile tubes and freeze at -20°C or lower in *non*-frost-free freezer.

- (f) Thaw tubes and use as needed. Typical shelf life is 6 months. If the solution turns yellow, the penicillin has deteriorated; discard the tubes.

b. Supplies

- (1) Sterile 1- and 10-ml pipettes and pipette bulb

- (2) Sterile polystyrene capped tubes (12 by 75 mm)

- (3) Sterile wooden applicator sticks or inoculating loops

2. Procedure

- a. Remove desired number of reagent tubes from freezer and allow to thaw at room temperature (one tube per organism).

- b. With a sterile loop or applicator stick, add four or five colonies to the test solution to make an opaque, milky suspension.

- c. Observe for color change. A positive reaction will occur in less than 15 min. If no color change occurs within 15 min, the test is negative. A color change after 15 min usually indicates deterioration of the substrate not related to the presence of beta-lactamase and should not be considered positive. Since positive reactions for some staphylococci may take up to 1 h, results that turn positive after 15 min may not be reliable for these bacteria.

3. Reading reactions

- a. Positive: violet (red) changes to yellow.

- b. Negative: no change in color occurs.

VI. IODOMETRIC METHOD

Include QC information on reagent container and in QC records.

A. Materials**1. Media and reagents**

- a. Penicillin (6,000 µg/ml) dissolved in phosphate buffer (pH 6.0, 0.05 to 1 M)

Store at 2 to 8°C. Shelf life is 24 h.

- b. Starch reagent

Add 1 g of soluble starch to 100 ml of distilled water and heat in a boiling water bath until starch dissolves. Store at 2 to 8°C. Shelf life is 1 week.

VI. IODOMETRIC METHOD*(continued)*

- c. Iodine reagent
Dissolve 2.03 g of iodine and 53.2 g of potassium iodide in a small volume of distilled water and q.s. to 100 ml. Store at 2 to 8°C in dark bottle; replace if precipitate is apparent. Shelf life is 2 months.
2. Supplies
 - a. Empty sterile microdilution tray or small test tube
 - b. Sterile 1.0-ml pipettes and pipette bulb
 - c. Sterile wooden applicator sticks or inoculating loops
- B. Procedure**
 1. Dispense 0.1 ml of the penicillin solution into a well of a microdilution tray (or a small test tube).
 2. Add test organism to make an opaque, milky suspension.
 3. Add 2 drops of the starch solution and mix.
 4. Let sit at room temperature (approximately 25°C) for 30 to 60 min.
 5. Add 1 drop of the iodine reagent.
 6. Shake or stir the mixture for 1 min.
 7. Observe for color change. Decolorization (to white) in less than 10 min indicates a positive reaction. If no color change occurs within 10 min, the test is negative. However, positive reactions for some staphylococci may take up to 1 h.
- C. Reading reactions**
 1. Positive: fading of blue color to colorless
 2. Negative: blue or purple color

POSTANALYTICAL CONSIDERATIONS**VII. RESULTS****A. Interpretation**

Interpret the color reaction for the respective test as described above.

B. Reporting suggestion

1. *Haemophilus influenzae*—beta-lactamase positive (amoxicillin and ampicillin resistant)
2. *Haemophilus influenzae*—beta-lactamase negative

VIII. PROCEDURE NOTES

- A.** For some bacteria there is a direct correlation between a positive beta-lactamase reaction and resistance to specific beta-lactam drugs that might be prescribed for treatment of infections caused by them.
 1. *H. influenzae*: amoxicillin, ampicillin
 2. *Moraxella catarrhalis*: amoxicillin, ampicillin, penicillin
 3. *Neisseria gonorrhoeae*: amoxicillin, ampicillin, penicillin
 4. *Staphylococcus* spp.: amoxicillin, ampicillin, penicillin, carbenicillin, ticarcillin, mezlocillin, piperacillin
- B.** For organisms other than those listed above (with the exception of some anaerobes), beta-lactamase production cannot fully predict resistance to the various beta-lactam drugs that may be considered for use. Beta-lactamase testing as described here should not be used for these (e.g., *Enterobacteriaceae*, *Pseudomonas* spp.) in a clinical laboratory setting.
- C.** Beta-lactamase testing of staphylococci
 1. Staphylococci may require induction to demonstrate a positive beta-lactamase reaction. A negative test should not be reported unless the test has been performed on cells that have been subjected to an inducing agent.
 2. Microdilution MIC tests with penicillin may fail to detect penicillin-resistant (beta-lactamase-positive) staphylococci among some isolates that produce

VIII. PROCEDURE NOTES

(continued)

- small amounts of beta-lactamase. An induced-beta-lactamase test is needed to confirm an isolate as penicillin susceptible (1, 2) (*see* item II).
3. Beta-lactam agents other than oxacillin and cefoxitin can be used as inducing agents providing it can be demonstrated that they perform satisfactorily.
 4. Staphylococci may require up to 1 h to show a positive beta-lactamase test.
- D. Production of beta-lactamase is not the only mechanism of beta-lactam resistance in the species commonly tested (although it is the most common mechanism). Consequently, a positive beta-lactamase test by definition indicates resistance to the penicillinase-labile penicillins. However, a negative test *does not* guarantee susceptibility to these agents, and a conventional susceptibility test must be performed.
- E. The current NCCLS recommendations for routine testing of *M. catarrhalis* include performance of a beta-lactamase test only. This is because the incidence of resistance to other commonly prescribed agents is very low, as is the incidence of ampicillin, amoxicillin, and penicillin resistance due to a mechanism other than beta-lactamase production (1, 2).

APPENDIX 5.3–1

Summary of beta-lactamase testing methods

Test detail(s)	Acidimetric	Nitrocefin (chromogenic cephalosporin)	Iodometric
Substrate	Citrate-buffered penicillin plus phenol red	Nitrocefin	Phosphate-buffered penicillin plus starch-iodine complex
Reaction	Penicilloic acid produces pH decrease.	Color change when beta-lactam ring opened	Penicilloic acid reduces iodine and prevents it from combining with starch.
Results	Positive: yellow Negative: violet (red)	Positive: red Negative: no color change	Positive: colorless Negative: blue/purple

Method(s) generally satisfactory for various organisms

Organism(s)	Testing method		
	Acidimetric	Nitrocefin	Iodometric
<i>Haemophilus</i> spp.	×	×	
<i>Neisseria gonorrhoeae</i>	×	×	×
<i>Staphylococcus</i> spp.	×	×	×
<i>Moraxella catarrhalis</i>		×	
<i>Bacteroides</i> spp.		×	

5.4

Oxacillin Salt-Agar Screen Test To Detect Oxacillin (Methicillin)-Resistant *Staphylococcus aureus*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

A standard number of bacteria is inoculated onto Mueller-Hinton agar (MHA) containing 6 µg of oxacillin per ml and 4% NaCl. Following overnight incubation, the appearance of growth indicates that the

Staphylococcus aureus isolate is resistant to oxacillin and other penicillinase-stable penicillins (methicillin, nafcillin, cloxacillin, and dicloxacillin) (1).

II. SPECIMEN

Prepare inoculum from four or five isolated colonies of similar colony morphology grown overnight (18 to 24 h) on nonselective medium (e.g., BAP or CHOC).

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Media and reagents

1. MHA with 4% NaCl and oxacillin (6 µg/ml)
Store at 2 to 8°C.
2. Nutrient broth (e.g., Mueller-Hinton, TSB) or 0.9% saline (3.0- to 5.0-ml aliquots)
Store at 2 to 30°C.

B. Supplies

1. Sterile cotton-tipped swabs
2. Sterile plastic pipettes
3. McFarland 0.5 turbidity standard

C. Equipment

1. Calibrated loop (1 µl [0.001 ml])
2. Vortex mixer
3. Ambient-air incubator (34 to 35°C)

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

A. QC strains

1. *S. aureus* ATCC 29213—oxacillin susceptible
2. *S. aureus* ATCC 43300—oxacillin resistant

B. Perform QC with each test run and record results on QC form (Appendix 5.4–1).

V. PROCEDURE

A. Inoculum preparation

Using a loop or swab, transfer colonies to broth or saline to obtain an organism suspension that matches a McFarland 0.5 turbidity standard (1×10^8 to 2×10^8 CFU/ml); vortex thoroughly.

B. Inoculation and incubation

1. Method 1

Using a 1-µl loop that has been dipped in the standardized suspension, spot inoculate onto the surface of the plate to cover an area that is 10 to 15 mm in diameter.

V. PROCEDURE (*continued*)

2. Method 2
 - a. Dip a fresh sterile cotton swab into the standardized suspension and express any excess fluid against the side of the tube.
 - b. Spot inoculate onto the surface of the plate over an area that is 10 to 15 mm in diameter or streak an entire quadrant of the plate.
3. Several organisms can be tested on each plate.
4. Allow the inoculum to be absorbed into the agar.
5. Invert plates and incubate at 35°C (no higher) in an ambient-air incubator.
6. Examine after overnight incubation. If any isolates are susceptible, reincubate the plate until a full 24 h of incubation has occurred and examine again.
7. Do not reuse plates.

C. Reading plates

Examine plates closely with transmitted light.

POSTANALYTICAL CONSIDERATIONS**VI. REPORTING RESULTS**

- A. Interpretation
 1. No growth or a single colony: oxacillin susceptible
 2. >1 colony or a light film of growth: oxacillin resistant
- B. For oxacillin-resistant *S. aureus*, report all beta-lactams as resistant regardless of in vitro results. These beta-lactams include all penicillins, all cepheems, all carbapenems, and all beta-lactam–beta-lactamase inhibitor combination drugs.

VII. PROCEDURE NOTES

- A. Procedure
 1. Improper storage or exposure of oxacillin screen plates to higher temperatures may result in rapid deterioration of oxacillin, which is temperature labile.
 2. Incubation at temperatures of >35°C may adversely affect detection of oxacillin-resistant *S. aureus*.
 3. Plates must be examined very carefully using transmitted light. Although some resistant isolates may demonstrate confluent growth, isolates expressing a low frequency of resistance may appear as a few small colonies or fine haze of growth. Detection of growth may be enhanced using a dissection microscope or hand lens.
 4. Since other organisms may grow on oxacillin screen plates, care must be taken to use pure cultures.
 5. Resistant results can be reported after overnight incubation (16 to 20 h). Isolates susceptible after overnight incubation must be incubated for a full 24 h before final reading.
- B. Other
 1. The typical or intrinsically oxacillin (methicillin)-resistant *S. aureus* isolates possess the *mecA* gene, are associated with high oxacillin MICs (>16 µg/ml), and usually demonstrate resistance to multiple classes of antimicrobial agents, including clindamycin and erythromycin and sometimes chloramphenicol, tetracycline, trimethoprim-sulfamethoxazole, and the aminoglycosides. However, methicillin-resistant *S. aureus* (MRSA) organisms which are not multiresistant have been isolated from outpatients and inpatients.
 2. Borderline oxacillin (methicillin)-resistant *S. aureus* organisms lack the *mecA* gene and are usually not multiply resistant, and oxacillin MICs for these are often at or just above the susceptible breakpoint (>2.0 µg/ml), in contrast to MICs for intrinsically resistant isolates (>16.0 µg/ml). Occasionally, these organisms may grow on the oxacillin salt-agar screen plate. The

VII. PROCEDURE NOTES

(continued)

clinical significance of borderline resistant isolates has not been established, but some have suggested that infections caused by these are treatable with beta-lactam agents. Borderline resistant isolates are infrequently encountered.

3. Because the oxacillin screen plate method is reliable (and easy and inexpensive), it can be used to establish and evaluate the accuracy of other systems that have on occasion been shown to be less reliable in detecting MRSA (e.g., some of the rapid automated methods).
4. Tests for the *mecA* gene or for PBP2a, the gene product, are available and can be used for rapid detection of MRSA. They are also sometimes useful for definitive identification when borderline resistant results are encountered. There is currently a commercial latex agglutination test for PBP2a (2).

VIII. LIMITATIONS

The oxacillin salt-agar screen plate detects intrinsically oxacillin (methicillin)-resistant *S. aureus* but usually does not detect borderline oxacillin (methicillin)-resistant *S. aureus*.

5.5

Screen Tests To Detect High-Level Aminoglycoside Resistance in *Enterococcus* spp.

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

High-level aminoglycoside resistance (HLAR) in enterococci is most commonly detected by assessing growth at high concentrations of gentamicin (500 µg/ml) and sometimes streptomycin (1,000 µg/ml in broth and 2,000 µg/ml in agar) (1). Strains that show HLAR to gentamicin will not be

synergistically killed with combinations of cell wall-active drugs (generally ampicillin, penicillin, or vancomycin) plus gentamicin. HLAR to gentamicin also means HLAR to tobramycin, netilmicin, amikacin, and kanamycin. HLAR to streptomycin equals resistance to combinations of

cell wall-active drugs and streptomycin. See additional information in Appendix 5.5–1. The agar screen test is described in detail here, and reference is made to the disk diffusion and the broth microdilution MIC test procedures for detecting HLAR.

II. SPECIMEN

Prepare inoculum from four or five isolated colonies of similar colony morphology.

1. Log-phase or stationary-phase growth inoculum
Use colonies grown for 1 or 2 days on nonselective (e.g., BAP) or selective medium.
2. Direct colony suspension inoculum
Use colonies grown overnight on nonselective medium (e.g., BAP).
3. Subculture stock, frozen, or lyophilized isolates two times prior to testing.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Media and reagents

1. BHI agar screen plates prepared in quadrant plates for convenience
 - a. Quadrant 1, BHI agar control
 - b. Quadrant 2, 500 µg of gentamicin per ml
 - c. Quadrant 3, 2,000 µg of streptomycin per ml
Store at 2 to 8°C.
2. Nutrient broth (e.g., Mueller-Hinton, TSB) or 0.9% NaCl (3.0 to 5.0-ml aliquots)
Store at 2 to 30°C.

B. Supplies

1. Sterile cotton-tipped swabs
2. Sterile plastic pipettes
3. 0.5 McFarland turbidity standard

C. Equipment

1. Calibrated loop (10 µl [0.01 ml]) or 10-µl micropipette with sterile tips
2. Vortex mixer
3. Ambient-air incubator (34 to 35°C)

ANALYTICAL CONSIDERATIONS**IV. QUALITY CONTROL**

- A. QC strains
 - 1. *Enterococcus faecalis* ATCC 29212—susceptible to high concentrations of gentamicin and streptomycin
 - 2. *E. faecalis* ATCC 51299—resistant to high concentrations of gentamicin and streptomycin
- B. QC can be performed weekly if proficiency in performing daily QC has been documented (*see* procedure 5.2) and if the laboratory performs this test routinely. Always perform QC when new reagents are put into use.
- C. Record all results on QC worksheet (Appendix 5.5–2).

V. PROCEDURE

- A. **Inoculum preparation**
 - 1. Direct colony suspension method
 - Pick several colonies from a fresh (18- to 24-h) nonselective agar plate to broth or 0.9% NaCl.
 - 2. Log phase method
 - a. Pick four or five isolated colonies to 3.0 to 5.0 ml of broth.
 - b. Incubate at 35°C for 2 to 8 h until growth reaches the turbidity at or above that of a 0.5 McFarland standard.
 - 3. For either the log phase or direct colony suspension method, vortex well and adjust turbidity visually with sterile broth or 0.9% NaCl to match a 0.5 McFarland standard (1×10^8 to 2×10^8 CFU/ml). Alternatively, standardize suspension with a photometric device.
- B. **Inoculation and incubation**
 - 1. Use a 10- μ l micropipette with a sterile tip or calibrated loop to spot the inoculum onto the agar surface of each quadrant. The final concentration should be approximately 10^6 CFU.
 - 2. Allow the inoculum to be absorbed into the agar.
 - 3. Invert plates and incubate at 35°C in an ambient-air incubator for 24 h; if there is no growth at 24 h for streptomycin, reincubate streptomycin tests for an additional 24 h (total of 48 h).
- C. **Reading plates**
 - 1. Examine the control quadrant (no drug) for adequate growth.
 - 2. Examine drug quadrants for presence of growth (>1 colony indicates resistance).

POSTANALYTICAL CONSIDERATIONS**VI. RESULTS**

- A. **Interpretation**
 - 1. No growth (or one colony): no high-level resistance
 - 2. Growth at gentamicin (500 μ g/ml): high-level gentamicin resistance (also resistance to tobramycin, amikacin, netilmicin, and kanamycin)
 - 3. Growth on streptomycin (2,000 μ g/ml): high-level streptomycin resistance
- B. **Reporting suggestion**

Add comment to report: “Serious enterococcal infections require combination therapy with ampicillin, penicillin, or vancomycin plus an aminoglycoside. Bactericidal synergy occurs only when the bacterium under scrutiny is susceptible to both drugs.”

VII. PROCEDURE NOTES**A. Agar method**

1. Uninterpretable results may result from improper inoculation or the inability of the organism to grow on the particular agar base medium. The test should be repeated before reporting as uninterpretable.
2. Some isolates with streptomycin HLAR may not demonstrate resistance until after 48 h of incubation.
3. Most *Enterococcus faecium* organisms produce an aminoglycoside-modifying enzyme (6'-acetyltransferase) that makes them inherently resistant to amikacin, kanamycin, netilmicin, and tobramycin; this may not be expressed as HLAR (e.g., MIC may be $\leq 2,000$ $\mu\text{g/ml}$), but synergy will not occur with these agents.
4. Standard petri plates may be used as an alternative to quadrant petri plates. Three separate plates including one containing BHI, one containing gentamicin at 500 $\mu\text{g/ml}$, and one containing streptomycin at 2,000 $\mu\text{g/ml}$ are required.

B. Other methods

1. HLAR can also be determined using the standard disk diffusion method with special high-content disks (120 μg of gentamicin and 300 μg of streptomycin). Zones of 6 mm (no zone) indicate HLAR. Zones of 7 to 9 mm are inconclusive and require that isolates be retested by an agar dilution or broth dilution HLAR screen method. Zones of ≥ 10 mm indicate no HLAR (2).
2. HLAR can also be determined using the standard broth dilution MIC method by testing 500 μg of gentamicin and 1,000 μg of streptomycin per ml diluted in BHI broth (1). Growth is indicative of high-level resistance.
3. To detect HLAR to amikacin, use 2,000 μg of kanamycin per ml for the agar screen or broth dilution method.
4. Since gentamicin is the most widely used aminoglycoside (in combination with a cell wall-active drug) for treatment of serious enterococcal infections, an HLAR screen for gentamicin is often sufficient. However, if the isolate demonstrates high-level gentamicin resistance, screening for high-level streptomycin resistance is needed to identify those strains that might be high-level gentamicin resistant but not high-level streptomycin resistant. In this case, streptomycin could be used therapeutically.
5. Dextrose phosphate agar and broth have been shown to perform comparably to BHI in broth and agar screen tests.

VIII. LIMITATIONS

Occasional isolates that lack HLAR to gentamicin and streptomycin but show HLAR to amikacin and kanamycin may occur. This resistance would be detected only with a kanamycin screen test, which is generally not available in clinical laboratories and currently not addressed by the NCCLS.

APPENDIX 5.5-1

Aminoglycoside-modifying enzymes that confer HLAR on *Enterococcus* spp.

Enzyme	Inactivation ^a				
	Gentamicin	Streptomycin	Tobramycin	Amikacin/kanamycin	Netilmicin
6'-Adenylyltransferase [AAD (6')]	N	Y	N	N	N
3'-Phosphotransferase [APH (3')]	N	N	N	Y	N
2''-Phosphotransferase/6'-acetyltransferase [APH (2'')/AAC (6')]	Y	N	Y	Y	Y
6'-Acetyltransferase [AAC (6')] ^b	N	N	Y	Y	Y

^a Y, modifies the activity of the respective aminoglycoside; no synergy achievable with a cell wall-active agent. N, does not modify the activity of the respective aminoglycoside; synergy achievable.

^b Found in virtually all *E. faecium* organisms.

5.6

Agar Screen Test To Detect Vancomycin Resistance in *Enterococcus* spp.

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The vancomycin agar screen is used to detect vancomycin-resistant enterococcal colonies that have been isolated from clinical or surveillance cultures. A standard number of bacteria is inoculated onto BHI agar containing 6 µg of vancomycin per ml. Following incubation, the appear-

ance of growth indicates that the enterococcal isolate is likely to be resistant to vancomycin. MIC and species identification tests are subsequently required to determine if the isolate is a true vancomycin-resistant enterococcus (VRE) (1, 2).

II. SPECIMEN

Prepare inocula from four or five isolated colonies of similar colony morphology grown overnight (18 to 24 h) on agar medium (e.g., BAP, CAP, or enterococcal surveillance agar).

III. MATERIALS

A. Media and reagents

1. BHI agar plates with 6 µg of vancomycin per ml
Store at 2 to 8°C.
2. Nutrient broth (e.g., Mueller-Hinton, TSB) or 0.9% NaCl (3.0- to 5.0-ml aliquots)
Store at 2 to 8°C.

B. Supplies

1. Sterile cotton-tipped swabs
2. Sterile plastic pipettes
3. McFarland 0.5 turbidity standard

C. Equipment

1. 1.0-µl (0.001 ml) or 10-µl (0.01 ml) calibrated loop
2. Vortex mixer
3. 34 to 35°C ambient-air incubator

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

A. QC strains

1. *Enterococcus faecalis* ATCC 29212—vancomycin susceptible
2. *E. faecalis* ATCC 51299—vancomycin resistant

B. Frequency of testing QC strains

1. Weekly

If the vancomycin screen test is performed at least once a week and criteria for converting from daily to weekly testing have been met (*see* procedure 5.2)

2. Daily

If vancomycin screen test is performed less frequently than once a week

C. Record all results on QC worksheet (Appendix 5.6–1).

V. PROCEDURE**A. Inoculum preparation**

Using a loop or swab, transfer colonies to a nutrient broth or saline to obtain an organism suspension that matches a McFarland 0.5 turbidity standard (1.0×10^8 to 2×10^8 CFU/ml); vortex thoroughly.

B. Inoculation and incubation

1. Using a 1- or 10- μ l calibrated loop that has been dipped in the inoculum suspension, inoculate a section of the agar plate surface in a single streak (test up to six isolates/plate).
2. Allow the inoculum to be absorbed into the agar.
3. Invert plates and incubate at 35°C in an ambient-air incubator.
4. Examine after overnight incubation. If any isolates are susceptible, reincubate the plate until a full 24 h of incubation has occurred and examine again.

C. Reading plates

Examine plate for presence of growth (>1 colony indicates presumptive resistance).

D. Supplemental testing if the vancomycin screen plate demonstrates growth

1. Perform a vancomycin MIC test.
2. Perform tests for motility and pigment production to distinguish species with acquired resistance (VanA or VanB) from those with intrinsic, low-level resistance to vancomycin (VanC) such as *Enterococcus gallinarum* or *Enterococcus casseliflavus*. (See procedure 3.18.1 for procedures for species identification of enterococci.)

POSTANALYTICAL CONSIDERATIONS

VI. REPORTING RESULTS**A. Interpretation**

1. No growth or 1 colony: vancomycin susceptible
2. Growth of >1 colony: presumptively vancomycin resistant

B. Reporting

Report presumptive results.

Example: Presumptive VRE based on screen test; confirmatory tests pending.

VII. PROCEDURE NOTES**A.** The three common phenotypes of VRE are as follows.

1. VanA or high-level resistance, with vancomycin MICs of ≥ 64 μ g/ml, and resistance to teicoplanin (MICs of ≥ 16 μ g/ml)
2. VanB or low- to high-level resistance, with vancomycin MICs of 16 to 64 μ g/ml, and usually without teicoplanin resistance
3. VanC or intrinsic low-level resistance, with vancomycin MICs of 4 to 32 μ g/ml, without teicoplanin resistance and typically associated with *E. gallinarum* and *E. casseliflavus*

B. On occasion, *E. faecalis* ATCC 29212 may show slight growth on vancomycin screen plates.**C.** The medium described here is to be used for testing enterococci that have been isolated in culture and not as a primary plating medium for surveillance specimens (e.g., rectal swabs).**D.** Acquired vancomycin resistance (VanA or VanB) is most common in *Enterococcus faecium*, although it has been noted in *E. faecalis*. The epidemiologic significance of isolates with acquired vancomycin resistance is great, and patients colonized or infected with VRE require strict infection control precautions.

VII. PROCEDURE NOTES*(continued)*

- E. Low-level intrinsic vancomycin resistance (VanC) found in *E. gallinarum* and *E. casseliflavus* has not been shown to be of epidemiologic significance. Therefore, these are not reported as VRE for infection control purposes.
- F. The vancomycin screen plate as described here has been used to screen for vancomycin-intermediate *Staphylococcus aureus* (VISA). Any growth should be considered suspicious for VISA or vancomycin-resistant *S. aureus* (VRSA). For this purpose, include QC strains *E. faecalis* ATCC 51299 (resistant control) and *S. aureus* ATCC 29213 (susceptible control) (3).

VIII. LIMITATIONS

- A. The vancomycin screen plate does not determine the level of vancomycin resistance or the vancomycin phenotype.
- B. Vancomycin-resistant bacteria other than enterococci (e.g., gram-negative bacteria, *Leuconostoc* spp., *Lactobacillus* spp., *Pediococcus* spp., *Erysipelothrix rhusiopathiae*) may grow on the screen plates. Make certain that the test organism is *Enterococcus* spp. prior to testing.

Broth Microdilution MIC Test for Anaerobic Bacteria

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The broth microdilution MIC method can be used to measure (semiquantitatively) the in vitro activity of an antimicrobial agent against an anaerobic bacterial isolate. This procedure is very similar to the broth microdilution method used for aerobic bacteria. Various concentrations of antimicrobial agents are dispensed into a multiwell plastic tray and inoculated with a test isolate. After 48 h of incubation at 35°C in an anaerobic environment, the

MIC is determined by observing the lowest concentration of an antimicrobial agent which will inhibit visible growth of the test bacterium. MICs obtained are interpreted as susceptible, intermediate, or resistant, based on criteria defined by the NCCLS (1).

The anaerobic broth microdilution MIC method is described in detail in the NCCLS M11 standard (1). The recom-

mended medium is supplemented brucella broth (hemin, vitamin K₁, and 5% lysed horse blood). Anaerobic bacteria that grow poorly in supplemented brucella broth will not produce satisfactory results with this method and must be tested by an alternative method such as agar dilution. To date, the NCCLS method has been validated only for testing the *Bacteroides fragilis* group species.

II. SPECIMEN

Prepare inoculum directly from four or five isolated colonies of similar colony morphology grown anaerobically for 24 to 48 h on an anaerobic brucella blood agar plate.

- A. Use 24-h growth for rapid growers (e.g., *B. fragilis*), if sufficient growth is available; 48-h growth is required for most other organisms.
- B. Subculture stock, frozen, or lyophilized isolates two times prior to testing.
- C. Do not expose agar plates containing test isolates to air for longer than 20 to 30 min.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Media and reagents

See Appendix 5.7-1 for additional information.

1. Prepared broth microdilution panels containing antimicrobial agents diluted in brucella broth supplemented with (final concentrations) vitamin K₁ (1 µg/ml), hemin (5 µg/ml), and lysed horse blood (5%) in volumes of 0.1 ml of solution per well. Store at ≤ -60°C. See Appendix 5.7-2.
2. Brucella broth, supplemented with vitamin K₁, hemin, and 5% lysed horse blood dispensed in aliquots of 5 ml. Store at 2 to 8°C.
3. THIO, supplemented with vitamin K₁, hemin, and either a marble chip or sodium bicarbonate, dispensed in aliquots of 5 ml. Store at ambient temperature, protected from light.
4. Sterile 0.9% NaCl dispensed in aliquots of 28 ml in screw-cap tubes. Store at 2 to 8°C.
5. Sterile 0.9% NaCl dispensed in aliquots of 10 ml in screw-cap tubes. Store at 2 to 8°C.
6. Brucella agar supplemented with vitamin K₁, hemin, and sheep blood. Store at 2 to 8°C.
7. BAP. Store at 2 to 8°C.

III. MATERIALS (*continued*)**B. Supplies**

1. Sterile cotton-tipped swabs
2. Sterile plastic pipettes
3. 0.5 McFarland turbidity standard
4. Sterile, disposable, plastic multi-pronged inoculator sets (include inoculum reservoir) or other inoculating device
5. Plastic bags
6. Microdilution tray lids or empty microdilution trays

C. Equipment

1. Vortex mixer
2. Adjustable micropipette and sterile pipette tips

3. 35°C anaerobic atmosphere (in container large enough to hold panels) containing 5 to 10% H₂, 5 to 10% CO₂, and 80 to 90% N₂ (e.g., anaerobe chamber, anaerobe pouch, or anaerobic jar)
4. Viewing device to read inoculated MIC panels after incubation
5. Freezer ($\leq -60^{\circ}\text{C}$; sometimes a -20°C non-frost-free freezer is acceptable)
6. 35°C ambient-air incubator (CO₂)

ANALYTICAL CONSIDERATIONS**IV. QUALITY CONTROL****A. QC strains**

1. *B. fragilis* ATCC 25285
2. *Bacteroides thetaiotaomicron* ATCC 29741
3. *Eubacterium lentum* ATCC 43055

B. Monitoring accuracy

1. Test QC isolates by following routine procedures, and record results on a QC log sheet. Record lot numbers and expiration dates of microdilution panels. *See* Appendix 5.7–3.
2. Compare with expected results listed in the most recent NCCLS standards tables (1). Note any out-of-control results and document; proceed with corrective action if necessary.

C. Testing recommendations

1. Test all three QC strains with each new lot or each new shipment of panels.
2. Test all three QC strains with each run. However, if only a few panels are to be set on patients' isolates, it is acceptable to test one QC strain with the run. Select the strain that gives the greatest number of on scale endpoints for the drugs on the panel.

D. Additional controls

1. Growth control well must demonstrate good growth; anaerobic purity plate must show good growth and be free of contaminating organisms.
2. Sterility control well and aerobic purity plate must be free of any growth.
3. Inoculum count verification plate should show approximately 50 to 200 colonies/plate.

V. PROCEDURE**A. Organizational considerations**

Inoculum suspensions and the inoculation of the panels can be done outside of the anaerobic chamber. However, the time between isolate exposure to air and placement of the inoculated trays in an anaerobic environment should not exceed 30 min. When testing 10 or more isolates at one time, remove isolates from the anaerobic chamber in sets of 10 in order to minimize exposure of the isolates to oxygen during the procedure.

- B.** Allow frozen trays to thaw at room temperature (this can be done outside of the chamber).

V. PROCEDURE (*continued*)**C. Inoculum preparation**

1. Using a loop or swab, transfer colonies as follows.
 - a. Growth method
 - (1) Pick colonies from a supplemented brucella blood agar plate 24 to 48 h old to THIO or supplemented brucella broth. (Prior to using THIO, prereduce by boiling for 5 min and then cool.)
 - (2) Incubate at 35°C under anaerobic conditions for 4 to 6 h (but no longer than 24 h) or until the turbidity is equivalent to that of a 0.5 McFarland turbidity standard (1.5×10^8 CFU/ml). Ambient-air incubation is acceptable when using prereduced THIO. If turbidity is not reached by 24 h, use the direct colony suspension method.
 - b. Direct colony suspension method
 - (1) Pick colonies from a supplemented brucella blood agar plate 24 to 48 h old and suspend in brucella broth.
 - (2) Gently invert the tube or vortex to obtain a homogeneous suspension.
 - (3) Adjust the turbidity to match that of a 0.5 McFarland standard, which has been vortexed.
2. Prepare inoculum suspensions no more than 15 min before inoculation of panels.
3. For the intermediate dilution, calculate the volume of standardized suspension to be added to a 28-ml aliquot of 0.85% NaCl to obtain a final organism concentration of 10^5 CFU in each 0.1 ml of antimicrobial solution per well (10^6 CFU/ml).

Example: The following applies when using disposable plastic inoculator with prongs that deliver 0.01 ml per well.

- a. Prepare suspension equivalent to a 0.5 McFarland standard.
 - b. Add 2.0 ml of 0.5 McFarland-standardized suspension to 28 ml of prereduced saline (1:15 dilution = 10^7 CFU/ml). Mix tubes gently by inversion or vortexing.
 - c. Prongs deliver 0.01 ml into 0.1 ml of drug solution (1:10 dilution).
 4. The final organism concentration is 1×10^6 CFU/ml, compared to 5×10^5 CFU/ml for aerobes when using broth microdilution.
- D. Inoculation and incubation**
1. Within 15 min of preparing the inoculum, inoculate the MIC tray.
 2. Use sterile disposable plastic inoculators that deliver 0.01 ml.
 - a. Remove inoculator-reservoir set from its plastic packaging.
 - b. Pour diluted inoculum suspension into inoculum tray reservoir.
 - c. Dip prongs into the inoculum suspension.
 - (1) Orient the sterility well so that it does not get inoculated.
 - (2) Press down on the inoculator firmly to ensure that all prongs have come in contact with the inoculum in the reservoir tray.
 - (3) Carefully remove prongs from inoculum.
 - d. Inoculate the MIC tray by dipping the filled prongs carefully into the MIC tray. Press down on the inoculator firmly to ensure that all prongs have come in contact with the antimicrobial solutions in the tray.
 - e. Discard the prongs as biohazardous waste.
 - f. Prepare purity plates by subculturing separate 0.001 ml of inoculum from the reservoir onto an anaerobic BAP and an aerobic BAP. Discard liquid and reservoir tray as biohazardous waste.
 3. Cover panels with empty microdilution tray or tray lid.
 4. Incubate inoculated MIC panels and anaerobic purity plates at 35°C under anaerobic conditions for 48 h. Include an indicator of anaerobiasis.
 - a. Incubate in stacks of four trays or fewer, with an empty tray or lid on top of the stack.

POSTANALYTICAL CONSIDERATIONS

VI. REPORTING RESULTS
A. Interpretation

Interpret MIC based on criteria specified by the NCCLS (1).

B. Reporting

Report the MIC along with its categorical interpretation: susceptible (S), intermediate (I), or resistant (R).

Example: *B. fragilis*

<u>Drug</u>	<u>MIC (µg/ml)</u>	<u>Interpretation</u>
Ampicillin-sulbactam	8/4	S
Cefoxitin	8	S
Clindamycin	4	I
Metronidazole	1	S
Piperacillin-tazobactam	0.25	S

C. Important reporting rules

The majority of *B. fragilis* group isolates are beta-lactamase producers; therefore, these isolates do not require beta-lactamase testing and should always be reported as resistant to penicillin and ampicillin regardless of the MIC (1).

VII. PROCEDURE NOTES

- A.** See aerobic broth microdilution procedure (procedure 5.2) for additional record-keeping tips.
- B.** CHOC can be used in place of BAP for aerobic purity plates.
- C.** Occasionally, the skipping phenomenon occurs. Skipped wells are evidenced by growth at higher concentrations of an antimicrobial agent and a lack of growth at one or more of the lower concentrations. Evaluate each skipped well individually when determining if it is necessary to repeat MIC testing. In general, if more than two consecutive wells with no growth are followed by additional wells with growth, the results are questionable and the test should be repeated. See procedure 5.2 for a detailed discussion of this subject.
- D.** Most anaerobic isolates can be stored at $\leq -60^{\circ}\text{C}$ in 20% glycerol or 20% sterile skim milk.

VIII. LIMITATIONS

- A.** On rare occasions, clinical isolates of *B. fragilis* group organisms may not grow within 48 h in brucella broth supplemented with vitamin K₁, hemin, and 5% lysed horse blood. If no growth occurs after repeat testing, the agar dilution method should be used.
- B.** As with any procedure, experience is important. Those who perform broth microdilution susceptibility tests on anaerobes should have experience in anaerobic bacteriology. Laboratories with few requests for susceptibility tests should consider sending them to a referral laboratory with experience in anaerobic susceptibility testing.
- C.** This method has been validated by the NCCLS only for testing members of the *B. fragilis* group.
- D.** Because many infections involving anaerobes are polymicrobial and successful treatment often involves a combination of surgical intervention and the use of empirical broad-spectrum, antimicrobial therapy, the relative importance of the susceptibility of a single organism to predict a favorable clinical outcome is difficult to determine.
- E.** Anaerobic organisms differ markedly in size and shape; therefore, a standardization of inocula by using a 0.5 McFarland standard may not yield 1.5×10^8 CFU/ml for all organisms.

VIII. LIMITATIONS (*continued*)

- F.** Beta-lactamase testing with a chromogenic cephalosporin-based method can be performed with anaerobic species. A beta-lactamase-producing isolate should be reported as resistant to penicillin and ampicillin, regardless of the MIC. Some anaerobic species are known to be resistant to beta-lactam antimicrobial agents by mechanisms other than beta-lactamases. Therefore, a negative beta-lactamase test does not ensure susceptibility to all beta-lactam antimicrobial agents.

APPENDIX 5.7–1**Preparation of Media and Reagents**

- A. Supplemented brucella broth (1, 2)**
1. Use the following formulation of brucella broth powder.

pancreatic digest of casein10 g
peptic digest of animal tissue10 g
dextrose 1 g
yeast extract 2 g
sodium chloride 5 g
sodium bisulfite0.1 g
 2. Combine the following in 900 ml of distilled water.

brucella broth powder28 g
hemin stock solution 1 ml
vitamin k ₁ working solution 1 ml
 3. Boil to dissolve.
 4. Dispense in convenient-size aliquots.
 5. Autoclave broth at 121°C for 15 min.
 6. Cool to ≤4°C.
 7. Add 100 ml of sterile lysed horse blood to 900 ml of broth (or appropriate amount if dispensed in smaller volumes).
 8. Cap tightly, and store at 2 to 8°C for up to 1 month.
 9. If broth is to be used for inoculum suspension preparation, it is not necessary to add blood.
- B. Enriched THIO (1, 2)**
1. Use the following formulation of enriched THIO powder:

pancreatic digest of casein17 g
papaic digest of soybean meal 3 g
dextrose 6 g
sodium chloride2.5 g
sodium thioglycolate0.5 g
agar0.7 g
L-cystine0.25 g
sodium sulfite0.1 g
 2. Combine the following in 1,000 ml of distilled water.

THIO powder without indicator30 g
hemin stock solution 1 ml
vitamin k ₁ working solution 1 ml

APPENDIX 5.7-1 (continued)

3. Boil to dissolve agar (THIO broth contains a small amount of agar).
 4. Dispense in 5-ml amounts into screw-cap tubes (13 by 100 mm).
 5. Autoclave at 121°C for 15 min.
 6. Cool to 48 to 50°C.
 7. Add 0.25 ml of filter-sterilized sodium bicarbonate stock solution per 5 ml of THIO.
 8. Alternatively, substitute three or four marble chips per 5 ml of THIO for sodium bicarbonate. Add before autoclaving.
 9. Cap tightly, and store at 2 to 8°C in the dark for up to 6 months.
 10. For optimal performance of broth, boil THIO broth for 5 min and cool it to room temperature prior to use.
- C. Hemin stock solution (final concentration, 5 mg/ml)
1. Dissolve 0.1 g of hemin in 2 ml of 1.0 N sodium hydroxide (American Chemical Society certified).
 2. Bring volume to 20 ml with distilled water. Hemin must be completely dissolved before the addition of water.
 3. Sterilize at 121°C for 15 min.
 4. Store at 2 to 8°C in a tightly closed container, protected from light, for up to 1 month.
- D. Vitamin K₁ stock solution (final concentration, 10 mg/ml)
1. Add 20 ml of 95% ethanol to 0.2 ml of vitamin K₁ (3-phytylmenadione), and mix thoroughly.
 2. Store at 2 to 8°C in a tightly closed dark container for up to 1 year.
- E. Vitamin K₁ working solution (final concentration, 1 mg/ml)
1. Add 1 ml of vitamin K₁ stock solution to 9 ml of sterile distilled water, and mix thoroughly.
 2. Store at 2 to 8°C in tightly closed dark container for up to 1 month.
- F. Lysed horse blood (50%)
1. Aseptically mix equal volumes of defibrinated horse blood and sterile distilled water.
 2. Freeze at -20°C or lower and thaw the horse blood five to seven times until the cells are thoroughly lysed (blood will be translucent and dark red).
 3. Clarify blood by centrifuging at 12,000 × g for 20 min.
 4. Decant supernatant and check for clarity. Recentrifuge if necessary. Discard sediment.
 5. Store at -20°C for up to 6 months in conveniently sized aliquots.
 6. Bring to room temperature before use.
 7. Ready-to-use lysed horse blood is commercially available.

The test medium used in these panels may vary from the NCCLS recommendations. If so, it is the manufacturer's responsibility to prove equivalence to a reference method and provide any variation in QC values for the recommended QC strains.

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

A standardized inoculum of bacteria is swabbed onto the surface of a Mueller-Hinton agar (MHA) plate. Etest strips containing a continuous gradient of antimicrobial concentrations are placed on the agar surface. After overnight incubation, an elliptical zone of inhibition forms as the antimicrobial agent inhibits growth. The

MIC is read where growth intersects the Etest strip. MICs can be interpreted as susceptible, intermediate, or resistant based on the tables in the NCCLS MIC standard (1).

The Etest is a commercial antimicrobial gradient product and is not specifi-

cally addressed in NCCLS standards. However, the NCCLS does acknowledge Food and Drug Administration (FDA)-cleared antimicrobial gradient tests that perform comparably to NCCLS reference methods as acceptable for use in clinical laboratories (1).

II. SPECIMEN

Prepare inocula from four or five isolated colonies of similar colony morphology.

A. Log-phase growth inoculum

Use colonies grown for 1 or 2 days on nonselective or selective (e.g., MAC) medium

B. Direct colony suspension inoculum

Use colonies grown overnight on nonselective medium (e.g., BAP or CHOC).

C. Subculture stock, frozen, or lyophilized isolates two times prior to testing.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Media and reagents

1. Agar plates (approximately 4 mm deep)

a. MHA

☑ **NOTE:** When testing oxacillin or methicillin with *Staphylococcus* spp., use MHA supplemented with 2% NaCl.

b. MHA with 5% sheep blood (BMHA)

c. *Haemophilus* test medium

d. GC agar base with defined supplements

Store at 2 to 8°C.

2. Nutrient broth (e.g., Mueller-Hinton, TSB) or 0.9% NaCl (3.0- to 5.0-ml aliquots)

Store at 2 to 30°C.

3. Etest strips (AB Biodisk North America, Inc., Piscataway, N.J.)

Store with desiccant at -20°C and handle strips according to the manufacturer's instructions.

B. Supplies

1. Sterile cotton-tipped swabs

2. Sterile plastic pipettes

3. McFarland 0.5 and 1.0 turbidity standards

C. Equipment

1. Forceps

2. Scissors

3. Sterile petri plate

4. Movable light source

5. Vortex mixer

6. 34- to 35°C ambient-air incubator; CO₂ incubation for some organisms

7. Etest applicator (optional)

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL**A. QC strains**

1. *Escherichia coli* ATCC 25922
2. *Staphylococcus aureus* ATCC 29213
3. *Pseudomonas aeruginosa* ATCC 27853
4. *E. coli* ATCC 35218
5. *Enterococcus faecalis* ATCC 29212
6. *E. faecalis* ATCC 51299
7. *Neisseria gonorrhoeae* ATCC 49226
8. *Haemophilus influenzae* ATCC 49247
9. *H. influenzae* ATCC 49766
10. *Streptococcus pneumoniae* ATCC 49619
11. Additional QC strains as described by the manufacturer

B. Monitoring accuracy

1. Test QC strains by following routine procedure, and record results in QC notebook. Record lot numbers and expiration dates of Etest strips and agar. See Appendix 5.8–1.
2. Compare to expected results (*see* NCCLS QC tables) (1). Note any out-of-control result and document; proceed with corrective action, if necessary.

C. Daily QC testing

1. QC testing is in control if no greater than 1 out of 20 consecutive results is outside specified accuracy limits.
2. If any more than 1 of 20 results is out of control, corrective action is required.

D. Weekly QC testing

1. Frequency of QC testing
 - a. QC testing can be reduced from daily to weekly providing a laboratory can document proficiency in performing this test by performing QC daily (or each day patient tests are performed) until 20 consecutive days of testing have been obtained.
 - b. Proficiency in performing QC tests is confirmed if, for each antimicrobial agent-QC organism combination, no more than 1 of 20 results are outside accuracy limits.
 - c. If 2 or 3 of 20 results are out of control, continue testing until 30 days of testing have been accomplished. If no more than 3 of 30 results are outside the accuracy limits, weekly QC testing can begin.
 - d. Document proficiency each time a new antimicrobial agent is added to the testing protocols.
2. Weekly QC testing is in control if all MICs are within specified accuracy limits.
3. If any weekly result is out of control, return to daily QC to define the problem, as explained in item IV.E below.
4. Perform QC testing each time a new lot or new shipment of materials (MHA, Etest strips, etc.) is put into use.

E. Corrective action

1. Out of control due to obvious error (e.g., use of wrong Etest strip or QC strain, obvious contamination, or incorrect incubation conditions): record the reason for the out-of-control result and retest the same day. If the repeat result is in range, no further action is needed.
2. Out of control not due to obvious error
 - a. Test the antimicrobial agent(s) with appropriate QC strain(s) for five consecutive test days. Record all results.

IV. QUALITY CONTROL (continued)

- b. For each antimicrobial agent-QC strain combination, all of the five MICs must be within the acceptable control limits. Weekly testing may be resumed.
- c. If the problem is not resolved (one or more MICs are outside the accuracy control limits), continue daily QC until the problem can be resolved.
- d. Investigate possible systemic problems (e.g., review reading of Etest strips, standardization of inoculum, storage and expiration of reagents, incubation conditions, equipment, and maintenance and purity of QC strain).
- e. In order to return to weekly testing, satisfactory performance for another 20 or 30 consecutive days must be documented as described above.
- f. During corrective action, carefully evaluate whether patient reports will be affected. It may be necessary to use an alternate test method until the problem is resolved.

V. PROCEDURE

See Appendix 5.8–2 for a summary of testing conditions for various organisms.

- A. Bring agar plates and containers of Etest strips to room temperature before use. Ensure that the surface of the agar is dry before use.
- B. Inoculum preparation
Using a loop or swab, transfer colonies as follows.
 1. Standard method (log-phase growth)
 - a. Pick four or five isolated colonies to 3.0 to 5.0 ml of broth.
 - b. Incubate at 35°C for 2 to 8 h until growth reaches the turbidity at or above that of a 0.5 McFarland standard.
 2. Direct colony suspension method
Pick several colonies from a *fresh* (18- to 24-h) nonselective agar plate to broth or 0.9% NaCl.
 3. For either method, vortex well and adjust turbidity visually with sterile broth or 0.9% NaCl to match a 0.5 McFarland standard (1×10^8 to 2×10^8 CFU/ml). Alternatively, standardize suspension with a photometric device.
- C. Inoculation of agar plate
 1. Within 15 min of adjusting turbidity, dip a sterile cotton swab into the inoculum and rotate against the wall of the tube above the liquid to remove excess inoculum.
 2. Swab entire surface of agar plate three times, rotating plate approximately 60° between streaking to ensure even distribution. Finally, run swab around the edge of the agar to remove any excess moisture.
 3. Allow inoculated plate to stand for approximately 10 to 15 min. This is critical for maximum performance of the Etest.
- D. Application of Etest strips
 1. Make certain MIC scale faces upward; do not touch the underside (antimicrobial side) of the strip.
 2. Using forceps or your fingers, grab the end of the strip labeled “E”; use care to take one strip only.
 3. If an applicator is used, follow manufacturer’s directions for this apparatus.
 4. Apply strips to the agar surface with the highest concentration near the edge of the petri dish.
 - a. For a 100-mm plate, use only one or two strips per plate.
 - b. For a 150-mm plate, place one to six strips on the plate equal distances apart, radiating from the center of the plate. The “E” end of the strip should point to the rim of the petri dish. Templates are provided by the manufacturer (optional).

V. PROCEDURE (*continued*)

5. Once the strip is in place, remove large air bubbles underneath by using forceps and gently pressing on the strip, beginning at the lower edge of the bubble and moving up the concentration gradient of the strip toward the E. Small bubbles will not interfere.
6. *Do not* relocate an Etest strip once it has landed on the agar surface. The antimicrobial agent is immediately released into the agar. If the strip is accidentally placed upside down, carefully pick it up, turn it over, and place it on the agar surface. If the strip touches the counter or another object, it can still be used providing it does not contact moisture.

E. Incubation

1. Incubate plates within 1 h of Etest application (except for anaerobes which should be incubated immediately). See Appendix 5.8–2 for incubation recommendations and special considerations.
2. Invert plates and stack plates no more than five high.
3. Incubate for 16 to 20 h at 35°C in an ambient-air incubator.
 - a. Incubate all staphylococci that are susceptible to penicillinase-resistant penicillins (oxacillin, methicillin, nafcillin) for an additional 4 to 8 h (total of 24 h).
 - b. Incubate all staphylococci and all enterococci that are susceptible to vancomycin for an additional 4 to 8 h (total of 24 h).

F. Reading plates

1. Read plates only if lawn of growth is confluent or nearly confluent.
2. Remove the cover of the petri dish, hold plate to a transmitted-light source, and read MIC at the point where growth intersects the Etest strip. If using opaque media (e.g., BMHA), use reflected light; a hand lens may help. Read for complete inhibition of all growth, including haze and isolated colonies.
3. If there is no inhibition of growth, report the MIC as greater than the highest concentration on the Etest strip.
4. If the zone does not intersect the strip (zone is below the strip), report MIC as less than the lowest concentration.
5. For MICs that fall between markings, use the higher value.
6. When testing hemolytic organisms, measure the diameter of the zone of inhibition of growth and not the zone of inhibition of hemolysis.
7. Refer to the AB Biodisk technical guide, which contains photographs of equivocal intersections.
8. Strip placement and reading results
 - a. Application of a strip to a wet surface often results in growth that begins at the zone-strip intersection and continues up the side of the strip. Ignore this when reading the MIC. Excessively wet swabs and incomplete swabbing of plates may result in jagged edges and an uneven intersection at the MIC.
 - b. The organism and antimicrobial agent tested may have an effect on the appearance of the zone edge where growth intersects the Etest strip. AB Biodisk has extensive reading guidelines (including photographic examples) which must be used.

POSTANALYTICAL CONSIDERATIONS

VI. REPORTING RESULTS**A. Interpretation**

Interpret MICs based on criteria specified by the NCCLS (1).

B. Reporting

Report the MIC along with its categorical interpretation: susceptible (S), intermediate (I), or resistant (R).

Example: *S. pneumoniae*

<u>Drug</u>	<u>MIC (µg/ml)</u>	<u>Interpretation</u>
Penicillin	>2	R

C. If the Etest MIC falls between the twofold dilutions, round up to the next highest twofold dilution and then interpret the MIC.

D. Important reporting rules

- Report methicillin-, oxacillin-, or nafcillin-resistant staphylococci as resistant to all beta-lactam drugs (including beta-lactam–beta-lactamase inhibitor combinations, all cepheems, all penicillins, and carbapenems) regardless of results of in vitro susceptibility testing.
- Misleading results
Specific organism–drug combinations should not be reported, since susceptible results could be *dangerously misleading*.
 - First- and second-generation cephalosporins and aminoglycosides against *Salmonella* spp. and *Shigella* spp.
 - Cephalosporins, trimethoprim-sulfamethoxazole, clindamycin, and aminoglycosides (except for high-level-synergy testing for aminoglycosides) against enterococci
 - Cephalosporins against *Listeria* spp.
 - Beta-lactams against oxacillin-resistant *Staphylococcus* spp.
 - Cephalosporins, penicillins, and aztreonam against extended-spectrum beta-lactamase (ESBL)-producing *E. coli* and *Klebsiella* spp.
- For ESBL confirmatory testing, there is a single strip configured with cefotaxime on one end and cefotaxime with clavulanic acid on the other end. A similar strip with ceftazidime and ceftazidime-clavulanic acid is also available. Both are FDA cleared.

VII. PROCEDURE NOTES**A. Oxacillin (methicillin)-resistant staphylococci**

- Oxacillin is the recommended penicillinase-stable penicillin for testing, and oxacillin results can represent all penicillinase-stable penicillins (oxacillin, methicillin, and nafcillin and also cloxacillin dicloxacillin, and flucloxacillin). Testing of oxacillin with staphylococci should be performed in MHA supplemented with 2% NaCl (other drugs should not be tested on 2% NaCl-supplemented MHA).
- Clue to detection of methicillin (oxacillin)-resistant *S. aureus*: multiple resistance to other antimicrobial agents (beta-lactams, aminoglycosides, erythromycin, clindamycin, and tetracycline). Recently, strains of oxacillin-resistant *S. aureus* that are not multiply resistant have been encountered in isolates primarily from patients with community-acquired infections.

B. Media

- Thymidine can interfere with performance of sulfonamides and trimethoprim. Monitor media by testing *E. faecalis* ATCC 29212 and trimethoprim-sulfamethoxazole (MIC of 0.5/9.5 µg/ml indicates acceptable performance). Blood components (other than horse blood) contain thymidine and may interfere with testing of these agents.

VII. PROCEDURE NOTES*(continued)*

2. An increase in the cation content (Ca^{2+} , Mg^{2+}) of the medium results in an increase in the MICs of aminoglycosides for *P. aeruginosa* and an increase in MICs of tetracycline for all organisms. A decrease in cation content has the opposite effect. Monitor cation content by testing aminoglycosides with *P. aeruginosa* ATCC 27853 and making sure results are within defined QC limits.
3. Increased zinc ions may cause increased MICs with carbapenems.
4. Variation in calcium ions affects the results of daptomycin tests.

VIII. LIMITATIONS

- A. The Etest (an agar-based technique) correlates with the reference agar dilution procedure. However, certain discrepancies between Etest MICs and MICs from non-agar-based systems such as broth microdilution and from other automated systems based on different technical principles may occur as a consequence of the different characteristics inherent in these methods.
- B. Numerous factors can affect Etest MICs, such as inoculum size, rate of growth, formulation and pH of media, incubation environment and length of incubation, drug diffusion rate, and measurement of endpoints. Therefore, strict adherence to protocol is required to ensure reliable results.
- C. The Etest has been evaluated for other organisms in addition to those listed in Appendix 5.8–2. It is the responsibility of the laboratory to ensure that there are sufficient data to warrant use of Etest for testing bacteria isolated from patients' specimens, particularly for organism-Etest antimicrobial agent combinations not yet FDA cleared. Contact AB Biodisk for additional information.

APPENDIX 5.8-2

Quick reference list for performing Etest^a

Organism	Agar	Inoculum method	Incubation length (h)	Incubation atmosphere ^b
Testing cleared by FDA				
<i>Enterobacteriaceae</i>	MHA	DCS/LPG	16–20	Ambient air
<i>Pseudomonas aeruginosa</i>	MHA	DCS/LPG	16–20	Ambient air
<i>Stenotrophomonas maltophilia</i>	MHA	DCS/LPG	24	Ambient air
<i>Acinetobacter</i> spp.	MHA	DCS/LPG	24	Ambient air
<i>Haemophilus</i> spp. ^c	HTM	DCS	20–24	CO ₂
<i>Neisseria gonorrhoeae</i>	GC (1% defined supplement)	DCS	20–24	CO ₂
<i>Staphylococcus</i> spp.	MHA (add 2% NaCl to media for oxacillin) ^d	DCS	16–18; 24 (oxacillin ^d and vancomycin)	Ambient air
<i>Enterococcus</i> spp.	MHA	DCS/LPG	24 (HLAR at 48)	Ambient air
<i>Streptococcus</i> spp.	BMHA	DCS	24	CO ₂
<i>Streptococcus pneumoniae</i> ^e	BMHA	DCS	20–24	CO ₂
Anaerobes ^{c,*}	Brucella blood agar supplemented with vitamin K and hemin	DCS/LPG	24–72	Anaerobic environment
Testing not cleared by FDA as of August 2002				
<i>Neisseria meningitidis</i>	BMHA (or CMHA)	DCS	24	CO ₂
<i>Moraxella</i> spp. ^f	MHA	DCS	18–24	CO ₂
<i>Corynebacterium</i> spp. ^g	BMHA	DCS	18–24 (48 h if <i>C. jeikeium</i>)	Ambient air (CO ₂ if necessary)
<i>Listeria</i> spp.	BMHA	DCS	18–24	Ambient air
<i>Pasteurella multocida</i>	BMHA	DCS	18–24	Ambient air
<i>Eikenella corrodens</i> ^g	BMHA	DCS	18–24	CO ₂

^a This table is divided into two sections. The first part lists aerobic organisms and rapidly growing facultatively anaerobic organisms for which the FDA has cleared certain Etest strips for testing in the clinical laboratory. The second part lists organisms for which Etest studies have been performed but for which Etest strips have not yet been granted clearance by the FDA. Testing of Etest strip-organism combinations that are not yet FDA cleared should be done with caution. Always check the Etest package insert or contact the manufacturer to determine the FDA clearance status for testing an agent against a particular isolate from a patient. Not every drug is cleared for each organism group listed. Abbreviations: CMHA, chocolate, MHA; DCS, direct colony suspension standardized to a 0.5 McFarland turbidity standard; DCS/LPG, direct colony suspension or log-phase growth standardized to a 0.5 McFarland turbidity standard; GC, GC agar base with 1% defined supplement; HTM, *Haemophilus* test medium.

^b All incubation temperatures are 34 to 35°C.

^c Use a photometric device to adjust turbidity. This step is critical in avoiding erroneous results due to under- or overinoculation.

^d And other penicillinase-stable penicillins.

^e Use broth for inoculum suspension.

^f Generally, only a beta-lactamase test is warranted for *Moraxella catarrhalis*.

^g Use a 1.0 McFarland standard for inoculum preparation (manufacturer's recommendation).

5.9

Agar Dilution MIC Test for Anaerobic Bacteria

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The anaerobe agar dilution MIC method is a semiquantitative method for the determination of in vitro activity of an antimicrobial agent against anaerobic bacterial isolates. A series of agar plates, each containing a unique concentration of an antimicrobial agent, are inoculated with up to 36 isolates. After 48 h of incubation at

35°C in an anaerobic environment, the MIC is determined by observing the lowest concentration of antimicrobial agent which will inhibit visible growth of the test isolate. MICs obtained are interpreted as susceptible, intermediate, or resistant based on criteria defined by the NCCLS (2).

Recommendations for performance of the agar dilution method for susceptibility testing of anaerobic bacteria are found in the NCCLS M11 standard (2). This method uses brucella agar supplemented with hemin, vitamin K₁, and laked sheep blood, which is satisfactory for testing most anaerobic species.

II. SPECIMEN

Prepare inoculum directly from four or five isolated colonies of similar colony morphology grown anaerobically for 24 to 48 h on an anaerobic brucella blood agar plate.

- A. Use 24-h growth for rapid growers (e.g., *Bacteroides fragilis* group), if sufficient growth is available; 48-h growth is preferable for most other species.
- B. Subculture stock, frozen, or lyophilized isolates two times prior to testing.
- C. Do not expose agar plates containing test isolates to air for longer than 20 to 30 min.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Media and reagents

See Appendix 5.9-1 for additional information.

1. Brucella agar supplemented with (final concentrations) vitamin K₁ (1 µg/ml), hemin (5 µg/ml), and laked sheep blood (5%). Store at 2 to 8°C.
2. Broth media
 - a. Brucella broth dispensed in aliquots of 5 ml. Store at 2 to 8°C.
 - b. THIO supplemented with vitamin K₁, hemin, and either a marble chip or sodium bicarbonate dispensed in aliquots of 5 ml. Store at 2 to 8°C.
3. Sterile 0.9% NaCl dispensed in aliquots of 9 ml in screw-cap tubes. Store at 2 to 8°C.

4. Sterile 0.9% NaCl dispensed in aliquots of 9.9 ml in screw-cap tubes. Store at 2 to 8°C.

5. Brucella agar deeps supplemented with vitamin K₁ and hemin. Store at 2 to 8°C.

B. Supplies

1. Sterile cotton-tipped swabs
2. Sterile polystyrene screw-cap tubes (e.g., 16 by 125 mm for making antimicrobial agent dilutions and 20 by 15 mm for agar deep tubes)
3. Sterile plastic pipettes
4. 0.5 McFarland turbidity standard
5. Sterile 100-mm round petri plates or 100-mm square petri plates

III. MATERIALS (continued)**C. Equipment**

1. Vortex mixer
2. Adjustable micropipette and sterile pipette tips
3. 35°C anaerobic atmosphere (in container large enough to hold plates) containing 5 to 10% H₂, 5 to 10% CO₂, and 80 to 90% N₂ (e.g., anaerobe chamber, anaerobe pouch, or anaerobic jar)
4. Boiling water bath, steamer, or autoclave to melt agar
5. 48 ± 2°C water bath
6. Steers replicator (autoclaved)
7. 35°C ambient-air incubator (CO₂)
8. Bunsen burner

ANALYTICAL CONSIDERATIONS**IV. QUALITY CONTROL****A. QC strains**

1. *B. fragilis* ATCC 25285
2. *Bacteroides thetaiotaomicron* ATCC 29741
3. *Eubacterium lentum* ATCC 43055

B. Monitoring accuracy

1. Test QC isolates by following routine procedures, and record results on a QC log sheet. Record lot numbers and expiration dates of medium and antimicrobial agents. See Appendix 5.9–2.
2. Compare with expected results listed in the most recent NCCLS standards tables (2). Note any out-of-control results and document; proceed with corrective action if necessary.

C. Include at least two of the QC strains listed above with each set of clinical isolates being tested. Ideally, the QC strains selected should provide on-scale MICs for each of the antimicrobial agents being tested.**D. Additional controls**

1. Positive growth control plate (anaerobically incubated plate without antimicrobial agent) must demonstrate good growth (confluent spot) and not show any contaminating organisms. If adequate growth is not obtained on the positive growth control plate, the MICs should not be read or interpreted for that organism.
2. Negative growth control plate (aerobically incubated plate without antimicrobial agent) must be free of any growth.
3. Purity plate should demonstrate a pure culture.
4. Inoculum count verification plate should show approximately 50 to 200 colonies.

V. PROCEDURE**A. Organizational considerations**

Agar dilution is a very complicated, multistep procedure performed over several days. It is important to completely plan out the entire procedure and have all supplies and work areas ready in advance in order to complete an agar dilution run in a timely manner. See Appendix 5.9–3 for work flow suggestions. This procedure can be performed by a single person; however, it is much easier and more efficient when at least two people are involved. Inoculum suspensions and the inoculation of the agar plates can be done outside of the anaerobic chamber. However, the time between isolate exposure to air and placement of the inoculated plates in an anaerobic environment should not exceed 30 min.

B. Preparation of antimicrobial agent-containing plates

1. Determine antimicrobial agents and concentrations to be tested. At a minimum, test six dilutions (two dilutions below the susceptible breakpoint; three dilutions representing the susceptible, intermediate, and resistant interpretive categories; and one dilution above the resistant breakpoint). Additional dilutions may be required to include concentrations that would represent acceptable ranges for QC organisms.

V. PROCEDURE (*continued*)

2. Label one petri plate for each concentration of each antimicrobial agent to be tested. Also label control plates equal to twice the number of antimicrobial agents plus two in which to pour agar without antimicrobial agent. Stack plates in an organized fashion.
3. Label one test tube (16 by 125 mm) with the intermediate concentration (10 times the final concentration) for each dilution of each antimicrobial agent (*see* Appendix 5.9–4).
4. Thaw (at room temperature) stock solutions of antimicrobial agents.
5. Prepare intermediate dilutions of stock solutions.
6. Label one tube of agar for each antimicrobial dilution.
7. Melt agar tubes and make certain that the agar is completely liquefied.
8. Place tubes with melted agar into the 48°C water bath and allow them to equilibrate to the water bath temperature (approximately 20 min). Then perform the following.
 - a. Remove the melted agar deep; wipe off excess water.
 - b. Add 1 ml of laked sheep blood for round or 1.5 ml for square petri plates (*see* Appendix 5.9–5).
 - c. Add 2 ml of antimicrobial agent for round or 3 ml for square petri dishes.
 - d. For growth control plates, add the appropriate amount (2 or 3 ml) of sterile water in place of antimicrobial agent.
9. Mix by gently inverting and rotating tubes three times.
10. Pour agar into prelabeled petri plates on a level surface.
 - a. Make certain that the agar is evenly distributed in plate.
 - b. Rotate plate to move any bubbles to the edge of the plate.
 - c. If any bubbles remain on the central surface or if there are large bubbles on the edge, *quickly* pass a Bunsen burner flame over the surface to eliminate them before the agar solidifies.
11. Following solidification of the agar in the plates (5 to 10 min), the next step is drying the plates. If the plates are too moist, the inocula may run together. Suggestions for drying the plates include the following.
 - a. Allow the plates to remain with lids slightly ajar in a 35°C ambient-air incubator (preferably, one that is not humidified) for 45 to 60 min.
 - b. Invert plates and leave the lids ajar in a laminar-flow hood or biological safety cabinet for 30 to 45 min.
12. For routine testing, use plates as soon as they are dry or store at 2 to 8°C in a plastic bag for up to 7 days. Use plates containing imipenem, clavulanic acid, or any other antimicrobial agent of known instability on the day they are poured.

C. Inoculum preparation

1. Using a loop or swab, transfer colonies as follows.
 - a. Growth method
 - (1) Pick colonies from a supplemented brucella blood agar plate 24 to 48 h old to enriched THIO or supplemented brucella broth. (Prior to using THIO, prereduce by boiling for 5 min and then cool.)
 - (2) Incubate at 35°C under anaerobic conditions for 4 to 6 h (but no longer than 24 h) or until the turbidity is equivalent to that of a 0.5 McFarland turbidity standard (1.5×10^8 CFU/ml). Ambient-air incubation is acceptable when using prereduced THIO. If turbidity is not reached by 24 h, use the direct colony suspension method.
 - b. Direct colony suspension method
 - (1) Pick colonies from a supplemented brucella blood agar plate 24 to 48 h old, and suspend in brucella broth.
 - (2) Gently invert the tube or vortex to obtain a homogeneous suspension.
 - (3) Adjust the turbidity to match that of a 0.5 McFarland standard, which has been vortexed.

V. PROCEDURE (*continued*)

2. Prepare inoculum suspensions no more than 15 min before inoculation of plates.

D. Inoculation

1. Allow agar dilution plates to warm to room temperature, and label them.
2. Within 15 min of preparing the inoculum, inoculate the agar dilution plates.
3. Pipette approximately 0.5 to 0.6 ml of each standardized suspension into the appropriate well of a Steers replicator reservoir block. See layout example in Appendix 5.9–5.
4. Make certain that the plates contain some indication as to the orientation of inocula (e.g., labels or markings on plates or dye in one of the seed wells).
5. Inoculate plates in the following order.
 - a. Two control plates without drug: label as “pre-(name of antimicrobial agent 1).”
 - b. Antimicrobial agent 1 plates: lowest to highest concentrations (e.g., 0.06 to 128 $\mu\text{g/ml}$).
 - c. Two control plates without drug: label as “between (names of antimicrobial agents 1 and 2).” These plates are necessary to show that the organism is still viable throughout the inoculation process.
 - d. Antimicrobial agent 2 plates: lowest to highest concentrations
 - e. Two control plates without drug: label as “between (names of antimicrobial agents 2 and 3).”
 - f. Continue this pattern until all antimicrobial agent-containing plates are inoculated.
 - g. After the last antimicrobial agent (x) plate, inoculate two control plates without drug and label them “post-(name of antimicrobial agent x)”. No more than four antimicrobial dilution sets of plates should be inoculated using a single replicator seed tray-pin set in order to minimize the chance of antimicrobial agent carryover and contamination of the seed tray of the replicator. If more than four antimicrobial agents are tested, several replicators are needed.
 - h. An additional plate without drug can be inoculated and used as an inoculum control plate. Do not incubate, but store these plates at 4°C during the incubation period. Remove the plates from the refrigerator at the time the MICs are read. The inoculum control plates are often helpful when poor-growing organisms are encountered, as they allow for a comparison between poor growth and inoculum dried on the agar plate with no growth.
6. Inoculate plates by positioning inoculator prongs in reservoir block wells to pick up inocula (prongs of Steers replicator generally pick up 1 to 5 μl). Then carefully apply prongs to the agar surface (final inoculum concentration is approximately 10^5 CFU per spot). Perform this procedure slowly to avoid splashing, which can lead to cross-contamination of inocula.
7. Following inoculation, move each plate aside and allow it to dry (agar surface up) with the top slightly ajar.

E. Incubation

1. When inocula on the plates have dried (usually 5 to 10 min after inoculation), invert plates (cover down).
2. Incubate one plate from each pair of growth control plates inoculated at the beginning, between antimicrobial agents, and at the end of the procedure at 35°C in a CO₂ incubator (aerobic purity plates).
3. Incubate all antimicrobial agent-containing plates and remaining growth control and colony count plates in an anaerobic environment at 35°C in CO₂ for 42 to 48 h.
4. Incubate all plates with lid side down.

V. PROCEDURE (*continued*)**F. Reading MICs**

1. Following incubation, examine purity plates first. If a mixed culture is apparent, repeat the test.
2. Examine growth control plates.
 - a. Positive growth control plates should demonstrate a confluent spot indicating adequate growth. The growth pattern should be the same on all growth control plates throughout the run.
 - b. Negative growth control plates should show no growth.
 - c. If either type of growth control plate is unacceptable, repeat the test.
3. Read agar dilution plates in the order that they were stamped, and place each plate against a dark nonreflective background. It is helpful to line up all plates (lowest to highest concentration) of one antimicrobial agent and read one organism at a time.
4. The MIC is the lowest concentration of antimicrobial agent where a *marked* change in growth appears compared to the growth control plate. A marked change can consist of no growth, faint haze, one discrete colony, or several tiny colonies. NCCLS M11 contains photographs and is a good reference for reading appropriate endpoints (2).
5. Record results on agar dilution MIC worksheet (*see* Appendix 5.9–6).

G. Inoculum count verification plates

1. Colony counts should be performed periodically at the completion of a run to verify the inoculum concentration. Frequency of testing is up to the individual laboratory and should be based on the frequency of use of the test method. For laboratories that infrequently perform this procedure, colony counts should be done every time the test is performed. For laboratories that perform this procedure at least once a week, colony counts can be performed monthly.
2. Colony count procedure
 - a. Select approximately two to five wells to test.
 - b. Remove 0.01 ml from the respective replicator block well immediately after completion of the inoculation process and add this to 9.9 ml of 0.9% saline (1:1,000 dilution). Mix by at least three gentle inversions.
 - c. Transfer 0.1 ml from the first tube to a second tube containing 9.9 ml (1:100 dilution). Mix by at least three gentle inversions.
 - d. Plate 0.1 ml to a supplemented brucella blood agar plate.
 - e. Using a loop or bent glass (“hockey stick”), thoroughly spread the inoculum over the surface of the plate by streaking in several directions.
 - f. Incubate under anaerobic conditions for 48 h.
 - g. The plate count should be approximately 10^2 organisms (50 to 200 colonies per plate).

POSTANALYTICAL CONSIDERATIONS

VI. REPORTING RESULTS**A. Interpretation**

Interpret MIC based on criteria specified by the NCCLS (2).

B. Reporting

Report the MIC along with its categorical interpretation: susceptible (S), intermediate (I), or resistant (R).

Example: *B. fragilis*

<u>Drug</u>	<u>MIC (µg/ml)</u>	<u>Interpretation</u>
Ampicillin-sulbactam	8/4	S
Cefoxitin	8	S
Clindamycin	4	I
Metronidazole	1	S
Piperacillin-tazobactam	0.25	S

C. Important reporting rules

The majority of *B. fragilis* group isolates are beta-lactamase producers; therefore, these isolates do not require beta-lactamase testing and should always be reported as resistant to penicillin and ampicillin regardless of the MIC (1).

VII. PROCEDURE NOTES

- A.** For some fastidious isolates, it may be necessary to prereduce the plates and to perform all manipulations in an anaerobic environment.
- B.** CHOC can be used in place of BAP for aerobic purity plates.
- C.** With some anaerobic species, such as *E. lentum*, which either grow slowly or produce small colonies, multiple plates may need to be inoculated in order to obtain sufficient growth to make an inoculum suspension equivalent to a 0.5 McFarland standard.
- D.** Most anaerobic isolates can be stored at $\leq -60^{\circ}\text{C}$ in 20% glycerol or 20% sterile skim milk.

VIII. LIMITATIONS

- A.** Agar dilution method is the standard reference method for susceptibility testing of anaerobic bacteria; however, it is very labor-intensive and not ideal for testing a small number of isolates.
- B.** As with any procedure, experience is important. Those who perform agar dilution susceptibility tests on anaerobes should have experience in anaerobic bacteriology. Laboratories with few requests for susceptibility tests should consider sending them to a referral laboratory with experience in anaerobic susceptibility testing.
- C.** Anaerobic organisms differ markedly in size and shape; therefore, a standardization of inocula by using a 0.5 McFarland standard may not yield 1.5×10^8 CFU/ml for all organisms.
- D.** Modifications of this method and of the medium composition may permit the growth of the more fastidious anaerobic organisms, but appropriate QC tests must be included and the results must conform to published values. If modifications are made, reporting of results should acknowledge changes from standard methods.
- E.** Because many infections involving anaerobes are polymicrobial and successful treatment often involves a combination of surgical intervention and the use of empirical broad-spectrum antimicrobial therapy, the relative importance of the susceptibility of a single organism to predict a favorable clinical outcome is difficult to determine.

VIII. LIMITATIONS (continued)

- F.** When testing anaerobic species that are known to swarm (e.g., *Clostridium difficile* or *Clostridium tetani*), empty wells should be left between the test isolates in the Steers replicator reservoir block. With *Clostridium septicum*, it is recommended that only one isolate be tested per plate.
- G.** Beta-lactamase testing with a chromogenic cephalosporin-based method can be performed with anaerobic species. A beta-lactamase-producing isolate should be reported as resistant to penicillin and ampicillin, regardless of the MIC. Some anaerobic species are known to be resistant to beta-lactam antimicrobial agents by mechanisms other than beta-lactamases. Therefore, a negative beta-lactamase test does not ensure susceptibility to all beta-lactam antimicrobial agents.

APPENDIX 5.9–1

Preparation of Media and Reagents

- A.** Supplemented brucella blood agar (1, 2)
1. Use the following formulation of brucella agar powder.

pancreatic digest of casein	10 g
peptic digest of animal tissue	10 g
dextrose	1 g
yeast extract	2 g
sodium chloride	5 g
sodium bisulfite	0.1 g
agar	15 g
 2. Combine the following in 1,000 ml of distilled water.

brucella agar powder	43 g
hemin stock solution	1 ml
vitamin K ₁ working solution	1 ml
 3. Boil to dissolve agar.
 4. Autoclave at 121°C for 15 min.
 5. Cool to 48 to 50°C.
 6. Aseptically dispense molten agar into sterile screw-cap tubes (17 or 27 ml depending on the size of the petri dishes being used). See Appendix 5.9–5.
 7. Cap tightly, and store at 2 to 8°C for up to 1 month.
 8. Add laked sheep blood just before adding the antimicrobial dilutions (final concentration, 5%). See item V.B in procedure 5.9 for more details.

APPENDIX 5.9–1 (continued)

- B. Enriched THIO (1, 2)
- Use the following formulation of enriched THIO powder.

pancreatic digest of casein	17 g
papaic digest of soybean meal	3 g
dextrose	6 g
sodium chloride	2.5 g
sodium thioglycolate	0.5 g
agar	0.7 g
L-cystine	0.25 g
sodium sulfite	0.1 g
 - Combine the following in 1,000 ml of distilled water.

THIO medium powder without indicator ...	30 g
hemin stock solution	1 ml
vitamin K ₁ working solution	1 ml
 - Boil to dissolve agar (THIO contains a small amount of agar).
 - Dispense in 5-ml amounts into screw-cap tubes (13 by 100 mm).
 - Autoclave at 121°C for 15 min.
 - Cap tightly, and store at 2 to 8°C in the dark for up to 6 months.
 - Just prior to use, boil for 5 min and cool. Add 0.25 ml of filter-sterilized sodium bicarbonate stock solution per 5 ml of THIO.
 - Alternatively, substitute three or four marble chips per 5 ml of THIO instead of sodium bicarbonate. Add before autoclaving.
- C. Hemin stock solution (final concentration, 5 mg/ml)
- Dissolve 0.1 g of hemin in 2 ml of 1.0 N sodium hydroxide (American Chemical Society certified).
 - Bring volume to 20 ml with distilled water. Hemin must be completely dissolved before the addition of water.
 - Sterilize at 121°C for 15 min.
 - Store at 2 to 8°C in a tightly closed container, protected from light, for up to 1 month.
- D. Vitamin K₁ stock solution (final concentration, 10 mg/ml)
- Add 20 ml of 95% ethanol to 0.2 ml of vitamin K₁ (3-phytylmenadione), and mix thoroughly.
 - Store at 2 to 8°C in tightly closed dark container for up to 1 year.
- E. Vitamin K₁ working solution (final concentration, 1 mg/ml)
- Add 1 ml of vitamin K₁ stock solution to 9 ml of sterile distilled water, and mix thoroughly.
 - Store at 2 to 8°C in tightly closed dark container for up to 1 month.
- F. Laked sheep blood
- Lyse blood by freezing at –20°C or below.
 - Thaw blood by either rapidly thawing in a water bath at 35 to 37°C or slowly thawing overnight at 2 to 8°C.
 - Store at –20°C for up to 6 months in 50- to 100-ml aliquots.
 - Bring to room temperature and mix thoroughly by inverting several times before use.
 - Ready-to-use laked sheep blood is commercially available.
- G. Sodium bicarbonate stock solution (final concentration, 20 mg/ml)
- Dissolve 2 g of sodium bicarbonate in 100 ml of distilled water.
 - Filter sterilize through a membrane filter (0.20- to 0.22- μ m pore size) into a sterile screw-cap container.
 - Store at 2 to 8°C in a tightly closed container for up to 1 month.

APPENDIX 5.9-3

Timetable for Agar Dilution Susceptibility Testing of Anaerobic Bacteria

- A. 3 to 4 weeks (or more) before run
 1. Read procedure carefully.
 2. Check supplies of the following, and order what is necessary.
 - a. Antimicrobial agents
 - b. Solvents and diluents
 - c. Supplies
 - d. Ingredients necessary for preparation of agar and broth media
- B. 2 weeks before run
 1. Order or prepare agar and broth media.
 2. Order sheep blood.
 3. Prepare antimicrobial stock solutions and freeze.
- C. 5 to 7 days before run
 1. Subculture test isolates and QC organisms from $\leq -60^{\circ}\text{C}$ freezer to supplemented brucella blood agar plate. Check purity of isolates.
 2. Lase sheep blood if not purchased as ready to use. Store in refrigerator or freezer.
- D. 3 to 4 days before run
 1. Subculture test and QC organisms a second time onto anaerobic supplemented brucella blood agar plates.
 2. Number and list test isolates on form for recording results.
 3. Prepare supplemented brucella agar deeps.
- E. 1 day before run
 1. Label antimicrobial dilution tubes and add appropriate volumes of diluent to them. Cap tubes tightly.
 2. Label petri plates and mark for correct orientation.
 3. Make certain a $48 \pm 2^{\circ}\text{C}$ water bath is available for the next day.
 4. Autoclave Steers replicators.
 5. If using the growth method, inoculate test and QC isolates to enriched THIO and incubate at 35°C for 6 to 24 h.
- F. Day of run
 1. Remove antimicrobial stock solutions from freezer and thaw them at room temperature.
 2. Remove laked sheep blood from refrigerator or freezer and allow it to warm to room temperature.
 3. Melt agar tubes and place them in water bath.
 4. Prepare intermediate dilutions of antimicrobial agents from stock solutions.
 5. Disinfect area where plates are to be poured.
 6. Add laked sheep blood and antimicrobial solutions to agar deeps.
 7. Pour plates.
 8. Allow agar to solidify in plates. (*Note:* Allow approximately 30 min per antimicrobial agent per person to make dilutions and pour plates; e.g., it will take one person approximately 1.5 h to do steps F.4 through 7 for three antimicrobial agents.)
 9. Allow plates to dry with their lids ajar in an incubator.
 10. Prepare and standardize inoculum suspensions (allow 30 to 45 min for 36 isolates).
 11. Pipette inoculum suspensions into Steers replicator reservoir block.
 12. Inoculate plates.
 13. When inocula have dried, invert and place them in an anaerobe jar or anaerobic chamber. Incubate for 42 to 48 h.
 14. Incubate aerobic plates in a 5 to 7% CO_2 incubator at 35°C .
 15. Autoclave Steers replicator and rinse thoroughly with tap and distilled water. Dry.
- G. After incubation
 1. Check positive growth control plates.
 2. Check negative growth (contamination) control plate.
 3. Read and record results.

APPENDIX 5.9-4

Preparation of antimicrobial dilutions from stock solutions^a

Concn (µg/ml) of antimicrobial solution	Amt (ml) of:		Intermediate antimicrobial concn (µg/ml) ^b
	Antimicrobial solution	Diluent	
5,120	2	2	2,560
5,120	2	6	1,280
2,000	6.4	3.6	1,280

^a Reproduced with permission from NCCLS. 2003. *Performance Standards for Antimicrobial Susceptibility Testing of Anaerobic Bacteria*. Thirteenth informational supplement M100-S13. NCCLS, Wayne, Pa. Copies of the current edition may be obtained from NCCLS, 940 West Valley Rd., Suite 1400, Wayne, PA 19087-1898. See also NCCLS. 2001. *Methods for Antimicrobial Susceptibility Testing of Anaerobic Bacteria*, 5th ed. Approved standard M11-A5. NCCLS, Wayne, Pa. The antimicrobial agent is diluted 10-fold when it is added to the agar. Therefore, the intermediate antimicrobial concentration is 10 times the final concentration of the antimicrobial agent in the agar.

^b Begin with stock solution at a concentration of 5,120 or 2,000 µg/ml.

APPENDIX 5.9-5

Volumes of components required for preparation of agar dilution plates when using round or square petri plates

Component	Vol (ml) required	
	Round plate	Square plate
Agar	17	25.5
Blood	1	1.5
Antimicrobial dilution	2	3
Total	20	30

Patterns for arrangement of isolates in Steers replicator

5.10.1

Minimum Bactericidal Concentration Testing

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The minimum bactericidal concentration (MBC) test can be used to assess the ability of an antimicrobial agent to kill a bacterial isolate. MBC tests are performed after consultation in very select clinical situations when it is necessary to determine the bactericidal activity of an antimicrobial agent against a bacterial isolate. These situations include those in which immune mechanisms offer little help in eradicating the infecting organisms, such as in patients with endocarditis or osteomyelitis or in immunosuppressed patients, particularly those with neutropenia. Bactericidal tests provide a rough prediction of bacterial eradication, but other factors may also impact the bacteriologic re-

sponses of patients. MBC testing is an accepted parameter in the evaluation of new antimicrobial agents and is frequently used as a research tool.

Although MIC tests have been well standardized, this is not the case for tests that assess bactericidal activity. The MBC and time-kill curve procedures described here represent the authors' recommendations.

Following performance of a conventional broth macrodilution or microdilution MIC susceptibility test (5), the tubes or wells containing concentrations of antimicrobial agent equal to and greater than the MIC are subcultured to determine whether the initial inoculum was inhibited

from multiplying (static action) or was killed (bactericidal action) (4). The MBC test endpoint is defined as the lowest concentration of antimicrobial agent that kills $\geq 99.9\%$ of the test inoculum. *The 99.9% cutoff is an arbitrary in vitro value with 95% confidence limits that has uncertain clinical relevance.* Generally, MBC tests are performed with one or two specific antimicrobial agents rather than the panel of antimicrobial agents commonly employed in routine MIC testing. In contrast to MIC tests, organisms in the MBC test inoculum must be in the log phase of growth, since many antimicrobial agents exert a bactericidal effect only on growing bacteria (4).

II. SPECIMEN

- A. Prepare inoculum from four or five isolated colonies of similar colony morphology grown for 18 to 24 h on BAP or nonselective supplemented media if necessary.
- B. Subculture stock, frozen, or lyophilized isolates three times prior to testing.

III.A. MATERIALS:
MACRODILUTION METHOD

Include QC information on reagent container and in QC records.

- A. **Media and reagents (storage conditions)**
The media listed include those necessary for testing rapidly growing aerobic bacteria. Refer to Appendix 5.10.1–1 for a complete listing of suggested media for testing fastidious aerobic bacteria.
 1. Cation-adjusted Mueller-Hinton broth (CAMHB) dispensed in approximately 250-ml aliquots into flasks and in 5-ml aliquots into tubes. Store at 2 to 8°C.
 2. Sterile 0.9% NaCl dispensed in 0.9-ml aliquots into capped tubes. Store at 2 to 8°C.
 3. BAP. Store at 2 to 8°C.
 4. Antimicrobial agent stock solutions, 1 ml of 1,280- $\mu\text{g/ml}$ solution. Store at -70°C . Refer to procedure 5.14 for preparation.
 5. Beaker of 95% ethanol to sterilize bent glass rods (optional)

III.A. MATERIALS: MACRODILUTION METHOD (continued)

6. Media for maintenance of QC organisms
 - a. TSA slants. Store at 2 to 8°C.
 - b. Brucella broth–15% glycerol dispensed into vials appropriate for freezing. Store at 2 to 8°C.
- B. Supplies**
1. Sterile acid-washed borosilicate glass test tubes (13 by 100 mm) with metal or plastic closures
 2. Sterile 1-, 5-, and 10-ml glass or plastic serologic pipettes and pipette bulb
 3. McFarland 0.5 turbidity standard
 4. Sterile disposable polystyrene capped tubes (5 ml; 12 by 75 mm)
 5. Sterile cotton-tipped swabs
- C. Equipment**
1. Test tube racks with 12 spaces per row
 2. Micropipettes, 10- and 100- μ l capacity with sterile disposable tips
 3. Calibrated 0.001-ml loop
 4. Vortex mixer
 5. Mechanical test tube shaker (fitted in incubator)
 6. –70°C freezer
 7. 35 \pm 2°C ambient-air incubator (CO₂ incubation needed for some organisms)
 8. Bunsen burner and bent glass rod “hockey sticks” (optional)

ANALYTICAL CONSIDERATIONS

IV.A. QUALITY CONTROL: MACRODILUTION METHOD

- A. QC strains**
1. Choose QC strains according to individual antimicrobial agents tested. (See NCCLS standard M7 for details on choosing appropriate QC strains and expected results [5]. See procedure 5.13 for information on appropriate storage and maintenance of QC strains.)
 - a. Test QC strains according to the standard procedure for testing patient isolates.
 - b. Select a QC strain that will give a midrange endpoint for the antimicrobial agent tested.
 2. Record MIC test results for individual agents on QC log worksheet (Appendix 5.10.1–2), and compare MICs obtained with expected results.
- B.** Growth control tube should show 3 to 4+ turbidity. Purity plate should show good growth and no contaminating organisms.
- C.** Sterility control should be free of any growth.
- D.** Inoculum controls should show approximately 75 to 150 colonies.
- E.** Test considered in control
1. Test broth supports growth of the test and control organisms.
 2. MICs for QC strains are within acceptable limits for each individual agent.
 3. MBCs for QC strains are within acceptable limits for each individual agent. This is an optional QC parameter (8).
 4. Growth and inoculum controls show appropriate growth.
 5. Purity plates are free of contaminating organisms.
- F.** Do not report patient results if any result is out of control (at any point during testing).
1. Notify supervisor.
 2. Ascertain the reason for failure, remedy the situation, and repeat the test.
 3. See troubleshooting tips in procedures 5.2 and 5.13.

V.A. PROCEDURE: MACRODILUTION METHOD

- A. Final concentrations to test**
1. Determine MIC for test isolate.
 2. Generally, include final concentration ranges from at least eight times the expected MIC to one-half or one-fourth the expected MIC. A range from 128 to 0.06 μ g/ml is usually adequate. Avoid testing high concentrations that may not be clinically achievable.

**V.A. PROCEDURE:
MACRODILUTION METHOD**
(continued)

3. Determine the number of tubes to prepare. Include enough tubes for QC. Each tube will contain a 1-ml volume of antimicrobial agent.

B. Antimicrobial agent working concentrations

See procedure 5.14 for antimicrobial stock solution preparation.

1. Assemble 14 sterile glass test tubes for each antimicrobial agent to be tested.
2. Label the tubes 1 through 14. Place tubes 1 through 12 in the first row and tubes 13 and 14 in the second row of a test tube rack.
 - a. Tube 14 is the broth sterility control (broth only).
 - b. Tube 13 is the growth control (antimicrobial agent-free broth plus organism).
 - c. Tubes 1 through 12 are for antimicrobial agent dilutions.
3. Using a 10-ml pipette, dispense 1 ml of broth into tubes 2 through 14.
4. Dispense 1.8 ml of broth into tube 1.
5. Use a 1-ml pipette (or a 1,000- μ l micropipette) to add 0.2 ml of 1,280- μ g/ml stock solution to 1.8 ml of CAMHB in tube 1 to obtain a solution of 128 μ g/ml.
6. Vortex.
7. Using a new pipette, transfer 1 ml from tube 1 into tube 2.
8. Vortex.
9. Repeat steps V.A.B.7 and 8 sequentially through tube 12.
10. Discard 1 ml from tube 12.
11. The final concentrations of antimicrobial agent will be 128 to 0.06 μ g/ml when the tubes are inoculated. If the volume of inoculum exceeds 10% of the tube volume, the diluting effect of the inoculum on the antimicrobial agent must be taken into account (5).

C. Preparation of inoculum

1. Using a sterile swab, transfer organisms from four or five colonies of similar morphology to 5 ml of CAMHB to obtain a suspension equivalent to the turbidity of a McFarland 0.5 standard.
2. Transfer 0.1 ml of the standardized suspension to 5 ml of CAMHB.
 - a. Fastidious organisms may require transfer of a larger volume to achieve the required turbidity in a reasonable time.
 - b. Do not test fastidious organisms that do not grow well in broth.
3. Vortex for 15 to 20 s.
4. Incubate on a mechanical shaker at $35 \pm 2^\circ\text{C}$ until visibly turbid. Do not allow growth to produce heavy turbidity. This preparation should correspond to an early to mid-logarithmic growth phase for most rapidly growing organisms. Growth phase may be confirmed by monitoring an organism growth curve in broth for 4 to 6 h.
 - a. Sample aliquots of broth and organism every 30 min.
 - b. Enumerate organisms by performing serial dilution bacterial counts on agar.
 - c. Plot CFU per milliliter versus time on semilog paper.
 - d. Determine approximate time and approximate turbidity density required to reach mid-logarithmic growth.
5. Adjust turbidity of the suspension with sterile 0.85% NaCl to match a McFarland 0.5 turbidity standard (approximately 1.5×10^8 CFU/ml).
6. Add 0.3 ml of the standardized log-phase suspension to 9.7 ml of CAMHB (1:32 dilution) to obtain a suspension containing 4×10^6 to 5×10^6 CFU/ml. (This volume of inoculum suspension is sufficient to inoculate six sets of antimicrobial dilution tubes.)
7. Vortex.
8. Use the inoculum suspension within 15 min of preparation.

**V.A. PROCEDURE:
MACRODILUTION METHOD**
(continued)

D. Inoculation and incubation

1. Using a micropipette to inoculate tubes, add 0.1 ml of suspension containing 5×10^6 CFU/ml by placing the pipette tip just below the broth meniscus.
 - a. Use a new pipette tip for each tube, and avoid contact of the tip with the wall of the tube.
 - b. Mix by gently drawing solution back and forth into the pipette tip 6 to 10 times without causing air bubbles or splashes.
 - c. Final organism concentration is approximately 5×10^5 CFU/ml.
2. Using a 0.001-ml calibrated loop, inoculate a purity plate by subculturing 0.001 ml of the McFarland 0.5-matched suspension onto the surface of a BAP. Streak for isolation.
3. Prepare an inoculum count verification plate as follows.
 - a. Remove 0.1 ml from tube 13 (drug-free growth control) immediately after inoculation.
 - b. Add to 0.9 ml of saline (1:10). Vortex.
 - c. Transfer 0.1 ml of solution from tube prepared in step V.A.D.3.b into 0.9 ml of saline (1:10). Vortex.
 - d. Transfer 0.2 ml of solution from tube prepared in step V.A.D.3.c into 0.8 ml of saline (1:5). Vortex.
 - e. Plate 0.1 ml of the final dilution onto the surface of a BAP. Perform in duplicate (should contain approximately 100 CFU).
 - f. Allow the inoculum to dry slightly, and spread it thoroughly across the agar surface as described in Appendix 5.10.1–3.
4. Incubate the rack of tubes at $35 \pm 2^\circ\text{C}$ for 20 h. Note the time.
5. Invert and incubate purity and inoculum count verification plates at $35 \pm 2^\circ\text{C}$.
6. After 20 h of incubation, remove the rack from the incubator.
7. Gently vortex or swirl each tube by hand. This mixing should draw any organisms from the top of the meniscus back into the broth containing antimicrobial agent.
8. Place the rack of tubes back into the incubator, and incubate for an additional 4 h (24 h total).

E. Reading and recording MICs

1. Examine corresponding purity plate. If results are mixed, repeat the test.
2. Examine growth control (tube 13) for 3 to 4+ turbidity, indicating adequate growth. Assess growth as follows.
 - a. \pm to 1+, very light haze in tube
 - b. 2+, light haze in tube
 - c. 3+ to 4+, heavy turbidity or fine granular growth throughout tube or dense precipitate at bottom of tube, with hazy supernatant
3. Examine the uninoculated broth control (tube 14). Compare questionable growth with that in this tube when necessary.
4. Examine the inoculum count verification plate. Record results on worksheet (Appendix 5.10.1–4). If count is inadequate (<75 or >150 CFU), repeat the test. Determine the actual number of organisms tested in each tube as follows.
 - a. Count the colonies growing on the plate.
 - b. Multiply the number of colonies by the reciprocal of the volume of the aliquot plated (0.1 ml) and the dilution factor (5×10^2).
Example: $123 \text{ CFU} \times 1/0.1 \text{ ml} \times (5 \times 10^2) = 6.2 \times 10^5 \text{ CFU/ml}$
5. Examine tubes 1 through 12. Pick each tube up, gently mix the contents, and hold the tube in transmitted light. Look for growth as evidenced by a button in the bottom of the tube, turbidity, or a combination of both compared with the growth and sterility control tubes.
6. Determine the MIC (the lowest concentration of antimicrobial agent that completely inhibits the growth of the organism).
7. Record results on worksheet (Appendix 5.10.1–4).

**V.A. PROCEDURE:
MACRODILUTION METHOD**
(continued)

F. Preparation and incubation of MBC subcultures

It is recommended that 100- μ l aliquots be subcultured to a single agar plate; however, a procedure for this volume as well as for 10 μ l is described, since some laboratories may elect to go with the smaller volume.

1. Using a 10- or 100- μ l micropipette, mix the solution by aspirating it up and down 6 to 10 times, and remove an aliquot from each of the tubes showing no growth except tube 14.
2. Plate each sample onto a BAP, using one of the following methods (perform subcultures in duplicate).
 - a. Plate 10- μ l aliquots onto one-fourth of an agar plate, and spread the aliquot over the entire quadrant.
 - b. Plate 10- or 100- μ l aliquots onto a single agar plate.
 - (1) Allow samples to air dry for 15 to 20 min.
 - (2) Use a bent glass rod to spread the aliquot over the entire plate surface (see Appendix 5.10.1–3).
3. Invert plates, and incubate them at $35 \pm 2^\circ\text{C}$.
4. Read preliminary results daily and final results (number of colonies growing on each subculture plate) at the following times.
 - a. 24 h for rapidly growing gram-negative rods
 - b. 48 h for staphylococci and enterococci
 - c. 72 h for all other organisms

G. Determining the MBC

1. From the initial MIC inoculum, determine the number of colonies allowable for a 99.9% MBC endpoint.
 - a. If a 10- μ l aliquot was plated, use Appendix 5.10.1–5, and record the number of allowable colonies based on the final inoculum size.
Example: If inoculum was 6.2×10^5 CFU/ml, then >29 CFU is defined as the rejection value.
 - b. Based on plating a 100- μ l sample, calculate the rejection value.
Example: initial inoculum \times aliquot plated \times allowable viable percent
 $= (6.2 \times 10^5 \text{ CFU/ml}) \times 0.1 \text{ ml} \times 0.001 = 62 \text{ CFU}$. A plate showing >62 CFU does not meet the 99.9% endpoint; ≤ 62 colonies indicate $\geq 99.9\%$ killing.
2. Examine each subculture plate, and record the number of colonies.
3. The MBC is defined as the lowest concentration showing $\geq 99.9\%$ killing.
 - a. With 10- μ l aliquot subcultures, when the sum of the colonies growing on duplicate subcultures of each dilution is equal to or less than the rejection value, that dilution is bactericidal at $\geq 99.9\%$. Below is an example of how to use Appendix 5.10.1–5 for an organism for which the MIC is 8 $\mu\text{g/ml}$ and with an inoculum of 6.2×10^5 CFU/ml (TNTC, too numerous to count).

Tube no.	Amount of agent ($\mu\text{g/ml}$)	CFU/plate	Total CFU	$\geq 99.9\%$ Kill
1	128	2, 0	2	Yes
2	64	3, 8	11	Yes
3	32	10, 8	18	Yes
4	16	15, 11	33	No
5	8	TNTC	TNTC	No

MBC = 32 $\mu\text{g/ml}$

- b. With 100- μ l aliquot subcultures, when the number of colonies growing on both duplicate subcultures is equal to or less than the rejection value, that dilution is bactericidal at $\geq 99.9\%$.

PREANALYTICAL CONSIDERATIONS

III.B. MATERIALS: MICRODILUTION METHOD

Include QC information on reagent container and in QC records.

A. Media and reagents (storage conditions)

The media listed include those necessary for testing rapidly growing aerobic bacteria. Refer to Appendix 5.10.1–1 for a complete listing of suggested media for testing fastidious aerobic bacteria.

1. CAMHB dispensed in approximately 250-ml aliquots into flasks and in 5-ml aliquots into tubes. Store at 2 to 8°C.
2. Sterile 0.9% NaCl dispensed in 0.9-ml aliquots into capped tubes. Store at 2 to 8°C.
3. BAP. Store at 2 to 8°C.
4. Antimicrobial agent stock solution, 1 ml of 1,280- μ g/ml solution. Store at -70°C . See procedure 5.14 for preparation.
5. Beaker of 95% ethanol to sterilize bent glass rods (optional)
6. Media for maintenance of QC organisms
 - a. TSA slants. Store at 2 to 8°C.
 - b. Brucella broth–15% glycerol dispensed into vials appropriate for freezing. Store at 2 to 8°C.
7. Sterile distilled water with 0.02% Tween 80 dispensed in aliquots of 25 ml in screw-cap tubes. Store at 25°C.

B. Supplies

1. Prepared broth microdilution (U-bottom) tray containing 100 μ l of antimicrobial solution per well. Store at -70°C . See procedures 5.2 and 5.15.

2. Microdilution tray sealers
3. Sterile single-inoculum reservoir trays
4. Sterile disposable plastic multi-pronged inoculators (or other inoculating device)
5. Sterile 1-, 5-, and 10-ml glass or plastic serologic pipettes and pipette bulb
6. McFarland 0.5 turbidity standard
7. Sterile disposable polystyrene capped tubes (5 ml; 12 by 75 mm)
8. Sterile cotton-tipped swabs

C. Equipment

1. Micropipettes, 100- and 1,000- μ l (optional) capacity with sterile disposable tips
2. Calibrated 0.001-ml loop
3. Microdilution tray reading device
4. Microdilution tray storage container
5. Vortex mixer
6. Mechanical test tube shaker (fitted in incubator)
7. -70°C freezer
8. $35 \pm 2^{\circ}\text{C}$ ambient-air incubator (CO₂ incubator needed for some organisms)
9. Bunsen burner and bent glass rod “hockey sticks” (optional)
10. Mechanical microdilution tray shaker-mixer (optional)

ANALYTICAL CONSIDERATIONS

IV.B. QUALITY CONTROL: MICRODILUTION METHOD

See item IV.A above.

V.B. PROCEDURE: MICRODILUTION METHOD

A. Final concentrations to test

1. Determine MIC for test isolate.
2. Generally, include final concentration ranges from at least eight times the expected MIC to one-half or one-fourth the expected MIC. A range from 128 to 0.06 μ g/ml is usually adequate. Avoid testing high concentrations that may not be clinically achievable.
3. Determine the number of broth microdilution trays to prepare. Include enough trays for QC. For example, testing the organism of interest in duplicate with one QC strain singly requires three trays. The final volume of each well will be 100 μ l.

**V.B. PROCEDURE:
MICRODILUTION METHOD**
(continued)

B. Preparation of trays

Prepare broth microdilution tray containing 100 μ l of antimicrobial solution per well (see procedure 5.14 for antimicrobial stock solution preparation and procedures 5.2 and 5.15 for routine broth microdilution methods).

1. Format a 96-well microdilution tray with serial twofold dilutions (128 to 0.06 μ g/ml), or use a prepared, commercially purchased tray.
2. When preparing trays, use one well as the broth sterility control and two wells for the antimicrobial agent-free growth controls. If a commercially prepared tray is used, remove contents from a well of low concentration (preferably that of a narrow-spectrum beta-lactam; do not use quinolone or aminoglycoside wells), wash the well several times with 100- μ l aliquots of CAMHB, and replace the contents of the well with 100 μ l of CAMHB.
3. Multiple agents can be tested on one tray.
4. Test one organism per tray.

C. Preparation of inoculum

1. Using a sterile swab, transfer organisms from four or five colonies of similar morphology to 5 ml of CAMHB to obtain a suspension with a turbidity approximately equal to that of a McFarland 0.5 standard.
2. Transfer 0.1 ml of the standardized suspension to 5 ml of CAMHB.
 - a. Fastidious organisms may require transfer of a larger volume to achieve the required turbidity in a reasonable time.
 - b. Do not test fastidious organisms that do not grow well in broth.
3. Vortex for 15 to 20 s.
4. Incubate on a mechanical shaker at $35 \pm 2^\circ\text{C}$ until visibly turbid. Do not allow growth to produce heavy turbidity. This preparation should correspond to an early to mid-logarithmic growth phase for most rapidly growing organisms. Growth phase may be confirmed by monitoring an organism growth curve in broth for 4 to 6 h.
 - a. Sample aliquots of broth and organism every 30 min.
 - b. Enumerate organisms by performing serial dilution bacterial counts on agar.
 - c. Plot CFU per milliliter versus time on semilog paper.
 - d. Determine approximate time and approximate turbidity density required to reach logarithmic growth.
5. Adjust turbidity with sterile 0.9% NaCl to match a McFarland 0.5 turbidity standard (approximately 1.5×10^8 CFU/ml).
6. Calculate volume of standardized suspension to be added to 25 ml of water diluent to obtain final organism concentration of approximately 5×10^5 CFU/ml in each well.

Example: When using a disposable plastic multipronged inoculating device that delivers 0.01 ml per well

McFarland 0.5 suspension = 1.5×10^8 CFU/ml

Add 0.8 ml of suspension to 25 ml of water diluent (1:31 dilution) = 4×10^6 to 5×10^6 CFU/ml

Prongs deliver 0.01 ml of suspension = 4×10^4 to 5×10^4 CFU per well (4×10^5 to 5×10^5 CFU per ml)

7. Vortex.

8. Use the inoculum suspension within 15 min of preparation.

D. Inoculation and incubation

1. Add 0.8 ml of standardized suspension to 25 ml of water-Tween 80.
2. Mix by inverting tubes five or six times (try to avoid producing air bubbles).
3. Within 15 min, inoculate the MIC tray.
 - a. Remove the inoculator-reservoir set from the plastic packaging.
 - b. Remove prongs from the reservoir tray, and pour contents of the diluted inoculum into the tray.

**V.B. PROCEDURE:
MICRODILUTION METHOD**
(continued)

- c. Dip prongs into the inoculum suspension.
 - (1) Orient sterility well so that it is not inoculated.
 - (2) Press down on the inoculator firmly to ensure that all prongs come in contact with the organism solution.
 - d. Inoculate MIC tray by dipping the filled prongs carefully into the MIC tray.
 - e. Discard prongs.
 - f. If the volume of inoculum exceeds 10% of the well volume, the diluting effect of the inoculum on the antimicrobial agent must be taken into account (5).
 4. Using a 0.001-ml calibrated loop, inoculate a purity plate by subculturing 0.001 ml of the McFarland 0.5-matched suspension onto the surface of a BAP. Streak for isolation.
 5. Prepare an inoculum count verification plate.
 - a. Remove 0.1 ml from one of the agent-free growth control wells after inoculation (optional: remove only 0.05 ml).
 - b. Add to 0.9 ml of sterile 0.9% NaCl (1:10) (optional: add only 0.45 ml). Vortex.
 - c. Transfer 0.1 ml from tube prepared in step V.B.D.5.b into 0.9 ml of sterile 0.9% NaCl (1:10) to obtain a 1:100 dilution of the initial inoculum ($1:10 \times 1:10 = 1:100$). Vortex.
 - d. Transfer 0.2 ml of solution from tube prepared in step V.B.D.5.c into 0.8 ml of sterile 0.9% NaCl (1:5). Vortex.
 - e. Plate 0.1 ml of the final dilution onto the surface of a BAP. Perform in duplicate.
 - f. Allow the inoculum to dry for 15 to 20 min, and spread it thoroughly across the agar surface as described in Appendix 5.10.1–3.
 - g. BAP plate will contain approximately 100 CFU.
 6. Stack inoculated MIC trays in stacks of no more than four, and place the stacks in a microdilution tray storage container with the top loose (or into plastic bags). An empty tray can be placed on top of the stack.
 7. Incubate MIC trays at $35 \pm 2^\circ\text{C}$ for 24 h. Note the time.
 8. Invert the plates, and place purity and inoculum verification control plates at $35 \pm 2^\circ\text{C}$ for rapidly growing organisms.
 9. After 24 h of incubation, remove the trays and plates from the incubator.

E. Reading and Recording MICs

 1. Place the tray on an appropriate reading device, and read broth microdilution MICs as described in procedure 5.2.
 2. Examine growth well for 3 to 4+ turbidity, indicating adequate growth. Assess growth as follows.
 - a. \pm to 1+, very light haze in well
 - b. 2+, light haze in well
 - c. 3+ to 4+, heavy turbidity or fine granular growth throughout well or dense precipitate at bottom of well with hazy supernatant
 3. Examine the uninoculated broth control. Compare questionable growth with that in this well when necessary.
 4. Examine corresponding purity control plate. If results are mixed, repeat the test.
 5. Examine the inoculum count verification plate. Record results on worksheet (Appendix 5.10.1–4). If the count is inadequate (<75 or >150 CFU), repeat the test.
 - a. Count the colonies growing on the plate.
 - b. Multiply the number of colonies by the reciprocal of the volume of the aliquot plated and the dilution factor.
Example: $123 \text{ CFU} \times (1/0.1 \text{ ml}) \times (5 \times 10^2) = 6.2 \times 10^5 \text{ CFU/ml}$

**V.B. PROCEDURE:
MICRODILUTION METHOD**
(continued)

6. Examine each well, and record growth or no growth for each well.
7. Determine the MIC (the lowest concentration of antimicrobial agent that completely inhibits the growth of the organism).
8. Record results on worksheet (Appendix 5.10.1–4).

F. Preparation and incubation of MBC subcultures

1. Mix the contents of each well to achieve a uniform suspension of organisms by using one of the following methods.
 - a. Place tray on a mechanical microdilution tray shaker-mixer. Set the speed high enough to displace the well contents halfway up the internal wall. Shake for approximately 1 min.
 - b. Aspirate the contents of a well in and out of a 100- μ l pipette tip 6 to 10 times.
 - c. Gently tap the plate against a solid object until a uniform suspension is obtained in each well.
2. Using a 100- μ l micropipette, remove the entire contents of each well showing no visible growth, except sterility control well.
3. Plate each 100- μ l sample onto a separate BAP.
4. Allow samples to air dry for 15 to 20 min.
5. Spread samples over the entire plate surface with a bent glass rod (see Appendix 5.10.1–3).
6. Invert plates, and incubate them at $35 \pm 2^\circ\text{C}$.
7. Read preliminary results daily and final results (number of colonies growing on agar) at the following times.
 - a. 24 h for rapidly growing gram-negative rods
 - b. 48 h for staphylococci and enterococci
 - c. 72 h for all other organisms

G. Determining the MBC

See item V.A above.

POSTANALYTICAL CONSIDERATIONS

VI. REPORTING RESULTS

A. Interpretation

1. Record MICs for each agent tested on the worksheet (Appendix 5.10.1–4). Interpret results according to criteria in procedure 5.2.
2. Record MBCs for each agent tested on the worksheet (Appendix 5.10.1–4).
3. There are currently no established criteria for interpretation of MBCs.

B. Reporting

Report MIC (and interpretation) and MBC.

Example: *Staphylococcus aureus*

<u>Drug</u>	<u>MIC ($\mu\text{g/ml}$)</u>	<u>Interpretation</u>	<u>MBC ($\mu\text{g/ml}$)</u>
Oxacillin	≤ 0.5	S	≤ 0.5
Vancomycin	1	S	2

VII. PROCEDURE NOTES

A. Planning antimicrobial concentration ranges to test

1. The dilution scheme described here is appropriate for testing most antimicrobial agents. However, in some situations, testing of higher or lower concentrations may be warranted. A 12-tube set of antimicrobial concentrations is not mandatory; i.e., a 10-tube set may be satisfactory. Generally, use two or three concentrations below the expected MIC and five or six concentrations above the expected MIC. However, there is no standardized range to

VII. PROCEDURE NOTES

(continued)

test. Do not test extremely high concentrations that are interpreted as resistant and represent levels not achievable clinically.

a. Example: Cefazolin MIC for *Escherichia coli* = 4 µg/ml

Test concentrations ranging from 0.5 to 128 µg/ml.

b. Example: Ciprofloxacin MIC for *E. coli* = 0.125 µg/ml

Test concentrations ranging from 0.015 to 8 µg/ml.

2. Some investigators test only the MIC, two times the MIC, and four times the MIC for antimicrobial agents known to be bactericidal with organisms that do not routinely exhibit various phenomena such as the paradoxical effect, tolerance, or persistence (e.g., *E. coli* and gentamicin).
3. Commercially prepared panels can be adapted for MBC determination as described in item V.B above.

B. Procedure

1. Alternative broth macrodilution methods include using a 2- or 10-ml final tube volume. Inocula and dilutions must be adjusted accordingly.
2. When anaerobes are tested, use a final inoculum of 1×10^6 to 5×10^6 CFU/ml (6).
3. High final inoculum densities (5×10^7 CFU/ml) are sometimes tested to study inoculum effect. However, after 24 h of incubation, tubes or wells at or above the obvious MIC usually appear slightly turbid or hazy or have a small pellet at the bottom of the tube or well. An additional control is needed to differentiate between true growth turbidity and background turbidity when a final inoculum of 10^7 organisms per ml is used. Set up an additional broth tube or well containing 0.0002% merthiolate solution inoculated with the organism suspension for comparison. Prepare an additional 1:100 dilution to enumerate initial inoculum from growth control. A 99.9% MBC endpoint results in 100 times the allowable number of viable CFU, so subcultures require a 1:100 dilution before being plated onto agar media to facilitate counting bacterial colonies.
4. Slightly turbid broth hazes are sometimes observed during reading of the broth macrodilution MIC when standard inoculum densities at antimicrobial concentrations above an obvious endpoint are used. Process for MBC determination to determine if viable organisms, a contaminant, or nonviable organisms are present at the 24-h endpoint.
5. To determine MBCs, two subculture volumes (10 and 100 µl) have been used for broth macrodilution methods. The larger volume is preferred, and 100 µl should always be used for broth microdilution methods. Do not use volumes of <10 µl, because too few colonies may be transferred. Use of volumes of >100 µl may result in antimicrobial agent carryover.
 - a. Subculture volume depends on the following.
 - (1) Material costs (e.g., plate four samples per agar plate with 10 µl or one sample per agar plate with 100 µl)
 - (2) The nature of the organism tested and previous published references (e.g., swarming *Proteus* species, staphylococci)
 - (3) Contribution of drug carryover
 - (4) Numbers of CFU remaining in MIC tube (<10, 100, 500), desired lower limit of detection, and initial inoculum size (standard or high)
 - b. Do not use a disposable multiprong inoculator device to subculture MBCs, because the volume transferred is too variable.
6. Antimicrobial agent carryover may be a problem when high concentrations are tested, and this may prevent viable bacteria from growing into colonies on agar. Suggested ways to overcome this problem (10) are as follows.
 - a. Test concentrations no more than 16 times the MIC so that effects are overcome by dilution onto agar medium.

VII. PROCEDURE NOTES*(continued)*

- b. Use an entire agar plate, and spread the sample over a large surface area.
 - c. Enzymatically inactivate penicillin or ampicillin by overlaying the spread aliquot with 0.1 ml of a broad-spectrum beta-lactamase such as Penase.
 - d. Filter aliquots over sterile disposable 0.2- μ m-pore-size filters, and re-suspend the organisms in broth.
 - e. Chemically inactivate the antimicrobial agent.
 - f. Remove the antimicrobial agent by using Amberlite beads (Rohm and Hass Co.).
7. Medium described here for testing MICs and MBCs does not contain serum, which determines the contribution of protein-binding effects. A human serum broth diluent 1:1 ratio (CAMBH-human serum) could be used for antimicrobial agents that are highly protein bound (4).
 8. Do not test known bacteriostatic antimicrobial agents for MBCs. Consult published references for the agent and organism of interest.
 9. Organisms not in logarithmic growth phase may be tested with novel agents to determine differences in bactericidal activity between the two phases. However, most antimicrobial agents exert a bactericidal effect only on actively growing bacteria.
 10. Plates used for subculturing organisms should not be freshly prepared, because the excess moisture on the agar surface will not evaporate quickly and developing bacterial colonies may coalesce. Freshly prepared or purchased commercial media should be allowed to sit out overnight without plastic packaging at room temperature to allow excess moisture to evaporate. Subculture aliquots will then quickly wick into the agar, dispersing residual antimicrobial agent and reducing the activity against viable organisms.
 11. Take appropriate precautions when working with 95% ethanol. It is highly flammable.
 12. Do not use calibrated loops for subculturing aliquots to determine MBCs. The loops are too variable for subculturing potentially low numbers of bacteria that might be significant in these tests.
 13. Insufficient contact between the bacteria and the antimicrobial agent may occur when bacteria adhere to the tube or well in which the test is performed and escape the antibacterial action of the agent during incubation. Mixing the contents of the tube prior to subculturing for MBC testing resuspends the organisms. A falsely elevated MBC may result. Acid-washed glass tubes and inoculation of antimicrobial dilutions by using a subsurface inoculation technique minimize this event. It has not been established if this phenomenon occurs in microdilution wells.
 14. CO₂ incubation alters pH and affects the activities of some antimicrobial agents. It should therefore be avoided.

C. Interpretation

1. In general, bactericidal antimicrobial agents produce MBCs within 2 twofold dilutions of the MIC.
2. Numerous interpretative problems that may be related to technical or biological issues can occur with MBC test results. These have been described by various investigators (1, 2, 3, 7, 9, 10) and for various organisms such as *S. aureus*, usually with beta-lactams.

VII. PROCEDURE NOTES

(continued)

- a. The paradoxical effect, or Eagle effect, occurs when increasing numbers of bacteria survive at progressively higher concentrations of antimicrobial agent even though several lower concentrations meet the 99.9% MBC endpoint. This effect may be observed with various bacterial species and antimicrobial agents, particularly beta-lactam agents.
- b. Persisters are small numbers of bacteria that survive the bactericidal effect of an antimicrobial agent so that in the MBC test, they would appear as colonies numbering close to the 0.1% cutoff. A few concentrations may meet the 99.9% MBC definition, but several concentrations will exhibit growth just in excess of the rejection value. Retesting the MICs for persisters results in MICs identical to those for the original organism culture.
- c. Tolerance occurs when a significant percentage of cells survive the apparent bactericidal effect of an antimicrobial agent without an accompanying MIC increase. With the MBC test, this can be observed when a series of dilutions grow organisms 10 to 100 times the allowable rejection value. The MBC/MIC ratio is ≥ 32 after 24 h of incubation of the MIC test.
- d. If a paradoxical effect, persisters, or tolerance seems to be occurring, try the following.
 - (1) Reconfirm the MICs for surviving organisms to determine if resistant subpopulations have been selected.
 - (2) Repeat MIC and MBC tests with a fresh subculture of the original isolate to confirm if the effect is repeatable when the same method is used.
 - (3) Determine if organisms were in mid-logarithmic phase when tested.
 - (4) Perform a time-kill assay to determine the validity of the phenomenon.

VIII. LIMITATIONS

- A. Although parts of the MBC procedures described above have been published in NCCLS documents (4), they are not considered standardized methods. This and other references describe multiple alternatives and comparisons for several steps in the MBC procedure (7, 9).
- B. The clinical value and interpretation of the MBC are limited because of various technical issues and unknown correlation with clinical outcome. However, clinicians may be able to assess patient response to an antimicrobial agent regimen.
- C. Broth macrodilution and microdilution results may not produce the same MBC endpoint results because of technical differences in the methods.

MBC testing conditions for various bacteria^a

Organism or group	Broth diluent for MIC ^b	MBC		
		Subculture agar	Length (h)	Incubation ^c Atmosphere
Members of the family <i>Enterobacteriaceae</i> and non-glucose-fermenting gram-negative rods	CAMHB	BAP ^a	24	Ambient air
<i>Enterococcus</i> spp.	CAMHB	BAP	48	Ambient air
<i>Haemophilus</i> spp.	HTM	CHOC	72	Ambient air (CO ₂ if needed)
<i>Staphylococcus</i> spp.	CAMHB ^d	BAP	48	Ambient air
<i>Streptococcus pneumoniae</i>	CAMHB with 2–5% LHB or THB	BAP	72	Ambient air (CO ₂ if needed)
<i>Streptococcus</i> spp.	CAMHB with 2–5% LHB or THB	BAP	72	Ambient air (CO ₂ if needed)
Nutritionally variant <i>Streptococcus</i> spp.	CAMHB or THB with 0.001% pyridoxal HCl	CHOC with 0.001% pyridoxal HCl	72	CO ₂

^a Inhibitory portion of test is to be incubated for 24 h. This table applies to broth macrodilution and microdilution.^b Specified broth appropriate for growing inoculum to log phase and for time-kill assays. HTM, *Haemophilus* test medium; LHB, lysed horse blood; THB, Todd-Hewitt broth.^c All incubations were at 35°C.^d Add 2% NaCl for penicillinase-resistant penicillins (oxacillin, methicillin, nafcillin, cloxacillin, dicloxacillin, and flucloxacillin).

APPENDIX 5.10.1–2

Worksheet for MIC and MBC QC (see p. 5.10.1.16)

APPENDIX 5.10.1–3**Technique for Using Bent Glass Rod “Hockey Sticks” for Colony Counts**

- A. Allow broth aliquot transferred onto agar to dry slightly (15 to 20 min). Agar plates should be free of excess moisture to prevent the development of coalescing bacterial colonies.
- B. Using one sterile rod, spread the aliquot evenly across the entire surface in two or three different directions to create a bacterial lawn.
- C. To sterilize the glass rod, *use extreme caution* when performing the following procedure, because 95% ethanol is very flammable. Acetone or methanol may be used in place of 95% ethanol.
 1. Place ethanol in a glass beaker large enough to accommodate the bent length of the rod. The ethanol should be deep enough to cover the bent end of the rod. Restore the ethanol volume as needed. Place beaker in a metal or glass pan or bowl to confine accidental spills. Keep a large nonburnable container (e.g., metal waste can or bucket) nearby to place over beaker and pan to extinguish accidental fires.
 2. Place incinerator with flame well away from the ethanol, and/or contain it in a flame-resistant box.
 3. Submerge bent portion of rod into 95% ethanol for at least 1 min.
 4. Remove the rod from the ethanol, and allow excess liquid to drain into beaker.
 5. Place rod containing residual alcohol in the burner flame to ignite the alcohol and sterilize the rod.
 6. Hold rod parallel to the bench top until the flames have subsided.
 7. Lay rod parallel to the bench top on a test tube rack to cool.
 8. Reuse once rod has cooled.
- D. Clean rods in detergent and water after use.

6×10^6	273	99	99
7×10^6	318	99	99
8×10^6	364	99	99
9×10^6	409	99	99
1×10^7	455	99	99

^a When the sum of colonies from duplicate samples was equal to or less than the rejection value, the antimicrobial agent was declared lethal (a 0.999 or greater reduction in the final inoculum). (Adapted with permission from **R. D. Pearson, R. T. Steigbigel, H. T. Davis, and S. W. Chapman**. 1980. Method for reliable determination of minimal lethal antibiotic concentrations. *Antimicrob. Agents Chemother.* **18**:699–708.) A 5% error (pipette error plus full sampling error for determination of inoculum) was used. Error was based on duplicate samples for determination of the final inoculum size.

^b As determined from colony count plate.

^c Number of colonies.

^d Sensitivity and specificity were calculated for each specific final inoculum concentration and rejection value.

5.10.2

Time-Kill Assay

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The time-kill assay is used for examining the rate at which concentrations of an antimicrobial agent(s) kill a bacterial isolate. Time-kill assays can be used to study both concentration-dependent and time-dependent bactericidal activities of antimicrobial agents. Time-kill assays are used to evaluate new antimicrobial agents and combinations of agents (*see* procedure 5.10.3); confirm the paradoxical effect, persists, or tolerance; and help explain treatment failures in clinical situations in which bactericidal activity may be crucial to patient outcome.

Although the time-kill assay has been described in an NCCLS protocol (1), the assay, like the minimal bactericidal concentration (MBC) method, and the sample

times for bacterial enumeration have not been standardized.

A standardized inoculum is added to broth containing various concentrations of an antimicrobial agent and to broth without agent (control). At the initial time of inoculation and at various times thereafter, the numbers of viable CFU remaining are determined by performing serial dilution bacterial colony counts on an aliquot from each test vial. Results for the control and each agent concentration are plotted versus time. Generally, a 3- \log_{10} CFU/ml decrease in bacterial counts in antimicrobial solution compared with counts for the growth control indicates an adequate bactericidal response.

Prior to performance of the time-kill assay, several parameters must be defined. Determine the MIC of the specific antimicrobial agent for the organism of interest by a standard MIC procedure, preferably a broth macrodilution method. From the MIC, determine other concentrations of antimicrobial agent to test, usually the MIC, two times the MIC, and four times the MIC. Depending on the mechanism of action (e.g., cell wall-active agent) and growth rate of the organism, determine sample time points (usually 4, 8, 24, and sometimes 48 h after inoculation). For rapidly bactericidal agents such as quinolones or aminoglycosides, shorter sampling periods may be suitable (e.g., 1, 2, 4, 6, and 24 h).

II. SPECIMEN

See procedure 5.10.1, item II.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Media and reagents (storage conditions)

The media listed include those necessary for testing rapidly growing aerobic bacteria. Refer to Appendix 5.10.2–1 for a complete listing of suggested media for testing fastidious aerobic bacteria.

1. Cation-adjusted Mueller-Hinton broth (CAMHB) dispensed in approximately 250-ml aliquots into flasks and in 5-ml aliquots into tubes. Store at 2 to 8°C.
2. Sterile 0.9% NaCl dispensed in 0.9-ml aliquots into capped disposable polystyrene tubes (12 by 75 mm). Store at 25°C.
3. Sterile 0.9% NaCl dispensed in 9.9-ml aliquots into capped disposable polystyrene capped tubes (17 by 100 mm) (optional). Store at 25°C.
4. BAP. Store at 2 to 8°C.
5. Antimicrobial agent stock solution, 1 ml of 1,280- μ g/ml solution. Store at -70°C . See procedure 5.14 for preparation.
6. Beaker of 95% ethanol to sterilize bent glass rods (optional)
7. Media for maintenance of QC organisms
 - a. TSA slants. Store at 2 to 8°C.
 - b. Brucella broth–15% glycerol dispensed into vials appropriate for freezing. Store at 2 to 8°C.

III. MATERIALS (*continued*)**B. Supplies**

1. Sterile acid-washed borosilicate glass test tubes (16 by 150 mm) with metal or plastic closures
2. Sterile disposable screw-cap tubes (50 ml; 30 by 115 mm)
3. Sterile disposable polystyrene capped tubes (5 ml; 12 by 75 mm)
4. Sterile 1-, 5-, and 10-ml glass or plastic serologic pipettes and pipette bulb
5. Sterile cotton-tipped swabs
6. McFarland 0.5 and 1.0 turbidity standards
7. Semilog graph paper, 10 cycle (or 10 by 10 graph paper if counts are converted to \log_{10} units before being graphed)

C. Equipment

1. Test tube racks with 12 spaces per row
2. Test tube rack to accommodate 50-ml tubes
3. Micropipette, 100- μ l capacity with sterile disposable tips
4. Automatic single-channel micropipette to deliver 500 μ l (optional)
5. Calibrated 0.001-ml loop
6. Vortex mixer
7. Mechanical test tube shaker (fitted in incubator)
8. -70°C freezer
9. $35 \pm 2^{\circ}\text{C}$ ambient-air incubator (CO_2 incubation needed for some organisms)
10. Bunsen burner and bent glass rod "hockey sticks" (optional)

ANALYTICAL CONSIDERATIONS**IV. QUALITY CONTROL**

There are no standard QC recommendations for time-kill assays, but see the MBC procedure in procedure 5.10.1. Additionally, the following parameters should be controlled.

A. Test media

1. Growth control tube should support growth of the test strain.
2. Sterility control tube should show no growth.

B. Inoculum

1. Purity plate should show good growth and no contaminating colonies.
2. Colony count at time zero in growth control tube should be between 10^5 and 10^6 CFU/ml of final inoculum.

C. Antimicrobial agent concentration in reaction tubes

1. Aliquots of each dilution should be tested by broth macrodilution or microdilution methods with appropriate QC strains (refer to appropriate previous procedures).
2. Results must be within acceptable MIC ranges for test to be in control.

V. PROCEDURE**A. Final concentrations to test**

1. Determine MIC for test isolate by broth macrodilution.
2. Test these final concentration ranges: MIC, two times the MIC, and four times the MIC (and one-fourth and one-half the MIC if desired).
 - a. **Example:** Vancomycin MIC for *Staphylococcus aureus* = 0.25 $\mu\text{g/ml}$.
Test vancomycin concentrations of 0.25, 0.5, and 1 $\mu\text{g/ml}$ (and 0.06 and 0.125 $\mu\text{g/ml}$ if desired) in 10 ml of CAMHB each.
 - b. Test separate control tubes, one containing 10 ml of CAMHB plus inoculum (growth control) and one containing 10 ml of CAMHB only (sterility control).
3. Determine number of tubes and volume of antimicrobial agent to prepare, including enough tubes for QC.

V. PROCEDURE (*continued*)**B. Preparation of antimicrobial agent working concentrations**

See procedure 5.14 for antimicrobial stock solution preparation.

1. Prepare intermediate dilutions of the stock antimicrobial agent.
 - a. Dilute stock solution in sterile water (or other appropriate diluent) so that the concentration is 100 times the highest concentration that will be tested in the time-kill test. For example, if the highest concentration tested is 1 µg/ml, dilute 1,280-µg/ml stock 1:12 (0.25 ml into 2.75 ml) to obtain 100 µg/ml.
 - b. In tubes (12 by 75 mm), perform 2 (or 4 if one-half and one-fourth MICs will be tested) serial twofold dilutions to obtain solutions of 50.0 and 25.0 µg/ml (and 12.0 and 6.0 µg/ml if desired). For example, dilute 0.5 ml of 100-µg/ml stock into 0.5 ml of sterile water to obtain 50 µg/ml. Then dilute 0.5 ml of 50-µg/ml stock into 0.5 ml of sterile water to obtain 25 µg/ml and so forth.
2. Prepare final working concentrations of antimicrobial agents for time-kill assay.
 - a. Assemble one 50-ml tube (30 by 115 mm) for each concentration (procedure below describes preparation of 20-ml volumes of each drug concentration, which is sufficient for one kill curve and QC or two kill curves).
 - (1) Use 10 ml for each drug concentration in the time-kill assay.
 - (2) Use 1 ml for MIC for QC strain.
 - b. Dispense 19.8 ml of CAMHB into each tube.
 - c. Add 0.2 ml of 100-fold-concentrated antimicrobial agent to obtain a 1:100 dilution. For example, dilute 0.2 ml of 100-µg/ml stock into 19.8 ml of CAMHB to obtain 1 µg/ml. Then dilute 0.2 ml of 50-µg/ml stock into 19.8 ml of CAMHB to obtain 0.5 µg/ml.
 - d. Vortex.
3. Dispense 10 ml of each final concentration into sterile glass tubes (16 by 150 mm) for time-kill assay.
4. Dispense 10 ml of CAMHB into each control and sterility tube.
5. Dispense appropriate volumes of antimicrobial agent concentrations and growth control broth for QC MIC (e.g., 1 ml each for broth macrodilution MIC; follow the protocol for performing MIC QC in procedure 5.2).

C. Inoculum preparation

See Appendix 5.10.2–2 also.

1. Using a sterile swab, transfer organisms from four or five colonies of similar morphology to 5 ml of CAMHB to obtain a suspension equivalent to the turbidity of a McFarland 0.5 standard.
2. Transfer 0.1 ml of the standardized suspension to 5 ml of CAMHB.
 - a. Fastidious organisms may require transfer of a larger volume to achieve the required turbidity in a reasonable time.
 - b. Do not test fastidious organisms that do not grow well in broth.
3. Vortex for 15 to 20 s.
4. Incubate on a mechanical shaker at $35 \pm 2^\circ\text{C}$ until visibly turbid. Do not allow growth to produce heavy turbidity. This preparation should correspond to an early to mid-logarithmic growth phase for most rapidly growing organisms. Growth phase may be confirmed by monitoring an organism growth curve in broth for 4 to 6 h.
 - a. Sample aliquots of broth and organism every 30 min.
 - b. Enumerate organisms by performing serial dilution bacterial counts on agar.
 - c. Plot CFU per milliliter versus time on semilog paper.
 - d. Determine approximate time and approximate turbidity density required to reach mid-logarithmic growth.

V. PROCEDURE (*continued*)

5. Adjust turbidity of suspension with sterile 0.9% NaCl to match a McFarland 1.0 turbidity standard (approximately 3.0×10^8 CFU/ml).
6. Dilute standardized suspension 1:5 by adding 1 ml of suspension to 4 ml of CAMHB (approximately 6×10^7 CFU/ml).

D. Inoculation and incubation

1. Add 0.1 ml of inoculum containing 6×10^7 CFU/ml to each tube containing 10 ml except sterility control tube.
 - a. Use a new pipette tip for each tube.
 - b. Vortex gently.
 - c. Final organism concentration is approximately 6×10^5 CFU/ml.
2. Using a 0.001-ml calibrated loop, inoculate a purity plate by subculturing 0.001 ml of the McFarland 1.0 standard suspension onto the surface of a BAP. Streak for isolation.
3. Immediately after inoculation, remove 0.1 ml from each reaction tube to perform serial dilution bacterial plate counts for time zero. Refer to Appendix 5.10.2–3.
4. Incubate tubes and purity plate at $35 \pm 2^\circ\text{C}$.
5. At the next sample time (e.g., 4 h), remove tubes from the incubator.
 - a. Vortex gently.
 - b. Carefully remove a 0.1-ml aliquot from each tube (except sterility control) to perform serial dilution bacterial plate counts.
 - c. Remove aliquots from all tubes within 5 to 10 min so that the growth cycle is not disrupted by temperature changes.
6. Incubate tubes at $35 \pm 2^\circ\text{C}$ immediately after sampling.
7. Repeat steps V.D.5 and 6 for other time points as necessary.

E. Reading and recording results

1. At 24 h, visually inspect all reaction tubes and note the MIC in the time-kill assay tubes. Also perform serial dilution bacterial plate counts for all tubes, including the growth control.

Example: At 24 h, the vancomycin MIC = 0.25 $\mu\text{g/ml}$ for test isolate *S. aureus*.
2. After overnight incubation, confirm that test is in control (e.g., QC MIC, purity control). Final colony counts for some slower-growing organisms will require 48 or 72 h of incubation (*see* Appendix 5.10.2–1).
3. For each agent tested, record the MIC observed in the time-kill assay tubes on the worksheet (Appendix 5.10.2–4).
4. Determine the initial inoculum size at time zero to confirm that the appropriate initial bacterial density was tested (approximately 6×10^5 CFU/ml). Record data on the worksheet (Appendix 5.10.2–4).
5. Count the colonies on each of the serial dilution bacterial count plates. Record data on the worksheet (Appendix 5.10.2–4).
 - a. Average the counts from plates showing 30 to 300 CFU.
 - b. Do not use plates with <30 or >300 CFU in data tabulation unless these are the only counts available for the time point.
 - c. Convert to actual CFU per milliliter by multiplying average of raw counts by dilution factors (*see* Appendix 5.10.2–3).
 - d. Convert CFU per milliliter to \log_{10} data (optional).
6. Plot CFU per milliliter (*y* axis) versus time (*x* axis) as shown in Appendix 5.10.2–5. Use semilog paper for actual numbers (e.g., 8.4×10^7 CFU/ml) or graph paper (10 by 10) for numbers converted to \log_{10} values (e.g., 7.9 \log_{10} CFU/ml).

POSTANALYTICAL CONSIDERATIONS

VI. REPORTING RESULTS**A. Interpretation**

1. Interpret MICs according to criteria in procedure 5.2.
2. Determine which antimicrobial agent concentrations result in a 3-log₁₀ CFU/ml decrease compared with the growth control.
3. Determine the time required to obtain a 3-log₁₀ CFU/ml decrease compared with the growth control for all agent concentrations meeting this endpoint.

B. Reporting

1. Report MICs, and state whether bactericidal activity occurred at a particular concentration.

Example: For *S. aureus*, vancomycin MIC = 0.25 µg/ml. Vancomycin was bactericidal at concentrations of 0.25 µg/ml at 8 h and 0.5 µg/ml at 4 h.

2. Report results graphically as shown in Appendix 5.10.2–5.

VII. PROCEDURE NOTES**A. Procedure**

1. Various alternatives for several of the steps in the time-kill assay have been suggested.
 - a. Perform the test in larger volumes of media (e.g., 30 to 100 ml or more instead of 10 ml) so that there are more challenge bacteria.
 - b. Perform the test in smaller volumes of media (e.g., 1 or 2 ml) so that an MBC can be determined by using methods in procedure 5.10.1. Technical problems associated with large volumes could thus be avoided.
 - c. Incubate with agitation when volumes of >10 ml are tested.
 - d. Sample more frequently for quinolones and aminoglycosides.
2. Testing high concentrations of antimicrobial agents (e.g., a beta-lactam at 128 µg/ml) will require preparing more than 1 ml of 1,280-µg/ml stock or preparing 1 ml of 12,800-µg/ml stock reagent.
3. Serial dilution bacterial plate counts
 - a. Saline volumes (0.9 ml) for performing dilutions in preparation for colony counts should be dispensed aseptically after autoclaving to minimize volume inconsistencies that may occur during autoclaving of small volumes. Cap tubes tightly for storage to prevent evaporation. These tubes can be stored at 25°C for a few days, but 2 to 8°C is needed for longer storage.
 - b. When plating suspensions containing high numbers of bacteria (e.g., 10⁷ CFU/ml), one 9.9-ml dilution tube of saline can be used (to prepare a 1:100 dilution) in place of two 0.9-ml dilution tubes of saline, thereby minimizing dilution steps and number of plates.
 - c. The most concentrated sample tested, a 0.1-ml aliquot from the primary reaction tube, represents a 10⁻¹ dilution when CFU per milliliter are calculated. Therefore, if this aliquot is plated directly onto an agar plate, the lower limit of detection is 10 CFU/ml.
 - d. Bacterial colonies can be counted after 24 h of incubation in most situations, but an additional day of incubation usually results in larger colonies that are easier to count. Some fastidious organisms need >24 h of incubation (*see* Appendix 5.10.2–1).
 - e. Replicate counts from the same dilution should agree within 10%.
 - f. Antimicrobial agent carryover may be a problem when higher antimicrobial concentrations are tested (e.g., >128 µg/ml) or when a 0.1-ml aliquot from the primary reaction tube is plated onto agar. Enzymatic or chemical inactivators (such as beta-lactamase or a slightly acidic pH for aminoglycosides) can be incorporated into the subculture media (2). Spread the sample over a larger surface area to dilute the antimicrobial agent.

VII. PROCEDURE NOTES*(continued)*

- g. Use a latex finger cot, latex glove, or bandage on the thumb of the hand used to snap caps off saline dilution tubes to prevent blistering.
- 4. Higher initial starting bacterial densities (e.g., 6×10^7 CFU/ml) may be tested. Adjust dilutions accordingly.
- 5. Since the observed MIC may vary 1 twofold dilution between runs and between macro- and microdilution methods, test several concentrations above and below the expected MIC.
- 6. Inactivation of antimicrobial agents by organisms during the time-kill assay may result in organism regrowth after an initial decrease in viable organism counts.

B. Strategic planning of bacterial plate count dilutions

1. Growth control kinetics
 - a. Most rapidly growing organisms will multiply 2 to 3 \log_{10} CFU/ml in the first 4 h from an initial $5\text{-}\log_{10}$ CFU/ml inoculum.
 - b. Growth control tubes should be slightly turbid at 6 or 8 h after inoculation. Barely visible turbidity approximates 10^7 CFU/ml. McFarland turbidity standards can be used to determine approximate numbers of bacteria in reaction tubes. Use turbidity as a guide for planning dilutions. Nonviable cells sometimes contribute to turbidity.
 - c. Most organisms exhaust medium nutrients and do not exceed $10 \log_{10}$ CFU/ml at 24 h.
2. Agents exhibiting time-dependent killing (e.g., beta-lactams)
 - a. At concentrations equal to or higher than the MIC, organisms are killed slowly. The result is usually a decrease of approximately $1 \log_{10}$ CFU/ml in the first 4 h, $2 \log_{10}$ CFU/ml in 8 h, and $\geq 3 \log_{10}$ CFU/ml at 24 h.
 - b. At concentrations lower than the MIC, organisms are not killed and should mimic the growth control counts. A short lag in growth may be encountered at 4 h with the one-half MIC and will result in a 1- to $2\text{-}\log_{10}$ CFU/ml increase in growth from the initial inoculum.
3. Agents exhibiting concentration-dependent killing (e.g., glycopeptides, aminoglycosides, quinolones)
 - a. Organisms are killed faster with increasing concentrations, so for concentrations higher than the MIC, the kill curves will be greater than the curve for the observed MIC. Organisms are typically killed at approximately $1 \log_{10}$ CFU/ml/h at the MIC. At two and four times the MIC, organisms may decrease 2 and $3 \log_{10}$ CFU/ml, respectively, in the first hour.
 - b. At concentrations lower than the MIC (e.g., one-fourth and one-half the MIC), some subpopulations of organisms are killed, but other populations remain viable, resulting in curves that are higher than that for the MIC but lower than that for the growth control.
4. When initiating a study in which bactericidal action against the study organism is unknown, perform an extensive dilution series at each time point to accommodate a wide range of organism densities (e.g., 6 to 8 serial 10-fold dilutions at 12 h).
5. Enumerating bacterial colonies
 - a. If the only agar plates with viable bacteria show <30 or >300 colonies, count the colonies and record.
 - b. If the lowest dilution (0.1 ml from primary reaction plated on agar) results in no colonies, the lower limit of detection is ≤ 10 CFU/ml.
 - c. If the highest dilution of the series results in $>1,000$ colonies, record and graph as an absolute number (e.g., 10^6 CFU/ml) for an approximate curve. Footnote the graph, and note in procedure that the dilution series should be extended upon retesting.

VIII. LIMITATIONS

- A. See limitations under MBC testing procedure (procedure 5.10.1).
- B. If the time-kill assay runs for >48 h, the antimicrobial agent could be inactivated. If the time-kill assay runs for 48 h, an increase in bacterial counts after a notable decrease could occur because of selection of resistant mutants.

<i>Streptococcus pneumoniae</i>	CAMHB with 2–5% LHB or THB	BAP	72	Ambient air (CO ₂ if needed)
<i>Streptococcus</i> spp.	CAMHB with 2–5% LHB or THB	BAP	72	Ambient air (CO ₂ if needed)
Nutritionally variant <i>Streptococcus</i> spp.	CAMHB or THB with 0.001% pyridoxal HCl	CHOC with 0.001% pyridoxal HCl	72	CO ₂

^a Inhibitory portion of test is to be incubated for 24 h. This table applies to broth macrodilution and microdilution.

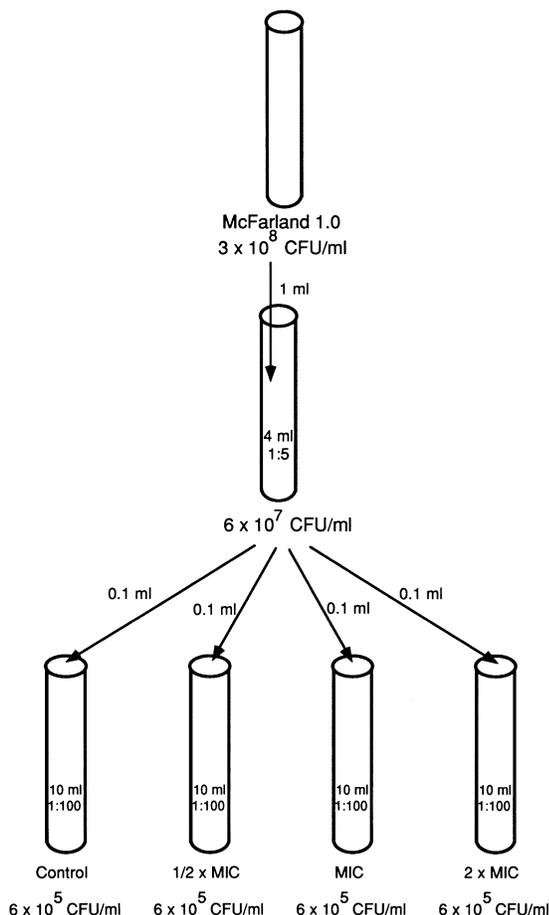

^b Specified broth appropriate for growing inoculum to log phase and for time-kill assays. HTM, *Haemophilus* test medium; LHB, lysed horse blood; THB, Todd-Hewitt broth.

^c All incubations were at 35°C.

^d Add 2% NaCl for penicillinase-resistant penicillins (oxacillin, methicillin, nafcillin, cloxacillin, dicloxacillin, and flucloxacillin).

APPENDIX 5.10.2–2

Preparation of inoculum for reaction tubes in time-kill assay.

APPENDIX 5.10.2–3

Determining Colony Counts from Control and Antimicrobial Tubes for Time-Kill Assay

A. Primary method

1. Perform serial dilution plate counts from the inoculated reaction tubes (growth control tube and antimicrobial tubes) in duplicate. The number of organisms in the control tube will increase with time, whereas the number of organisms in the antimicrobial agent-containing tubes will either increase or decrease depending on whether the antimicrobial agent kills the organism.
2. At time zero, which is the organism inoculation step, prepare 3 serial 10-fold dilutions (through 10^{-4}) in 0.9-ml aliquots of sterile 0.9% NaCl (as shown in Fig. 5.10.2–A1). Prepare dilutions by adding 0.1 ml of each higher concentration to 0.9 ml of 0.9% NaCl. Use a new pipette tip, and vortex well between dilutions.
3. Return primary reaction tubes to the incubator as quickly as possible.
4. Assuming that reaction tubes at time zero contain approximately 6×10^5 CFU/ml, plate 0.1 ml from the 10^{-2} , 10^{-3} , and 10^{-4} dilutions onto two separate agar plates as shown in Fig. 5.10.2–A1. Process as described in Appendix 5.10.1–3.

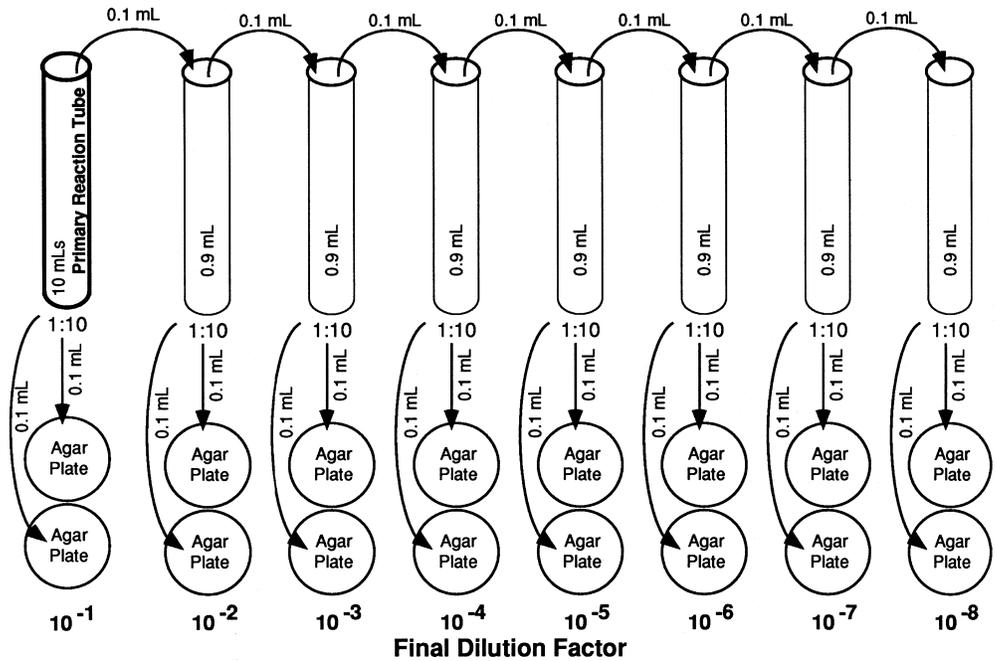

Figure 5.10.2–A1 Dilution scheme for bacterial colony counts.

APPENDIX 5.10.2–3 (continued)

5. At the next sample time following a defined interval of incubation (e.g., 4 h), prepare 4 10-fold dilutions (through 10^{-3}) from clear tubes and 6 10-fold dilutions (through 10^{-7}) from reaction tubes that demonstrate any evidence of turbidity. Dilute very turbid tubes to 10^{-8} . Plate 0.1-ml aliquots of each dilution as described above.
 - a. Depending on the time point and previous experience with the drug-organism combination, it may not be necessary to prepare and plate all dilutions from clear tubes.
 - b. Depending on the time point, degree of turbidity, and previous experience with the drug-organism combination, it may not be necessary to plate all dilutions from turbid tubes.
 - c. Plate 0.1 ml from each reaction tube onto two separate agar plates if they are needed for detecting low numbers of viable organisms. *Note:* One 9.9-ml saline tube can be used in place of two 0.9-ml saline tubes for a 1:100 dilution.
6. Following incubation of subculture plates for the times specified in Appendix 5.10.2–1, count the colonies on those plates that show between 30 and 300 colonies.
7. Determine the number of colonies in each reaction tube at each time by averaging the counts obtained.

Example: At 4 h in tube containing 1 μ g of vancomycin per ml

Dilution	No. of CFU		Average no. of CFU
10^{-2}	>300	>300	>300
10^{-3}	282	264	273*
10^{-4}	30	28	29*

*within acceptable counting range

$$\left. \begin{array}{l} \text{Average (actual) CFU/ml} \\ 273 \times 1/10^{-3} = 2.7 \times 10^5 \text{ CFU/ml} \\ 29 \times 1/10^{-4} = 2.9 \times 10^5 \text{ CFU/ml} \end{array} \right\} \text{average} = 2.8 \times 10^5 \text{ CFU/ml}$$

B. Alternative method (1)

1. Proceed with preparation of serial 10-fold dilutions as described above.
2. Instead of subculturing 0.1-ml aliquots to an entire agar plate, use a micropipette to subculture 0.025-ml aliquots (1:40 dilution) of each dilution in spots around the periphery of an agar plate as shown in Fig. 5.10.2–A2.
3. Incubate as described above, and count the colonies within each spot for those dilutions demonstrating a countable number of colonies.

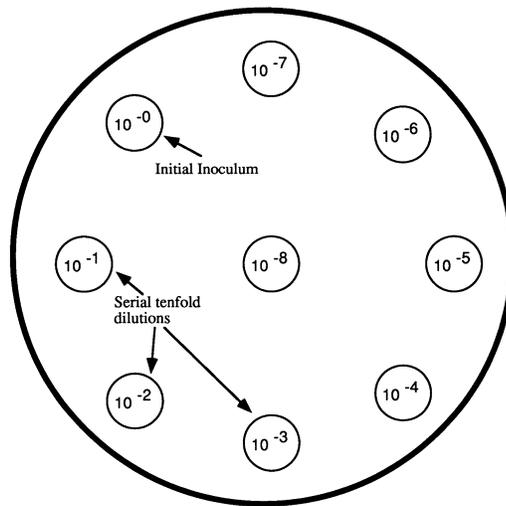

Figure 5.10.2–A2 Plate configuration for inoculating 0.25 ml of each dilution from reaction tube to agar plate for colony counts. (Adapted and reprinted with permission from **G. M. Eliopoulos and R. C. Moellering**, 1996. *Antimicrobial combinations*, p. 330–396, Fig. 9.5 [p. 339]. In V. Lorian [ed.], *Antibiotics in Laboratory Medicine*, 4th ed. The Williams & Wilkins Co., Baltimore, Md.)

APPENDIX 5.10.2–3 (continued)

4. Determine the number of colonies in the reaction tube by averaging the numbers of counts obtained. Multiply the count by 40 to obtain the CFU per milliliter in reaction tube. An example follows:

Dilution	No. of CFU		Average no. of CFU
	Confluent	Confluent	Confluent
10^{-1}	Confluent	Confluent	Confluent
10^{-2}	52	Confluent	52*
10^{-3}	5	7	6*
10^{-4}	0	0	0
10^{-5}	0	0	0
10^{-6}	0	0	0
10^{-7}	0	0	0
10^{-8}	0	0	0

*within acceptable counting range

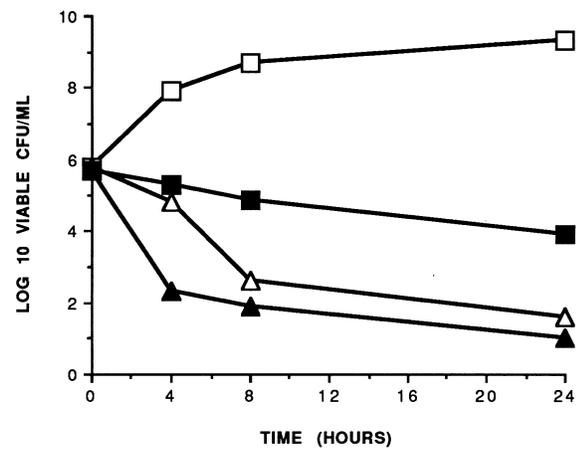

$$\text{Average CFU} = (5.6 \times 10^3) \times 40 = 224 \times 10^3 = 2.2 \times 10^5$$

5.10.3

Time-Kill Assay for Determining Synergy

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The time-kill assay can be used to study the dynamics of synergism or antagonism for a combination of antimicrobial agents by determining the number of viable bacteria remaining over time after exposure to each individual agent and various combinations. Therefore, time-kill assay data can assess both the rate and extent of killing. This method is used primarily to study organisms from patients with meningitis or endocarditis for whom clinical treatment failed or as a research tool to study novel antimicrobial agents.

The procedure described here is not a standardized procedure and represents

recommendations. Additionally, the steps in this procedure that are the same as those in the MBC and time-kill procedures have been cross-referenced to those in procedures 5.10.1 and 5.10.2.

Prior to performance of the time-kill assay, concentrations of individual agents and combinations most likely to result in synergism are planned from data resulting from a checkerboard synergism test (*see* procedure 5.12). The time-kill assay for synergism uses minimal bactericidal concentration (MBC) broth macrodilution and time-kill procedures described in procedures 5.10.1 and 5.10.2. However, only a

limited number of antimicrobial concentrations can be studied at one time because of practical limitations. Synergism in the time-kill assay is usually defined as a ≥ 2 -log₁₀ CFU/ml decrease by the combination compared with the most active single agent (1, 2). Antagonism is usually defined as a ≥ 2 -log₁₀ CFU/ml increase by the combination compared with the most active single agent; however, smaller log₁₀ CFU per milliliter increases may suggest antagonistic interactions (1, 2). The outcome can be represented graphically as in Appendix 5.10.3–2.

II. SPECIMEN

Refer to procedure 5.10.1.

III. MATERIALS

Refer to procedure 5.10.2.

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

There are no standard recommendations for time-kill synergy assays. However, refer to the MBC procedure in procedure 5.10.1, the time-kill procedure in procedure 5.10.2, and procedure 5.12. Additionally, the following parameters should be controlled.

- A. Test aliquots of each dilution of antimicrobial agent in reaction tubes by broth macrodilution or microdilution methods with appropriate QC strains (*see* procedure 5.10.1).
- B. Results must be within acceptable MIC ranges for test to be in control.

V. PROCEDURE**A. Planning concentrations to test**

1. Determine the MIC and MBC of each agent for the organism. Test the MIC and one-half, one-fourth, and two times the MIC *for each agent*.
 - a. **Example** (*see* procedure 5.12 for synergy examples): *Pseudomonas aeruginosa*, piperacillin MIC = 128 µg/ml; amikacin MIC = 32 µg/ml
 - b. Test piperacillin at 32, 64, 128, and 256 µg/ml and amikacin at 8, 16, 32, and 64 µg/ml.
2. Determine combination interaction by using broth microdilution checkerboard methods (*see* procedure 5.12).

Example: The combination of piperacillin and amikacin resulted in synergism at multiple combinations.
3. Choose combination concentrations most likely to result in synergism (or antagonism).
 - a. When synergism is expected, test combinations at one-fourth and one-eighth the MIC of each agent.

Example: Piperacillin MIC = 128 µg/ml; amikacin MIC = 32 µg/ml.
Test the combinations of piperacillin, 32 µg/ml, and amikacin, 8 µg/ml; and piperacillin, 16 µg/ml, and amikacin, 4 µg/ml.
 - b. When antagonism is expected, test combinations at two times the MIC of agent A and at two times the MIC of agent B.

B. Preparation of antimicrobial agent working concentrations

See procedure 5.14 for antimicrobial stock solution preparation.

1. Prepare intermediate dilutions of the stock antimicrobial agent. Dilute stock solution in sterile water (or other appropriate diluent) so that the concentration is 100 times the final concentration that will be tested in the time-kill test (*see* procedure 5.10.2).
2. Prepare final working concentrations of antimicrobial agents for the time-kill assay.
 - a. For individual agents, dispense the following into sterile glass tubes (16 by 150 mm).
 - (1) 9.9 ml of cation-adjusted Mueller-Hinton broth (CAMHB)
 - (2) 0.1 ml of 100-fold-concentrated antimicrobial agent solution
 - b. For combination agents, dispense the following into sterile glass tubes (16 by 150 mm).
 - (1) 9.8 ml of CAMHB
 - (2) 0.1 ml of 100-fold-concentrated antimicrobial agent A solution
 - (3) 0.1 ml of 100-fold-concentrated antimicrobial agent B solution

C. Inoculum preparation

See procedure 5.10.2.

D. Inoculation and incubation

See procedure 5.10.2.

E. Reading and recording results

See procedure 5.10.2, and modify the worksheet in Appendix 5.10.3–1 to record results for both individual agents and agent combinations at various times.

POSTANALYTICAL CONSIDERATIONS

VI. REPORTING RESULTS**A. Interpretation**

1. Interpret individual agent MICs according to criteria in procedure 5.2.
2. Determine for individual agents the log₁₀ CFU per milliliter decrease compared with the growth control at sample times.
3. Determine the difference in log₁₀ CFU per milliliter between the most active individual agent at one-fourth the MIC and the combination of agents A and B at one-fourth or one-eighth the MIC.

VI. REPORTING RESULTS*(continued)*

4. Determine whether the definition of synergism or antagonism is met (1, 2).
 - a. Synergism is usually defined as a ≥ 2 -log₁₀ CFU/ml decrease by the combination compared with the most active single agent.
 - b. Antagonism is usually defined as a ≥ 2 -log₁₀ CFU/ml increase by the combination compared with the most active single agent.
5. Determine the shortest period necessary to obtain synergism or antagonism.
6. Retest the MICs for organisms remaining after 24 h of antimicrobial action to confirm that a resistant subpopulation has not been selected.

B. Reporting

1. Report MIC results, and state whether bactericidal activity occurred at a particular concentration for individual agents.
2. Report results by stating whether synergism (or antagonism) occurred with a particular combination of agents.

Example: For *P. aeruginosa*, piperacillin MIC = 128 µg/ml, amikacin MIC = 32 µg/ml, and the combination of piperacillin at 32 µg/ml and amikacin at 8 µg/ml exhibited synergism at 4 h.
3. Report results graphically. Plot growth control, one-fourth MIC for agent A, one-fourth MIC for agent B, and one-fourth MIC for agents A and B combined. Refer to example in Appendix 5.10.3–3.

VII. PROCEDURE NOTES

See procedure 5.10.2

- A. When evaluating organisms from clinical treatment failures, actual (measured) or expected achievable antimicrobial agent concentrations can be used for individual and combination concentrations in place of MIC data.
- B. Ideally, concentrations of individual agents tested should not show significant killing when compared with the growth control.

VIII. LIMITATIONS

See procedure 5.10.2. The number of combination concentrations and sample times are limited to a few tests.

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Schlichter and MacLean first used serum inhibitory titers (SIT) to assess the effectiveness of penicillin in the treatment of subacute bacterial endocarditis (2). Other recognized clinical indications for obtaining serum bactericidal titers (SBT) to monitor effective therapy are osteomyelitis, closed-space infections such as meningitis or joint infection, and the use of oral antimicrobial agents after intravenous therapy. Controversy surrounds and will continue to surround the methodology, and there are few clinical situations in which the test is indicated.

There is currently no single standardized method for determining SIT and SBT. However, the NCCLS has described sev-

eral methods in an approved guideline which contains substantial information about the use of this test in addition to methods (1).

The single most contested issue is the choice of diluent for the test, and the second issue is the use of patient serum versus the use of an ultrafiltrate of patient serum (*see* Appendix 5.11-1). It is the author's preference to use broth without added serum and patient serum rather than ultrafiltrate.

The SIT and SBT tests are designed to determine the bacteriostatic and bactericidal activities of an antimicrobial agent(s) in a patient's serum against the patient's

own infecting organism. The test integrates the pharmacokinetic and pharmacodynamic properties of the antimicrobial agent(s) that the patient is receiving. The serum is diluted geometrically, and a standard inoculum of the patient's organism is added to each tube or well and then incubated for 24 h at 35°C. The SIT is the highest dilution of the serum that inhibits visible growth. A sample from each tube showing no growth is then plated onto agar without any antimicrobial agent and incubated for 24 to 72 h. The SBT is the highest dilution of the serum that reduces (kills) the concentration of the patient's organism by 99.9% (1).

II. SPECIMEN

Observe standard precautions.

A. Patient isolate

An 18- to 48-h agar plate (noninhibitory agar) containing a pure culture of the patient's infecting organism, streaked for isolation (minimum, 20 to 30 colonies)

B. Serum

1. Timing

a. Trough: 0 to 30 min prior to the next dose

b. Peak

(1) 60 min after a 30-min intravenous infusion of drug

(2) 60 min after an intramuscular dose of drug

(3) 90 min after an oral dose of drug

(4) If two or more antimicrobial agents are being administered concomitantly, collect the peak sample 60 min after the second drug is given. If one drug is given more frequently than the other, collect the sample following the less frequently given drug.

c. Trough and peak should ideally be collected around the same dose.

II. SPECIMEN *(continued)*

2. Collection and processing
 - a. Collect the following aseptically in a red-stopper Vacutainer tube.
 - (1) 2 to 5 ml of blood (1 to 2.5 ml of serum) for the microdilution procedure
 - (2) 5 to 7 ml of blood (2.5 to 3.5 ml of serum) for the macrodilution procedure
 - b. Place tube on ice, and deliver to laboratory immediately.
 - c. Centrifuge (before removing the stopper) long enough to obtain cell-free serum.
 - d. Using aseptic technique (for this step and all steps of the procedure), remove the serum to a sterile vial or small test tube.
 - e. Specimens can be kept at 2 to 8°C for up to 2 h.
 - f. Freeze serum (not blood) for up to 2 months at -20°C or lower if testing will be delayed (-70°C or lower is preferred and is necessary when patient has received very temperature-labile drugs such as imipenem or combinations containing clavulanic acid).
 - g. Never refreeze a thawed specimen prior to testing, as this could lead to significant antimicrobial inactivation.
- C. **Body fluids: CSF, joint fluid, peritoneal fluid, etc.**
 1. Collect in a sterile tube.
 2. Filter sterilize by using a 0.45- μm -pore-size filter if there is any suspicion that the fluid contains viable organisms.
 3. Volumes required are the same as those for serum.
 4. Follow handling and storage instructions for serum.

III.A. MATERIALS: MICRODILUTION PROCEDURE

Include QC information on reagent container and in QC records.

- A. **Media and reagents (storage conditions)**
The media listed include those necessary for testing rapidly growing and some other aerobic bacteria. Refer to Appendix 5.11–1 for information on serum diluents and use of ultrafiltrates. Refer to Appendix 5.11–2 for a complete list of suggested media for testing fastidious aerobic bacteria.
 1. Cation-adjusted Mueller-Hinton broth (CAMHB). Store at 2 to 8°C.
 2. Plated media
 - a. BAP. Store at 2 to 8°C.
 - b. CHOC. Store at 2 to 8°C.
 3. Sterile 0.9% NaCl. Store at 25°C.
- B. **Supplies**
 1. Red-stopper Vacutainer tubes (2- to 7-ml capacity)
 2. Sterile glass or plastic vial (2- to 5-ml capacity)
 3. Sterile glass test tubes (16 by 150 mm) with metal or plastic closures
 4. Sterile 1-, 5-, and 10-ml serological pipettes and pipette bulb
 5. McFarland 0.5 turbidity standard
 6. Sterile polystyrene 96-well U-bottom microdilution trays
 7. Sterile 0.05-ml pipette droppers (optional)
 8. Empty microdilution trays or tray-sealing tape
 9. Microdilution tray storage container or plastic bags
 10. Sterile V-shaped reservoir tray or petri plate (100 mm)
- C. **Equipment**
 1. Vortex mixer
 2. Micropipettes, 10-, 25-, 50-, and 100- μl capacity with sterile disposable tips
 3. 0.001-ml calibrated loops
 4. Eight-channel micropipette (optional), 50- μl capacity with sterile disposable tips
 5. Microdilution tray reading device (mirror, light box, etc.)
 6. Microdilution tray shaker-mixer (optional)
 7. 33 to 35°C ambient-air incubator (CO₂ incubation needed for some organisms)

ANALYTICAL CONSIDERATIONS**IV.A. QUALITY CONTROL:
MICRODILUTION PROCEDURE**

- A. Broth**
Assess the performance and chemical characteristics of each batch or lot of broth medium (*see* procedures 5.2 and 5.14).
1. Check the growth capability of the broth by using an ATCC strain similar to the patient's isolate. The broth must support growth.
 2. Perform a dilution susceptibility test with the antimicrobial agent(s) being administered to the patient. Use an ATCC QC strain that has an on-scale endpoint for the antimicrobial agent(s) in question. The MIC must fall within the acceptable range (*see* procedure 5.2).
- B. Controls**
1. The positive control must show heavy (3 to 4+) turbidity.
 2. The broth sterility well must show no growth.
 3. The serum (body fluid) sterility well must show no growth.
 4. The broth-plus-serum sterility well must show no growth.
 5. The purity and inoculum count verification plates must have no contaminating organisms.
 6. The SBT subcultures must have no contaminating organisms.
- C. The final inoculum must contain between 10^5 and 10^6 CFU/ml (20 to 200 colonies on inoculum count verification plate).**

**V.A. PROCEDURE:
MICRODILUTION PROCEDURE**

See Appendix 5.11–2, which gives testing conditions and media for various organisms.

A. Setup

1. Use a sterile 96-well U-bottom microdilution tray for each patient.
2. Label and mark in the following manner (*see* Appendix 5.11–3).
 - a. Use horizontal rows A and C for trough serum sample (run in duplicate).
 - b. Use horizontal rows E and G for peak serum sample (run in duplicate).
 - c. Use D12 and H12 for broth sterility controls (broth only).
 - d. Use B11 for trough serum sterility control (serum only).
 - e. Use F11 for peak serum sterility control (serum only).
 - f. Use B12 and F12 for broth-plus-serum comparison wells (to help ascertain growth versus protein precipitate).
 - g. Use wells A12, C12, E12, and G12 for growth control wells (broth plus organism).
3. The final volume of each well will be 0.1 ml. Each serum sample is run in duplicate.

B. Dilutions

1. Using a pipette dropper or other micropipette, add 0.05 ml of test broth to wells 2 to 12 in rows A, C, E, and G and to wells B12, D12, F12, and H12 (for an eight-channel pipetter, put a tip on every other channel for filling wells in rows A, C, E, and G).
2. Vortex patient serum.
3. Add 0.05 ml of patient serum to wells 1 and 2 of appropriate rows with a micropipette.
4. With a new pipette tip, mix serum and broth in well 2 by aspirating them in and out of the tip 6 to 10 times (an eight-channel pipetter with alternating tips could be used).
5. Use a new tip to withdraw 0.05 ml of this dilution, and add it to well 3.
6. Repeat this procedure through well 11, using a new tip for each dilution.
7. Discard 0.05 ml from well 11.

**V.A. PROCEDURE:
MICRODILUTION PROCEDURE**
(continued)

8. Add 0.1 ml of trough serum to well B11 and 0.05 ml of trough serum to well B12.
9. Add 0.1 ml of peak serum to well F11 and 0.05 ml of peak serum to well F12.

C. Inoculum preparation

1. Using a sterile loop, touch 5 to 10 colonies of the patient's organism, and inoculate them to 5 ml of CAMHB.
2. Incubate for 3 to 4 h at 35°C until the suspension is visibly turbid (logarithmic phase). Optimally place tube on a shaker.
3. Adjust the suspension to obtain a turbidity comparable to that of a McFarland 0.5 turbidity standard.
4. Add 0.05 ml of this suspension to 10 ml of CAMHB, and vortex (concentration = approximately 7.5×10^5 CFU/ml).
5. Use the inoculum suspension within 15 min.

D. Inoculation and incubation

1. Using a pipette dropper, micropipette, or eight-channel pipetter, add 0.05 ml of inoculum to each well in horizontal rows A, C, E, and G. (Do not touch liquid in wells.)
2. Seal tray with tray-sealing tape or an empty sterile microdilution tray, or place the tray in a plastic bag or other storage container to prevent evaporation during incubation.
3. Prepare a purity plate by thoroughly spreading 0.001 ml of the McFarland 0.5 suspension onto the surface of a 100-mm agar plate.
4. Prepare an inoculum count verification plate as follows.
 - a. Prepare a 1:100 dilution of the inoculum (0.1 ml of inoculum plus 9.9 ml of sterile 0.9% NaCl).
 - b. Vortex.
 - c. Use a 10- μ l (0.01-ml) micropipette or calibrated loop to transfer and thoroughly spread 0.01 ml of this dilution onto the surface of a BAP by streaking in several directions with a loop or bent glass rod ("hockey stick") (perform in duplicate).
5. Incubate trays at 35°C in an ambient-air incubator for 24 h (CO₂ may be required for some organisms; see Appendix 5.11-2).
6. After 20 h, remove trays from the incubator.
7. Mix the contents of each well to achieve a uniform suspension of organisms by one of the following methods.
 - a. Place the tray on a mechanical microdilution tray shaker-mixer, and set the speed high enough to displace the well contents halfway up the internal wall. Shake for approximately 1 min.
 - b. Gently tap the plate against a solid object until a uniform suspension is obtained in each well.
8. Then reincubate for another 4 h (total, 24 h).
9. Incubate the purity and inoculum count verification plates in an ambient-air incubator at 35°C (some fastidious organisms may require CO₂ or more than 24 h of incubation before colonies can be counted).

E. Reading and recording inhibitory titers

1. Place tray on reading device.
2. Examine growth control wells for 3 to 4+ turbidity, indicating adequate growth. Assess growth as follows.
 - a. \pm to 1+, very light haze in well
 - b. 2+, light haze in well
 - c. 3+ to 4+, heavy turbidity or fine granular growth throughout well or dense precipitate at bottom of well

**V.A. PROCEDURE:
MICRODILUTION PROCEDURE**
(continued)

- d. During incubation, serum proteins may precipitate and interfere with SIT interpretation. It may be impossible to report the SIT if growth cannot be distinguished from serum protein precipitation.
3. Examine uninoculated controls. Compare questionable growth with these when necessary.
4. Examine inoculum count verification plate. If count is inadequate (<20 or >200), repeat the test.
5. The SIT is the highest dilution of patient serum resulting in no visible growth after 24 h of incubation.
6. Record the results on a worksheet (Appendix 5.11–4) (examples follow).
 - a. If there is no growth in wells 1 to 5 of a horizontal row, the titer is 1:32.
 - b. If all 11 dilutions of patient serum show growth, the titer is <1:2.
 - c. If all 11 dilutions of patient serum show no growth, the titer is $\geq 1:2,048$.
7. In preparation for determining the SBT, calculate the inoculum colony count (final inoculum or actual number of organisms tested).
 - a. Count the colonies growing on each inoculum count verification plate, and average the two counts.
 - b. Multiply the average of the two counts by 10^4 (inoculum was diluted 1:100 for inoculum count verification, and you must multiply by 100 to convert to 1 ml).
 - c. Divide by 2 (inoculum was diluted 1:2 in the test).

F. Plating for bactericidal titers

1. After 24 h of incubation without additional shaking, use a micropipette to remove a 0.01-ml aliquot from the following.
 - a. Each well showing no growth
 - b. The well representing the highest dilution showing growth
 - c. Each control well
2. Plate each sample onto a quarter section of a BAP (do for each patient row), and spread the sample over the entire quadrant. Prepare these subcultures in duplicate. If a micropipette is used, use a new tip for each subculture.
3. Allow inocula to dry prior to incubation.

G. Incubation

1. Invert the plates, and incubate them at 35°C in an ambient-air incubator (CO₂ may be needed for some organisms; see Appendix 5.11–2).
2. Read preliminary results (number of colonies growing in each quadrant or spot) after 1 day of incubation.
3. Read the final results at the following times.
 - a. 24 h for rapidly growing gram-negative rods
 - b. 48 h for staphylococci and enterococci
 - c. 72 h for all other organisms

H. Determining bactericidal titers

1. Count the colonies growing in each quadrant or on each spot, and record on the worksheet.
2. Determine if a particular dilution is bactericidal.
 - a. Add the number of colonies growing in each quadrant from platings of duplicate wells (e.g., A1 + C1, A2 + C2, etc.).
 - b. Use Appendix 5.11–5 to determine whether this number of colonies is above or below the rejection value for the final inoculum that was calculated previously.
 - c. When the sum of colonies growing from subcultures of duplicate dilutions is equal to or less than the rejection value, that dilution of serum is declared bactericidal (indicating killing of 99.9% or more of the organisms tested).

V.A. PROCEDURE: MICRODILUTION PROCEDURE (continued)

3. Given here is an example of the use of Appendix 5.11–5 for a specimen with a trough SIT of 1:32, where all wells showing no growth and the lowest dilution showing growth (1:64) were subcultured (TNTC, too numerous to count).
 - a. Number of colonies on colony count plate = 100 CFU
 - b. Final calculated inoculum in each well: $(100 \times 10^4)/2 = 5 \times 10^5$ CFU/ml
 - c. Duplicate subculture rejection value = 25 CFU

Duplicate subcultures from wells	No. of CFU/quadrant	Total CFU	≥99.9% Killing
A1 + C1 (1:2)	2, 0	2	Yes
A2 + C2 (1:4)	3, 8	11	Yes
A3 + C2 (1:8)	10, 8	18	Yes
A4 + C4 (1:16)	15, 11	26	No
A5 + C5 (1:32)	TNTC	TNTC	No
A6 + C6 (1:64)	TNTC	TNTC	No

4. The SBT is the highest dilution of patient serum that results in killing of 99.9% or more of the organisms tested. The SBT is 1:8 in the example above.

PREANALYTICAL CONSIDERATIONS

III.B. MATERIALS: MACRODILUTION METHOD

Include QC information on reagent container and in QC records.

A. Media and reagents (storage conditions)

The media listed include those necessary for testing rapidly growing and some other aerobic bacteria. Refer to Appendix 5.11–1 for information on serum diluents and use of ultrafiltrates. Refer to Appendix 5.11–2 for a complete listing of suggested media for testing fastidious aerobic bacteria.

1. CAMHB. Store at 2 to 8°C.
2. Plated media
 - a. BAP. Store at 2 to 8°C.
 - b. CHOC. Store at 2 to 8°C.
3. Sterile 0.9% NaCl. Store at 25°C.

B. Supplies

1. Red-stopper Vacutainer tubes (2- to 7-ml capacity)
2. Sterile glass or plastic vial (2- to 5-ml capacity)

3. Sterile glass test tubes (16 by 150 mm) with metal or plastic closures
4. Sterile 1-, 5-, and 10-ml serological pipettes and pipette bulb
5. McFarland 0.5 turbidity standard
6. Sterile acid-washed borosilicate glass tubes (13 by 100 mm) with metal or plastic closures

C. Equipment

1. Vortex mixer
2. Micropipettes, 10-, 25-, 50-, and 100- μ l capacity with sterile disposable tips
3. 0.001- and 0.01-ml calibrated loops
4. 33 to 35°C ambient-air incubator (CO₂ incubation is needed for some organisms)

ANALYTICAL CONSIDERATIONS

IV.B. QUALITY CONTROL: MACRODILUTION PROCEDURE

A. Broth

Assess the performance and chemical characteristics of each batch or lot of broth medium (*see* procedures 5.2 and 5.14).

1. Check the growth capability of the broth by using an ATCC strain similar to the patient's isolate. The broth must support growth.
2. Perform a dilution susceptibility test with the antimicrobial agent(s) being administered to the patient. Use an ATCC QC strain that has an on-scale endpoint for the antimicrobial agent(s) in question. The MIC must fall within the acceptable range (*see* procedure 5.2).

**IV.B. QUALITY CONTROL:
MACRODILUTION PROCEDURE**
(continued)

- B. Controls**
1. The positive control must show heavy (3 to 4+) turbidity.
 2. The broth sterility tube must show no growth.
 3. The broth-plus-serum sterility tube must show no growth.
 4. The purity and colony count verification plates must have no contaminating organisms.
 5. The SBT subcultures must have no contaminating organisms.
- C. The final inoculum must contain between 10^5 and 10^6 CFU/ml (20 to 200 colonies on inoculum count verification plate).**

**V.B. PROCEDURE:
MACRODILUTION PROCEDURE**

See Appendix 5.11–2, which gives testing conditions and media for various organisms.

A. Setup

1. Assemble 14 sterile test tubes (13 by 100 mm) for each patient sample.
2. Label tubes 1 through 12, and place them in one row.
 - a. Tubes 1 through 11 are for serial dilutions of patient sera (1:2 to 1:2,048).
 - b. Tube 12 is for the growth control (broth plus organism).
 - c. Tube 13 is for the broth sterility control (broth only).
 - d. Tube 14 is for the serum sterility control (broth plus serum).
3. The final volume of each tube will be 1.0 ml. Each serum sample is run singly.

B. Dilutions

1. Use a sterile 5-ml pipette to add 1.0 ml of broth to tubes 2 through 14.
2. Vortex patient serum.
3. Use a sterile 2-ml pipette to add 1.0 ml of patient serum to tubes 1, 2, and 14.
4. Vortex tube 2.
5. Use a new sterile 2-ml pipette to transfer 1.0 ml of broth-serum mixture from tube 2 to tube 3. Vortex tube 3.
6. Repeat this procedure through tube 11, using a new pipette for each tube.
7. Discard 1.0 ml of mixture removed from tube 11.

C. Inoculum preparation

1. Using a sterile loop, touch 5 to 10 colonies of the patient's organism, and inoculate them to 5 ml of CAMHB.
2. Incubate for 3 to 4 h at 35°C until the suspension is visibly turbid (logarithmic phase). Optimally place tube on a shaker.
3. Adjust the suspension to obtain a turbidity comparable to that of a McFarland 0.5 turbidity standard.
4. Add 0.3 ml of this suspension to 9.7 ml of CAMHB (1:32 dilution), and vortex (concentration = approximately 4×10^6 to 5×10^6 CFU/ml).
5. Use the inoculum suspension within 15 min.

D. Inoculation and incubation

1. Using a micropipette to inoculate tubes, add 0.1 ml of inoculum to tubes 1 through 12 by placing the tip just under the meniscus of the liquid (final organism concentration, approximately 5×10^5 CFU/ml).
2. Mix by drawing the solution into the tip two or three times without causing air bubbles or splashing.
3. Use a new tip for each tube, and avoid contact of the tip with the wall of the tube.

**V.B. PROCEDURE:
MACRODILUTION PROCEDURE**
(continued)

4. Prepare a purity plate by subculturing 0.001 ml of the McFarland 0.5 suspension onto the surface of a 100-mm agar plate.
5. Prepare an inoculum count verification plate as follows.
 - a. Prepare a 1:100 dilution of the inoculum (0.1 ml of inoculum plus 9.9 ml of sterile 0.9% NaCl).
 - b. Vortex.
 - c. Use a 10- μ l (0.01-ml) micropipette or calibrated loop to transfer and thoroughly spread 0.01 ml of this dilution onto the surface of a BAP by streaking in several directions with a loop or bent glass rod ("hockey stick") (perform in duplicate).
6. Incubate tubes at 35°C in an ambient-air incubator for 20 h (CO₂ may be required for some organisms; *see* Appendix 5.11–2).
7. Incubate the purity and inoculum count verification plates in an ambient-air incubator at 35°C (some fastidious organisms may require CO₂ or more than 24 h of incubation before colonies can be counted).
8. Remove the rack from the incubator.
9. Gently swirl each tube by hand until a uniform turbidity is achieved (the object is to draw organisms from the top of the meniscus back into the broth antimicrobial mixture).
10. Place the rack back into the incubator, and incubate for another 4 h (24 h total).

E. Reading and recording inhibitory titers (after 24 h of incubation)

1. Examine growth control tubes for 3 to 4+ turbidity, indicating adequate growth. Assess growth as follows.
 - a. \pm to 1+, very light haze in tube
 - b. 2+, light haze in tube
 - c. 3+ to 4+, heavy turbidity or fine granular growth throughout tube or dense precipitate at bottom of tube
 - d. During incubation, serum proteins may precipitate and interfere with SIT interpretation. It may be impossible to report SIT if growth cannot be distinguished from serum protein precipitation.
2. Examine uninoculated controls. Compare questionable growth with these when necessary.
3. Examine inoculum count verification plate. If count is inadequate (<20 or >200), repeat the test.
4. The SIT is the highest dilution of patient serum resulting in no visible growth after 24 h of incubation.
5. Record the results on a worksheet (Appendix 5.11–4) (examples follow).
 - a. If there is no growth in tubes 1 through 5 of a row, the titer is 1:32.
 - b. If all 11 dilutions of patient serum show growth, the titer is <1:2.
 - c. If all 11 dilutions of patient serum show no growth, the titer is \geq 1:2,048.
6. In preparation for determining the SBT, calculate the inoculum colony count (final inoculum or actual number of organisms tested).
 - a. Count the colonies growing on each inoculum count verification plate, and average the two counts.
 - b. Multiply the average of the two counts by 10⁴ (inoculum was diluted 1:100 for inoculum count verification, and you must multiply by 100 to convert to 1 ml).
 - c. Divide by 2 (inoculum was diluted 1:2 in the test).

F. Plating for bactericidal titers

1. Use a micropipette to remove 0.01 ml of vortexed broth from the following tubes.
 - a. All tubes showing no growth
 - b. The tube representing the highest dilution showing growth
 - c. Each control tube (tubes 12, 13, and 14)

**V.B. PROCEDURE:
MACRODILUTION PROCEDURE**
(continued)

2. Plate each sample onto a quarter segment of a BAP, and spread the sample over the entire quadrant. Prepare these subcultures in duplicate. Use a new tip for each subculture.
3. Allow inocula to dry prior to incubation.

G. Incubation

1. Invert the plates, and incubate them at 35°C in an ambient-air incubator (CO₂ may be needed for some organisms; see Appendix 5.11–2).
2. Count the colonies growing in each quadrant after 1 day of incubation.
3. Read final results (number of colonies growing in each quadrant) at the following times.
 - a. 24 h for rapidly growing gram-negative rods
 - b. 48 h for staphylococci and enterococci
 - c. 72 h for all other organisms

H. Determining bactericidal endpoints

1. Count the colonies growing in each quadrant, and record on the worksheet.
2. Determine if a particular dilution is bactericidal.
 - a. Add the number of colonies growing in each quadrant from duplicate platings of each dilution.
 - b. Use Appendix 5.11–5 to determine whether this number of colonies is above or below the rejection value for the final inoculum that was calculated previously.
 - c. When the sum of colonies growing on duplicate subcultures of each dilution is equal to or less than the rejection value, that dilution of serum is declared bactericidal (indicating killing of 99.9% or more of the organisms tested).
3. An example of the use of Appendix 5.11–5 for a specimen with an SIT of 1:32 for which all tubes showing no growth and the lowest dilution showing growth (1:64) were subcultured is illustrated above in the microdilution procedure.

POSTANALYTICAL CONSIDERATIONS**VI. RESULTS****A. Interpretation**

The NCCLS provides the following “approximate” guidelines when using the microdilution method (1).

1. Bactericidal titers of 1:16 and 1:32 are frequently associated with favorable clinical outcomes in patients with endocarditis.
2. Bactericidal results of 1:2 or greater are frequently associated with favorable clinical outcomes in patients with skeletal infections.
3. There is much controversy surrounding interpretation beyond that described in items VI.A.1 and 2. It is suggested that the medical literature be followed for other applications and validations (1).

B. Providing QC is acceptable, report according to laboratory policy and format. The following is an example.

The trough serum collected 10-15-90 at 08:00 when tested against *Enterococcus* spp. was bacteriostatic at a dilution of 1:32 and bactericidal at a dilution of 1:8.

VII. PROCEDURE NOTES**A. Specimen**

1. Observe standard precautions when handling *all* patient specimens.
2. The decision to test peak or trough serum or both should be made by the physician based on knowledge of the clinical situation of the patient. These factors include but are not limited to the type(s) of antimicrobial agent(s) that the patient is receiving, the patient's immune status, and the patient's clinical isolate.
3. If the patient's isolate is unavailable, the test *cannot* be performed. It is inappropriate to substitute another isolate (such as an ATCC QC strain) for the patient's isolate (1).

B. Materials

1. The broth medium must permit growth of the organism and not inactivate the antimicrobial agents through pH variation, chelation, or other mechanisms.
2. Some prefer subculturing organisms for SBT to TSA plates rather than BAP. Either is acceptable, providing adequate growth is obtained. Contaminating bacteria are often more readily apparent on BAP.

C. Procedure

1. The outcome of this test is influenced by many technical factors and the fact that two different entities (serum and organism) are tested; thus, QC is difficult, and the protocol must be strictly adhered to in order to minimize artifacts and ambiguous results.
2. Testing must be performed on organisms in the log phase of growth, because the most effective killing of organisms and hence the greatest expression of antibacterial effectiveness occurs at the mid-logarithmic growth phase. A mechanical shaker may be used to accelerate growth. For slow-growing organisms, overnight incubation may be necessary.
3. Organisms can travel up and cling to the sides of non-acid-washed or plastic test tubes. These organisms will not be subjected to the lethal effects of the antimicrobial agent(s) being tested, and less bactericidal activity may be observed; i.e., a lower SBT may result. It has not been established if this phenomenon occurs in microdilution wells.
4. In the microdilution procedure, it is imperative that organisms not travel from one well to another and that no liquid be allowed to evaporate from the wells. Do not stack trays more than four trays high, so that the incubation temperature will be the same for all plates.
5. When subculturing for bactericidal endpoints, position the initial streak about 1 cm from the edge of the plate. Streak in four or five directions to spread the inoculum thoroughly so that individual colonies can be counted. This helps dilute the antimicrobial agent(s) so that it does not continue to inhibit growth of organisms.
6. Whether volumes greater than 0.01 ml should be subcultured for bactericidal determinations is a matter of controversy.
7. Some slow-growing organisms may require more than 24 h of incubation before the colony count can be determined (*see* Appendix 5.11–2).
8. The NCCLS describes an alternative macrodilution procedure where the final volume is 2.0 ml. However, the 1.0-ml volume is more frequently used (1).

D. Results

The clinical relevance of this test and the interpretation of the results are controversial. The NCCLS guidelines contain a thorough summary of the literature and an exhaustive list of references (1).

VII. PROCEDURE NOTES

(continued)

E. Other

1. Inhibitory titers for the microdilution method may tend to be a dilution higher than in the macrodilution method because of difficulty in observing small amounts of precipitate or turbidity in the wells (suspensions cannot be shaken or swirled as easily as with tubes). However, microdilution bactericidal titers should read the same as macrodilution titers.
2. Occasionally, an organism (particularly viridans group streptococci) does not grow satisfactorily in the microdilution system but produces satisfactory results with the macrodilution method.
3. Several problems are associated with the use of human serum in the clinical laboratory. These include but are not limited to transmission of infectious diseases, availability, cost, batch-to-batch variation, and difficulties in reading test results because of precipitation of serum proteins during incubation.
4. SBT activity relates to concentration of antimicrobial agent in patient serum. Other tests that complement this assay and are often performed instead of or in conjunction with it include the actual measurement of drug in patient serum. This can be done by using chemical or immunoassay techniques, and these methods are more standardized than SIT and SBT tests.
5. The lack of a standard test method has limited comparisons or pooling of results from one institution to another.

VIII. LIMITATIONS

Interpretation of the results of this test remains controversial, and the test should not be performed without consulting the director of the microbiology laboratory or an infectious disease physician. This test is designed primarily for aerobic bacteria that grow well after overnight incubation in CAMHB.

APPENDIX 5.11–1

Alternative Protocols for Variations in Sample or Diluent

If the antimicrobial agent in the patient's serum is appreciably protein bound, either an ultrafiltrate of the patient's serum or pooled human serum plus broth diluent should be used.

I. USE OF POOLED HUMAN SERUM AS DILUENT

A. Principle

Heat-inactivated normal human serum (NHS) can be added to broth for use as a diluent in order to minimize the effects of protein binding of the antimicrobial agent. Since some antimicrobial agents (e.g., some beta-lactams) are highly protein bound and since only unbound drug exerts antibacterial activity, use of a serum-broth diluent may more closely simulate antibacterial activity in vivo (1). Generally, titers will be lower when broth-serum is used, particularly when the patient is receiving a beta-lactam. Most studies using serum-broth diluents have included CAMHB as the broth, and projected activity with other broths can only be speculated.

B. Supplemental materials required

1. Media and reagents (storage conditions)
 - a. NHS, pooled or single donor. Store at -20°C .
 - b. Antibiotic medium 5 or nutrient agar. Store at 25°C .
 - c. 1 N HCl. Store at 25°C .
 - d. 1 N NaOH. Store at 25°C .
 - e. Materials needed to perform an acidimetric beta-lactamase test (*see* procedure 5.3)
2. Supplies
 - a. Sterile 100-mm petri plates
 - b. Sterile 6-mm filter paper disks
 - c. Filtration units with 5.0-, 0.8-, and 0.45- μm -pore-size filters
 - d. Sterile containers to hold approximately 100 ml of filtered serum
3. Equipment
 - a. 56°C water bath
 - b. pH meter
4. *Bacillus subtilis* ATCC 6633

C. QC

Serum must be free of beta-lactamase and antibacterial activity.

1. Test each batch or lot of NHS to make certain that it does not contain beta-lactamases.
 - a. Perform a beta-lactamase test on an aliquot of the NHS (*see* procedure 5.3).
 - b. Use the acidimetric method (other methods, including chromogenic cephalosporin methods, may give false-positive results).
2. Using a bioassay method, test each batch or lot of NHS to make certain that it does not contain nonspecific antibacterial activity.
 - a. Grow *B. subtilis* ATCC 6633 overnight at 35°C in CAMHB (turbidity should be at least that of a McFarland 4 standard).
 - b. Prepare 100 ml of antibiotic medium 5 according to the manufacturer's directions (only 5 ml is required for this test, but it is best to make agar in 100-ml volumes).
 - c. After autoclaving, place molten agar in a 56°C water bath, and allow it to equilibrate to 56°C .
 - d. Add 0.1 to 0.2 ml of the overnight suspension of *B. subtilis* (containing approximately 10^9 to 10^{10} CFU/ml) to the 100 ml of cooled agar.
 - e. Mix well.
 - f. Dispense a 5.0-ml aliquot into a 100-mm petri plate, and allow it to solidify.
 - g. Dispense a 20- μl aliquot of NHS onto a sterile 6-mm filter paper disk (perform in duplicate).
 - h. Place disks on surface of solidified agar.
 - i. Incubate plates overnight at 35°C .
 - j. Examine for any evidence of antibacterial activity (zone of inhibition) around disk.

APPENDIX 5.11-1 (continued)

- k. Results
 - (1) No zone of inhibition around the disk means that no antibacterial activity is present. The serum is acceptable for use as a diluent.
 - (2) Any zone of inhibition around the disk indicates antibacterial activity. The serum is not acceptable for use as a diluent.
 - D. Preparation of NHS (pooled or single donor)
 1. Determine the pH of each bottle of NHS before use, and filter the NHS (process approximately 100 ml at a time).
 - a. Adjust to pH 7.2 to 7.4 with 1 N HCl (approximately 0.1 ml of 1 N HCl changes the pH 0.1 U) or 1 N NaOH.
 - b. Filter the pH-adjusted 100 ml of NHS through a 5- μ m-pore-size filter (two filters will be needed, as filters clog after approximately 50 ml is filtered).
 - c. Filter again through a 0.8- μ m-pore-size filter (use two).
 - d. Finally, filter through a 0.45- μ m-pore-size filter.
 2. Aliquot 8-ml portions of filtered serum into sterile plastic tubes, and freeze at -20°C .
 - a. Microdilution: one 8-ml serum aliquot is needed for each microdilution tray (i.e., peak and trough samples run in duplicate).
 - b. Macrodilution: one 8-ml serum aliquot is needed for each patient sample (16 ml needed for trough and peak samples).
 - E. Method
 1. Thaw appropriate number of serum tubes.
 2. Heat inactivate serum at 56°C for 30 min.
 3. Dilute with 8 ml of CAMHB for a working solution.
 4. Follow the microdilution or macrodilution procedure, substituting 50:50 CAMHB-NHS for CAMHB when making the patient serum dilutions and preparing the inoculum.
- II. USE OF ULTRAFILTRATE OF PATIENT'S SERUM
- A. Principle

Ultrafiltrate of patient serum can be used instead of patient serum in order to minimize the effects of protein binding of the antimicrobial agent. Since some antimicrobial agents are highly protein bound and since only unbound drug exerts antibacterial activity, use of an ultrafiltrate of patient serum may more closely simulate antibacterial activity in vivo. Serum proteins and protein-bound antimicrobial agent are removed from patient serum during preparation of the ultrafiltrate. This ultrafiltrate contains only free antimicrobial agent and no serum proteins. Generally, titers obtained with ultrafiltrate will be 1 to 3 dilutions lower than those obtained with unfiltered patient serum diluted in CAMHB.
 - B. Supplemental materials needed
 1. Centrifree micropartition system YMT membrane (Amicon Corp., Danvers, Mass.)
 2. Millipore filter, 0.45- μ m pore size
 - C. Method
 1. Prepare the ultrafiltrate by centrifuging patient serum for 30 min at $1,000 \times g$ through a Centrifree micropartition system YMT membrane.
 2. Sterilize the ultrafiltrate by passage through a 0.45- μ m-pore-size Millipore filter.
 3. Use this ultrafiltrate in place of the patient's serum for the macrodilution or microdilution test.
 4. Ultrafiltrate can be frozen at -20°C or lower for up to 2 months for future testing.

Synergism Testing: Broth Microdilution Checkerboard and Broth Macrodilution Methods

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Microbiologists commonly use a two-dimensional, two-agent broth microdilution checkerboard to evaluate combinations of antimicrobial agents against microorganisms. A broth macrodilution limited series, agar dilution method, or disk diffusion method can also be used. Test methods are based on NCCLS broth dilution susceptibility methods (5) for evaluating the inhibitory or bactericidal activity (4) of specific concentrations in combination at a fixed time. In vitro interactions are calculated

algebraically and interpreted as synergistic, indifferent, or antagonistic depending on whether the antibacterial activity of the combination is greater than, equivalent to, or less than, respectively, the activities of the individual agents. In vitro interactions can also be represented geometrically with isobolograms (1).

Combination methods evaluating agent interaction are not routine. Situations in which to consider such testing include those in which the predictability of syn-

ergism is unknown, as with a new antimicrobial agent, or when the predictability is unreliable because of the development of bacterial resistance factors or treatment failures. Appendix 5.12–1 lists reported synergistic and antagonistic combinations in vivo for various organisms (2, 3, 6). Methods for determining synergistic activity have not been standardized, and controversy over the value of these tests in the clinical setting continues.

II. SPECIMEN

- A. Isolated colonies (minimum of three to five) of similar colony morphology grown overnight at 35°C on BAP (or nonselective supplemented medium if necessary)
- B. Isolates from frozen, lyophilized, or other stock conditions require three consecutive subcultures prior to testing.

III.A. MATERIALS: BROTH MICRODILUTION METHOD

Include QC information on reagent container and in QC records.

See procedure 5.2 for additional information, including testing materials and methods for testing fastidious organisms.

A. Media and reagents (storage conditions)

1. Cation-adjusted Mueller-Hinton broth (CAMHB) dispensed in approximately 250-ml aliquots into flasks and in 5-ml aliquots into capped tubes. Store at 2 to 8°C.
2. Diluents for antimicrobial agent stock solutions. Store at 2 to 8°C.
3. Sterile distilled reagent-grade water with 0.02% Tween 80 dispensed in 25-ml aliquots into screw-cap tubes. Store at 25°C.

4. Prepared microdilution synergy trays containing 100 µl of antimicrobial solution per well. Store at –70°C. See item V.A below.

5. BAP. Store at 2 to 8°C.

6. Sterile 0.9% NaCl

B. Supplies

1. Sterile 96-well polystyrene U-bottom microdilution trays
2. Microdilution tray lids, empty microdilution trays, or tray sealers
3. Sterile single-inoculum reservoir trays

III.A. MATERIALS: BROTH MICRODILUTION METHOD (continued)

4. Sterile disposable plastic multi-pronged inoculators (or other inoculating device)
5. Sterile polystyrene capped tubes (12 ml; 17 by 100 mm) or screw-cap tubes (50 ml; 30 by 115 mm)
6. Sterile reservoir for antimicrobial dilutions (V-shaped tray or sterile petri plate)
7. Sterile 1-, 5-, and 10-ml serologic pipettes and pipette bulb
8. Sterile cotton-tipped swabs
9. McFarland 0.5 turbidity standard
10. Microdilution tray storage container or plastic bags

C. Equipment

1. Automatic multichannel pipetter to deliver 50 μ l and sterile disposable tips
 NOTE: If only a few panels are being prepared, a single-channel pipette can be used.
2. 0.001-ml calibrated loop
3. Microdilution tray reading device
4. Vortex mixer
5. -70°C freezer
6. $35 \pm 2^{\circ}\text{C}$ ambient-air incubator (CO₂ incubation needed for some organisms)

ANALYTICAL CONSIDERATIONS

IV.A. QUALITY CONTROL: BROTH MICRODILUTION METHOD

- A. QC strains
 Choose QC strains according to individual antimicrobial agents tested. (See procedure 5.2 for additional QC recommendations.)
 1. **Example:** For piperacillin and amikacin, use *Escherichia coli* ATCC 25922 and *Pseudomonas aeruginosa* ATCC 27853.
 2. Test each QC organism on a separate panel according to the standard protocol for testing patient isolates.
 3. Record MIC results of individual agents, and compare MICs obtained with MICs expected.
- B. Growth controls
 Growth control should show heavy turbidity. Purity plate should show good growth and be free of contaminating organisms.
- C. Sterility control should be free of any growth.
- D. Inoculum controls
 Inoculum count verification plate should show approximately 75 to 150 colonies.
- E. If any QC result is out of control, inform supervisor, and proceed with corrective action. Document accordingly.

V.A. PROCEDURE: BROTH MICRODILUTION METHOD

- A. **Preparing checkerboard microdilution panels**
 1. Plan final concentrations of user-defined panel configuration (example in Appendix 5.12–2).
 - a. Determine single-agent MICs for test isolate, or use commonly tested therapeutic range.
 - (1) **Example:** *P. aeruginosa* isolated from a blood culture was associated with a piperacillin MIC of 128 $\mu\text{g/ml}$ and an amikacin MIC of 32 $\mu\text{g/ml}$.
 - (2) **Example:** To test several isolates of *P. aeruginosa*, use known MIC range (i.e., piperacillin MIC of 0.5 to 256 $\mu\text{g/ml}$ and amikacin MIC of 0.5 to 32 $\mu\text{g/ml}$).
 - b. Include concentrations ranging from four to eight times the expected MIC to at least 1/8 to 1/16 times the expected MIC in the final panel in order to observe the occurrence and magnitude of synergism or antagonism.
 - c. Determine the number of panels to prepare (one for each test isolate and one for each QC strain).

V.A. PROCEDURE: BROTH MICRODILUTION METHOD
(continued)

2. Prepare intermediate antimicrobial agent concentrations (*see* procedure 5.14 for antimicrobial stock solution preparation).
 - a. In separate tubes, prepare intermediate concentrations of each of the two antimicrobial agents as shown in Appendix 5.12–3. The intermediate concentrations are two times the final panel concentrations because equal volumes of each agent concentration are added to a well.
 - b. Prepare sufficient intermediate concentration volumes to dispense respective *x*- and *y*-axis concentrations as listed in Appendix 5.12–2.
 - (1) Examples of per-panel requirements
 - (a) Piperacillin (512 µg/ml): 8 wells × 0.05 ml per well = 0.4 ml of piperacillin at 1,024 µg/ml
 - (b) Piperacillin (256 µg/ml): 8 wells × 0.05 ml per well = 0.4 ml of piperacillin at 512 µg/ml
 - (c) Amikacin (64 µg/ml): 12 wells × 0.05 ml per well = 0.6 ml of amikacin at 128 µg/ml
 - (d) Continue accordingly.
 - (2) Include sufficient volumes for serial dilution and residual minimum volumes for reservoir (e.g., 2 to 5 ml of excess volume is needed).
3. Dispense antimicrobial agents into combination panel (0.1-ml final volume per well).
 - a. Follow the user-defined schematic in Appendix 5.12–2.

Example: Well D10 will contain 0.05 ml of piperacillin at 256 µg/ml and 0.05 ml of amikacin at 8 µg/ml, resulting in a 0.1-ml volume of piperacillin at 128 µg/ml and amikacin at 4 µg/ml per well.
 - b. Pour each working concentration (Appendix 5.12–3) into individual reservoirs.
 - c. Dispense drug A (piperacillin) with the eight-channel pipetter as follows.

■ **NOTE:** If an eight-channel pipetter is not used, fill each well individually.

 - (1) Add 0.05 ml of drug A (piperacillin at 1 µg/ml) to each well in column 2: A2, B2, C2, D2, E2, F2, G2, and H2.
 - (2) Add 0.05 ml of drug A (piperacillin at 2 µg/ml) to each well in column 3: A3 through H3.
 - (3) Continue to dispense the next-higher concentration of drug A into each well in the next column through column 12.
 - (4) Do not add drug to well H12 (sterility control).
 - d. Dispense drug B (amikacin) with the eight-channel pipetter as follows.
 - (1) Add 0.05 ml of drug B (amikacin at 2 µg/ml) to each well in row B: B1 through B12.
 - (2) Add 0.05 ml of drug B (amikacin at 4 µg/ml) to each well in row C: C1 through C12.
 - (3) Continue to dispense the next-higher concentration of drug B to each well in the next row through row H.
 - (4) Do not add drug to well H12 (sterility control).
 - e. Add 0.05 ml of CAMHB to wells A2 through A12.
 - f. Add 0.05 ml of CAMHB to wells B1, C1, D1, E1, F1, G1, and H1.
 - g. Add 0.1 ml of CAMHB to wells A1 and H12.
 - h. Use panels or seal with tape, place in tightly sealed plastic bags, and store at –70°C for up to 6 months.

B. Preparing inoculum

1. Using a sterile swab, transfer organisms from four or five colonies of similar colony morphology to 5 ml of CAMHB.
2. Incubate at 35°C until turbidity matches that of a McFarland 0.5 turbidity standard (approximately 1.5×10^8 CFU/ml).

V.A. PROCEDURE: BROTH MICRODILUTION METHOD
(continued)

3. For preparation of the intermediate inoculum dilution, calculate volume of standardized suspension to add to 25 ml of water diluent to obtain a final organism concentration of 3×10^5 to 5×10^5 CFU/ml in each well. For example, when using a disposable plastic multipronged inoculating device that delivers 0.01 ml per well, proceed as follows.
 - a. McFarland 0.5 suspension = 1.5×10^8 CFU/ml
 - b. Add 0.8 ml of suspension to 25 ml of water diluent (1:31 dilution) to achieve 4×10^6 to 5×10^6 CFU/ml.
 - c. Prongs deliver 0.01 ml, or 4×10^4 to 5×10^4 CFU/well (4×10^5 to 5×10^5 CFU/ml).

C. Inoculation and incubation

1. Add 0.8 ml of standardized suspension to 25 ml of water-Tween 80.
2. Mix by inverting tube five or six times (try to avoid producing air bubbles).
3. Within 1 h (immediately if testing fastidious organisms), inoculate the MIC tray.
 - a. Remove the inoculator-reservoir set from the plastic packaging.
 - b. Remove prongs from the reservoir tray, and pour contents of the diluted inoculum into the tray.
 - c. Dip prongs into the inoculum suspension.
 - (1) Orient sterility well (H12) so that it is not inoculated.
 - (2) Press down on the inoculator firmly to ensure that all prongs come in contact with the organism solution.
 - d. Inoculate MIC tray by dipping the filled prongs carefully into the MIC tray.
 - e. Discard prongs as biohazardous waste.
 - f. Using a 0.001-ml calibrated loop, inoculate a purity plate by subculturing 0.001 ml of inoculum from the reservoir onto BAP. Streak for isolation.
 - g. Periodically prepare an inoculum count verification plate to validate inoculum size.
 - (1) Immediately after inoculation, transfer 0.01 ml from the growth control well to 10.0 ml of sterile 0.9% NaCl, and vortex well.
 - (2) Plate 0.1 ml to BAP. Thoroughly spread over the surface of the BAP by streaking in several directions with a loop.
4. Stack inoculated MIC trays no more than four high, and place them in a microdilution tray storage container with the top loose.
5. Incubate MIC trays for 16 to 20 h at $35 \pm 2^\circ\text{C}$. CO_2 incubation alters the pH and affects the activity of some antimicrobial agents and should be avoided.
6. Incubate purity and inoculum verification control plates in CO_2 .

D. Reading MICs

1. Examine purity control plate. If results are mixed, repeat the test. When available, examine the inoculum count verification plate (should show 30 to 70 colonies).
2. Place tray on appropriate reading device.
3. Examine growth control well (A1) for heavy turbidity, indicating adequate growth.
4. Examine the uninoculated broth control. Compare questionable growth with that in this well when necessary.
5. The MIC is the lowest concentration of antimicrobial agent(s) causing complete inhibition of growth.
6. Examine drugs A and B as single agents, and record the MICs.
7. Examine each combination well, and record growth or no growth for each well.
8. Refer to Appendixes 5.12-4 and 5.12-5 for examples of outcome and how to record them.

VI.A. CALCULATIONS: BROTH MICRODILUTION METHOD

- A. For each combination interaction, calculate the fractional inhibitory concentration (FIC) of each agent as follows.
1. FIC of agent A = $\frac{\text{MIC of agent A in combination}}{\text{MIC of agent A alone}}$
 - a. Example, Appendix 5.12–4, well E5:
 $\frac{4 \mu\text{g/ml}}{128 \mu\text{g/ml}} = 0.03 = \text{FIC of piperacillin}$
 - b. Example, Appendix 5.12–5, well C12:
 $\frac{512 \mu\text{g/ml}}{128 \mu\text{g/ml}} = 4 = \text{FIC of piperacillin}$
 2. FIC of agent B = $\frac{\text{MIC of agent B in combination}}{\text{MIC of agent B alone}}$
 - a. Example, Appendix 5.12–4, well E5:
 $\frac{8 \mu\text{g/ml}}{32 \mu\text{g/ml}} = 0.25 = \text{FIC of amikacin}$
 - b. Example, Appendix 5.12–5, well C12:
 $\frac{2 \mu\text{g/ml}}{32 \mu\text{g/ml}} = 0.06 = \text{FIC of amikacin}$
 3. The FIC may be not determinable (ND) for some combinations of concentrations if MICs of the single agents occur at test range extremes (i.e., greater than the highest or less than or equal to the lowest concentration tested) and if combination MICs are not at least fourfold different.
 - a. **Example:** MIC of piperacillin alone is $>512 \mu\text{g/ml}$, and MIC in combination is $512 \mu\text{g/ml}$. Therefore, piperacillin FIC is ND.
 - b. **Example:** MIC of amikacin alone and in combination is $\leq 1 \mu\text{g/ml}$. Therefore, amikacin FIC is ND.
 4. If an FIC is ND, record, calculate other combination indices, and refer to item VIII.C.4 for instructions on analyzing ND results.
- B. Calculate the summation of FIC (ΣFIC) index for each combination as follows.
1. $\Sigma\text{FIC} = \text{FIC of agent A} + \text{FIC of agent B}$
 - a. Example, Appendix 5.12–4, well E5: $0.03 + 0.25 = 0.28$
 - b. Example, Appendix 5.12–5, well C12: $4 + 0.06 = 4.06$
 2. *Optional:* Record maximum ($\Sigma\text{FIC}_{\text{max}}$) and minimum ($\Sigma\text{FIC}_{\text{min}}$) values for the combination when testing an individual organism (see item VIII.C below).
 - a. Example, Appendix 5.12–4: $\Sigma\text{FIC}_{\text{max}} = 1.03$ (B10) and $\Sigma\text{FIC}_{\text{min}} = 0.25$ (D7)
 - b. Example, Appendix 5.12–5: $\Sigma\text{FIC}_{\text{max}} = 4.06$ (C12) and $\Sigma\text{FIC}_{\text{min}} = 0.625$ (F7)

POSTANALYTICAL CONSIDERATIONS

VII.A. REPORTING RESULTS: BROTH MICRODILUTION METHOD

- A. Providing QC is acceptable, interpret and record each summation (ΣFIC).
1. Interpretation of summation
 - a. Synergism, $x \leq 0.5$
 - b. Indifference, $0.5 < x \leq 4$
 - c. Antagonism, $x > 4$
 - d. **Examples:** $\Sigma\text{FIC} = 0.28 = \text{synergism}$
 $\Sigma\text{FIC} = 4.06 = \text{antagonism}$
 2. Definitions of synergism, indifference, and antagonism differ among investigators. Check journal instructions, study references, or other sources, such as reference 3.

VII.A. REPORTING RESULTS: BROTH MICRODILUTION METHOD (continued)

- B.** Report organism tested, single antimicrobial agent MICs, and combination interaction.
- Report each single-agent MIC, and give susceptibility interpretation (*see* procedure 5.2).
Example: *P. aeruginosa*
Piperacillin MIC = 128 µg/ml = resistant
Amikacin MIC = 32 µg/ml = intermediate
 - Report antimicrobial combination and interaction using one of the following formats.
 - For a single isolate tested, report an interaction.
 - Example:** The combination of piperacillin and amikacin resulted in synergism.
 - Even if synergism or antagonism occurs at only one Σ FIC within the combination, report the occurrence.
 - If both synergism (Σ FIC_{min}) and antagonism (Σ FIC_{max}) occur for one organism within the same combination and if only one interpretation is reported, report antagonism.
 - For a single isolate tested, report concentrations at which synergism occurs.
Example: The combination of piperacillin and amikacin resulted in synergism with piperacillin at 32 or 16 µg/ml in combination with amikacin at 4 µg/ml and with piperacillin at 4 or 8 µg/ml in combination with amikacin at 8 µg/ml.

PREANALYTICAL CONSIDERATIONS

III.B. MATERIALS: BROTH MACRODILUTION METHOD

Include QC information on reagent container and in QC records.

See procedure 5.10.1 for additional information, including testing materials and methods for testing fastidious organisms.

A. Media and reagents (storage conditions)

- CAMHB dispensed in approximately 250-ml aliquots into flasks and in 5-ml aliquots into capped tubes. Store at 2 to 8°C.
- Diluents for antimicrobial agent stock solutions. Store at 2 to 8°C.
- Broth macrodilution tubes containing 1-ml volumes of broth and antimicrobial agents. Store at -70°C. See item V.B below.
- BAP. Store at 2 to 8°C.
- Sterile 0.9% NaCl. Store at 25°C.

B. Supplies

- Sterile polystyrene capped tubes (5 ml; 12 by 75 mm)

- Sterile polystyrene capped tubes (12 ml; 17 by 100 mm) or screw-cap tubes (50 ml; 30 by 115 mm)
- Sterile 1-, 5-, and 10-ml serologic pipettes and pipette bulb
- Sterile cotton-tipped swabs
- McFarland 0.5 turbidity standard

C. Equipment

- 0.001-ml calibrated loop
- Vortex mixer
- 70°C freezer
- 35 ± 2°C ambient-air incubator (CO₂ incubator needed for some organisms)
- Optional equipment for dispensing antimicrobial agents: 500-µl single or repetitive dispensing pipetter with sterile disposable tips

ANALYTICAL CONSIDERATIONS

**IV.B. QUALITY CONTROL:
BROTH MACRODILUTION
METHOD**

- A. QC strains**
Choose QC strains according to individual antimicrobial agents tested (*see* procedure 5.2 for additional QC recommendations).
- 1. Example:** For piperacillin and amikacin, use *E. coli* ATCC 25922 and *P. aeruginosa* ATCC 27853.
 2. Test each QC organism in a separate tube set according to the standard protocol for testing patient isolates.
 3. Record MICs of individual agents, and compare MICs obtained with MICs expected.
- B. Growth controls**
Growth control should show heavy turbidity. Purity plate should show good growth and be free of contaminating organisms.
- C. Sterility control** should be free of any growth.
- D. Inoculum controls**
Inoculum count verification plate should show approximately 75 to 150 colonies.
- E.** If any QC result is out of control, inform supervisor, and proceed with corrective action. Document accordingly.

**V.B. PROCEDURE: BROTH
MACRODILUTION METHOD**

- A. Preparing broth macrodilution limited checkerboard**
1. Plan user-defined configuration as shown in Appendix 5.12–6.
 - a.** Determine single-agent MICs by broth macrodilution.
Example: Piperacillin MIC = 4 µg/ml and amikacin MIC = 8 µg/ml
 - b.** Test single-agent concentrations at one-half the MIC, the MIC, and two times the MIC, and test combination concentrations to detect synergism and antagonism as shown in Appendix 5.12–6.
 - c.** Determine number of sets of tubes needed (one set for each test isolate and one set for each QC strain).
 2. Prepare intermediate antimicrobial concentrations (*see* procedure 5.14 for antimicrobial stock solution preparation).
 - a.** In separate tubes, prepare intermediate concentration solutions of each of the two antimicrobial agents as shown in Appendix 5.12–7. The intermediate concentrations are four times the final tube concentrations shown in Appendix 5.12–6.
 - b.** Prepare sufficient volumes needed for each organism (0.5 ml of each drug concentration [intermediate concentration is four times the final concentration] required for each tube).
 - (1) Example of per-tube requirements
 - (a) Piperacillin (2 µg/ml) is used for three tubes (PP 2, PP 2 + AK 4, and PP 2 + AK 16): 0.5 ml × 3 tubes = 1.5 ml of piperacillin at 8 µg/ml
 - (b) Piperacillin (8 µg/ml) is used for five tubes (PP 8, PP 8 + AK 1, PP 8 + AK 2, PP 8 + AK 4, and PP 8 + AK 8): 0.5 ml × 5 tubes = 2.5 ml of piperacillin at 32 µg/ml
 - (2) Include sufficient volumes for serial dilutions, and allow extra volumes for pipetting (1 to 2 ml of excess volume is needed).
 3. Dispense antimicrobial agents into macrodilution tubes (0.5-ml volumes of each of the two antimicrobial agents).
 - a.** Follow the user-defined schematic in Appendix 5.12–6, and use intermediate antimicrobial agent concentrations from Appendix 5.12–7 to ob-

**V.B. PROCEDURE: BROTH
MACRODILUTION METHOD**
(continued)

tain solutions at twice the desired final concentration. For example, the tubes designated piperacillin (8 µg/ml) and amikacin (4 µg/ml) in Appendix 5.12–6 will contain 0.5 ml of piperacillin (32 µg/ml) and 0.5 ml of amikacin (16 µg/ml).

- b. Add 0.5 ml of drug A (four times the working solution) to appropriate tubes.
- c. Add 0.5 ml of drug B (four times the working solution) to appropriate tubes.
- d. Tubes now contain drug A at two times the actual test concentration and drug B at two times the actual test concentration.
- e. Dispense 1 ml of CAMHB to the growth control and medium sterility tubes.
- f. Store capped tubes at -70°C for up to 6 months.

B. Preparing inoculum

1. Using a sterile swab, transfer organisms from four or five colonies of similar colony morphology to 5 ml of CAMHB.
2. Incubate at 35°C until turbidity matches that of a McFarland 0.5 turbidity standard (approximately 1.5×10^8 CFU/ml).

C. Inoculation and incubation

1. Add 0.25 ml of standardized suspension to 25 ml of CAMHB (resulting suspension = 1.5×10^6 CFU/ml).
2. Mix by inverting tubes five or six times.
3. Use suspension within 1 h (immediately if testing fastidious organisms).
4. Using a sterile serologic pipette, add 1 ml of organism suspension to each tube. Inoculate organisms below the fluid meniscus (subsurface inoculation). Avoid touching the tube sides with the pipette. Use a separate sterile pipette for each inoculation.
 - a. Resulting suspension = 7.5×10^5 CFU/ml
 - b. Resulting antimicrobial agent concentration is diluted 1:2 to final desired concentration.
5. Using a 0.001-ml calibrated loop, inoculate a purity plate by subculturing 0.001 ml of inoculum from inoculum suspension (containing 1.5×10^6 CFU/ml) onto BAP. Streak for isolation.
6. Periodically, prepare an inoculum count verification plate to determine inoculum size.
 - a. Immediately after inoculation, transfer 0.01 ml from the growth control tube to 10.0 ml of sterile 0.9% NaCl, and vortex well.
 - b. Plate 0.1 ml to BAP. Thoroughly spread over the surface of a BAP by streaking in several directions with a loop.
7. Incubate tubes for 16 to 20 h at $35 \pm 2^{\circ}\text{C}$. CO_2 incubation alters the pH and affects the activity of some antimicrobial agents and should be avoided.
8. Incubate purity and inoculum count verification plates in CO_2 .

D. Reading MICs

1. Examine the corresponding purity control plate. If results are mixed, repeat the test. When available, examine the inoculum count verification plate (should show 75 to 150 colonies).
2. Examine growth control tube for heavy turbidity, indicating adequate growth.
3. Examine the uninoculated broth control tube. Compare questionable growth with this tube when necessary.

V.B. PROCEDURE: BROTH MACRODILUTION METHOD (continued)

4. The MIC is the lowest concentration of antimicrobial agent(s) demonstrating complete inhibition of growth.
5. Examine drugs A and B as single agents, and record the MICs.
6. Examine each combination tube, and record growth or no growth for each tube.
7. See Appendixes 5.12–8 and 5.12–9 for examples for outcome and recording.

VI.B. CALCULATIONS: BROTH MACRODILUTION METHOD

- A. For each combination, calculate the FIC index for each agent.
 1. FIC of agent A = $\frac{\text{MIC of agent A in combination}}{\text{MIC of agent A alone}}$
 - a. Example, Appendix 5.12–8:
 $\frac{1 \mu\text{g/ml}}{4 \mu\text{g/ml}} = 0.25 = \text{FIC of piperacillin}$
 - b. Example, Appendix 5.12–9:
 $\frac{>8 \mu\text{g/ml}}{4 \mu\text{g/ml}} \geq 4 = \text{FIC of piperacillin}$
 2. FIC of agent B = $\frac{\text{MIC of agent B in combination}}{\text{MIC of agent B alone}}$
 - a. Example, Appendix 5.12–8:
 $\frac{2 \mu\text{g/ml}}{8 \mu\text{g/ml}} = 0.25 = \text{FIC of amikacin}$
 - b. Example, Appendix 5.12–9:
 $\frac{1 \mu\text{g/ml}}{8 \mu\text{g/ml}} = 0.125 = \text{FIC of amikacin}$
 3. The FIC may be ND for some combination concentrations if MICs of the single agents occur at test range extremes (i.e., greater than the highest or less than or equal to the lowest concentration tested) and if combination MICs are not at least fourfold different.
 - a. **Example:** MIC of piperacillin alone and in combination is $>8 \mu\text{g/ml}$. Therefore, piperacillin FIC is ND.
 - b. **Example:** MIC of amikacin alone and in combination is $<1 \mu\text{g/ml}$. Therefore, amikacin FIC is ND.
 4. If an FIC is ND, record, calculate other combination indices, and refer to item VIII.C.4 for instructions on analyzing ND results.
- B. Calculate the ΣFIC for each combination.
 1. $\Sigma\text{FIC} = \text{FIC of agent A} + \text{FIC of agent B}$
 - a. Example, Appendix 5.12–8: $0.25 + 0.25 = 0.5$
 - b. Example, Appendix 5.12–9: $\geq 4 + 0.125 = \geq 4.125$
 2. *Optional:* Record $\Sigma\text{FIC}_{\text{max}}$ and $\Sigma\text{FIC}_{\text{min}}$ for the combination when testing an individual organism (see item VIII.C below).

POSTANALYTICAL CONSIDERATIONS

VII.B. REPORTING RESULTS: BROTH MACRODILUTION METHOD

- A. Providing QC is acceptable, interpret and record each ΣFIC .
 1. Interpretation of summation
 - a. Synergism, $x \leq 0.5$
 - b. Indifference, $0.5 < x \leq 4$
 - c. Antagonism, $x > 4$
 - d. **Examples:** $\Sigma\text{FIC} = 0.5 = \text{synergism}$
 $\Sigma\text{FIC} = \geq 4.125 = \text{antagonism}$

VII.B. REPORTING RESULTS: BROTH MACRODILUTION METHOD (continued)

2. Definitions of synergism, indifference, and antagonism differ among investigators. Check journal instructions, study references, or other sources, such as reference 3.
- B. Report organism tested, single antimicrobial agent MICs, and combination interaction.
 1. Report each single-agent MIC, and give susceptibility interpretation (*see* procedure 5.2).

Example: *P. aeruginosa*
Piperacillin MIC = 4 µg/ml = susceptible
Amikacin MIC = 8 µg/ml = susceptible
 2. Report antimicrobial combination and interaction using one of the following formats.
 - a. For a single isolate tested, report an interaction.
 - (1) **Example:** The combination of piperacillin and amikacin resulted in synergism.
 - (2) Even if synergism or antagonism occurs at only one Σ FIC within the combination, report the occurrence.
 - (3) If both synergism (Σ FIC_{min}) and antagonism (Σ FIC_{max}) occur for one organism within the same combination and if only one interpretation is reported, report antagonism.
 - b. For a single isolate tested, report concentrations at which synergism occurs.

Example: The combination of piperacillin and amikacin resulted in synergism with piperacillin at 1 µg/ml in combination with amikacin at 2 µg/ml.

VIII. PROCEDURE NOTES

A. Principle

1. The use of combinations of antimicrobial agents or concomitant agents accompanying one another is common practice, particularly in the treatment of seriously ill or immunocompromised patients. Combinations are usually empirically based on the antimicrobial spectrum and the causative bacterium, if known.
2. Potential benefits of antimicrobial combinations are provision of broad-spectrum antimicrobial coverage, minimization of resistance development, and production of a synergistic interaction to enhance bactericidal treatment efficacy while minimizing toxicity of certain frequently used agents. Disadvantages of concomitant therapy include a potential antagonistic interaction that could delay or impede treatment efficacy. Combinations may be composed of individual agents such as a beta-lactam and an aminoglycoside or as a fixed ratio such as with beta-lactam–beta-lactamase inhibitors or trimethoprim-sulfamethoxazole.
3. Fixed-ratio combinations are routinely tested as single agents in vitro by clinical laboratories using dilution or disk diffusion methods.
4. Theoretically, more than two agents may be tested. However, methods and mathematics become impractical and complex, and such testing is not recommended.

B. Methods

1. Microdilution checkerboard panels can be prepared manually (up to 20 panels) or with an automated 96-channel dispenser for larger batches (*see* procedure 5.15 for details on preparation methods).
2. A complete macrodilution checkerboard is too cumbersome to prepare and is not recommended.

VIII. PROCEDURE NOTES

(continued)

3. Alternative inoculum preparation methods may be used (log-phase suspensions must be used if bactericidal activity is to be determined) (*see* procedures 5.2 and 5.10).

C. Interpretation

1. The Instructions to Authors in the January issue of *Antimicrobial Agents and Chemotherapy* defines antagonism as $\Sigma\text{FIC} > 4$. This is in part because of the 1 twofold dilution variation allowable within the test system. If each agent varies by 1 dilution within the test system, it is possible to have $\Sigma\text{FIC} (4) = \text{FICa} (2) + \text{FICb} (2)$. Dilution ranges for testing, especially for a limited macrodilution series, must include a concentration above and below the expected MIC.
2. The concept of ΣFIC_{\min} and ΣFIC_{\max} (7) reflects interaction dynamics. Several combination concentrations are tested along the checkerboard, and multiple interaction indices are therefore calculated. This reporting method allows accounting for both synergism and antagonism if they are present within the same test panel against one isolate. Few investigators report ΣFIC_{\min} and ΣFIC_{\max} ; most workers report only the presence of antagonism or synergism, even if exhibited only once within the checkerboard.
3. Partial synergism is defined as $\Sigma\text{FIC} = 0.5 < x < 1.0$. This designation determines drug interactions in which MICs are decreased 1 twofold dilution but not 2 twofold dilutions. Partial synergism is differentiated from indifference. This designation of partial synergism is controversial.
4. ND interactions are not problematic if other interactions are present for the combination and provide useful information within clinically therapeutic parameters. However, if the MIC interaction ranges do not provide useful information, the test may need to be repeated on a newly designed panel with appropriate ranges.
 - a. **Example:** Piperacillin MICs are $>512 \mu\text{g/ml}$, and combination interactions result in piperacillin MICs of $512 \mu\text{g/ml}$. Repeat testing would be not useful, because piperacillin at $512 \mu\text{g/ml}$ indicates resistance.
 - b. **Example:** Amikacin MICs are $2 \mu\text{g/ml}$, and combination interactions result in amikacin MICs of $\leq 1 \mu\text{g/ml}$. Repeat testing with a panel reconfigured with amikacin at 0.25 to $16 \mu\text{g/ml}$ would be useful.
5. Checkerboards may also be graphically represented as isobolograms with interpretations (1). Checkerboard panels and isobolograms may not be meaningful to clinicians or easily reported in patient records (*see* Appendix 5.12–10).

D. Results

Bactericidal activities of the single agents and combinations can be determined when broth dilution and time-kill assay methods are used. Pay strict attention to technical details of the method described for single agents (e.g., use of log-phase inoculum suspension, use of subsurface inoculation technique to macrodilution tube inoculation, etc.; *see* procedure 5.10.1).

- A. Kill curve assays can also be used to assess bactericidal activities of combinations of agents (*see* procedure 5.10.3).
- B. Alternative bactericidal determination from broth microdilution method
 1. Although this method is not the same as that described in procedure 5.10, it has been used successfully in the author's laboratory for several years.
 2. Subculture entire well contents (0.1 ml) from wells for the MIC, two times the MIC, and four times the MIC of the individual agents (for example, Appendix 5.12–4, wells A10, A11, A12, G1, and H1) onto separate BAP.

VIII. PROCEDURE NOTES

(continued)

3. Subculture entire well contents (0.1 ml) for each combination interaction at the MIC, two times the MIC, and four times the MIC (for example, Appendix 5.12–4, wells B10, B11, B12, C9, C10, C11, D7, D8, D9, E5, E6, E7, F2, F3, F4, G2, and G3) onto separate BAP.
4. Streak aliquot in three directions to obtain isolated colonies. Incubate at 35°C overnight. Count colonies. Define MBC with a $\geq 99.9\%$ cutoff based on initial starting inoculum.
5. Calculate bactericidal indices by substituting MBC and fraction bactericidal concentration for MIC and FIC.

IX. LIMITATIONS

- A. Synergy testing methods are not standardized as to method reproducibility and interpretation. Synergy testing is often considered a clinical research procedure.
- B. QC parameters are undefined for antimicrobial agents in combination. Only individual agents have standard QC parameters. Internal records could note and establish QC strain combination results.
- C. Checkerboard testing may be considered imprecise because only 1-log₂ differences are tested, results are taken at only one time point, and testing is based on a linear dose-response curve unlike the exponential dose-response curves observed in vivo.
- D. Checkerboard combination interaction methods may not produce results that agree with time-kill methods, because each method measures different parameters.

APPENDIX 5.12–11

Synergy Testing by Disk Agar Diffusion Methods

With disk agar diffusion methods, organisms can be qualitatively screened for synergism, indifference, and antagonism against two antimicrobial agents. Results are best for studying antagonism (1).

Use standard techniques to determine zone diameters for individual antimicrobial agents of interest (*see* procedure 5.1). On another Mueller-Hinton agar plate, place disks separated by a distance equal to the sum of the zone radii for each disk tested separately. After incubation, observe the interface of the zones of inhibition. Theoretically, antagonism shows a truncated zone, indifference shows no change, and synergism shows an enhanced zone. Visualization of results may be difficult, especially if one agent has no zone of inhibition.

Reprinted from reference 1, Fig. 9.10, p. 344, with the permission of the publisher.

APPENDIX 5.12–12

Planning Studies

- A. Most studies test two antimicrobial agent combinations. Theoretically, more than two agents could be tested, but practicality obviates this choice because of the number of combinations that would be tested and the difficulty of determining the contribution of each agent.
- B. Antimicrobial agent concentration ranges to test must be planned on the basis of MICs, percent resistance among organisms tested, achievable concentrations in serum, etc. Numbers of organisms to test and study parameters define the best methods to use.
 1. For example, if the objectives of the study are to study a two-agent combination against 10 genera of gram-negative aerobic bacilli, with each genus composed of 100 species, a 96-well microdilution panel prepared with an automated 96-channel dispenser would be the most efficient. MIC interactions would range over 11 serial twofold concentrations of agent A and 7 serial twofold concentrations of agent B.

APPENDIX 5.12–12 (continued)

2. For example, if 25% of the *P. aeruginosa* strains are resistant to piperacillin and 10% are resistant to amikacin according to previously determined MICs, then the last two or three concentrations to be tested in the combination panel should be in the MIC resistance range, i.e., 128, 256, and 512 µg/ml for piperacillin and 32 and 64 µg/ml for amikacin.
3. For example, if study goals are to test for antagonism by using an agent that has been associated with this phenomenon, a limited microdilution or macrodilution checkerboard series can be prepared. Use a fixed concentration at the susceptibility breakpoint (e.g., ceftazidime at 8 or 16 µg/ml) combined with serial twofold dilutions of the second agent (e.g., piperacillin at 1 through 512 µg/ml). From this scheme, isolates for which the FIC ratio of piperacillin MICs in combination with 8 µg of ceftazidime per ml/piperacillin MICs alone was >4 (drug A portion of Σ FIC) would be scored as antagonistic regardless of the drug B portion (ceftazidime) of Σ FIC.
4. Even if the agent MICs are known, test a broad range of concentrations and not just the MIC and one-fourth, one-half, twice, and four times the MIC, because MICs can vary between methods. MICs can also vary within a method, and the magnitude of synergism or antagonism can be determined (e.g., synergism exhibited was ≤ 0.125 for each organism with piperacillin and amikacin in combination).

5.13

Quality Assurance Measures for Antimicrobial Susceptibility Testing

I. PRINCIPLE

QC is performed to ensure proper performance of antimicrobial susceptibility tests in order to provide accurate, reproducible, and timely results. The basic QC procedure used in clinical laboratories involves testing reference strains that have defined characteristics of susceptibility to the antimicrobial agent(s) tested. These strains must be properly maintained in order to

ensure their reliable performance. Testing the QC strains controls many parameters of the antimicrobial susceptibility test; however, testing the reference strains alone does not always ensure reliable results when testing patients' isolates. Inclusion of supplemental control strains (particularly if recommended in the man-

ufacturer's instructions when using a commercial test system), evaluation of susceptibility profiles on patients' isolates, verifying technologist competency, and review of cumulative susceptibility statistics are some of the additional measures that can be taken to further QC antimicrobial susceptibility tests.

II. REQUIREMENTS OF ACCREDITING AGENCIES FOR QUALITY CONTROL OF ANTIMICROBIAL SUSCEPTIBILITY TESTS

- A. CAP ([312] 966-5700; <http://www.cap.org/html/ftpdirectory/checklistftp.html>)
 1. Requirements stated in *CAP Accreditation Checklist* (1)
 2. Test organisms in pure cultures only.
 3. Check each new lot of disks for activity before use.
 4. Establish guidelines for the number and type of antimicrobial agents reported for bacteria isolated from different infection sites.
 5. For disk or dilution tests, test control organisms with each new lot or batch of antimicrobial agents or media and each day the test is performed.
 6. Control organisms can be tested weekly providing a laboratory can document satisfactory performance with daily control tests (as suggested in NCCLS guidelines).
 7. Establish tolerance (out-of-control) limits for antimicrobial potency.
 8. For disk diffusion or dilution tests, provide written criteria for interpretation of endpoints or zone sizes.
 9. Use a turbidity standard (or equivalent) to standardize the inoculum.
 10. Verify unusual or inconsistent results obtained when testing patients' isolates.
- B. Centers for Medicare and Medicaid Services, which administers Clinical Laboratory Improvement Amendments of 1988 (CLIA '88) ([202] 512-1530; <http://www.cms.gov/clia/>)
 1. Requirements in CLIA regulations (6)
 2. Check each new batch of media and each lot of antimicrobial disks before, or concurrent with, initial use, using approved reference organisms.
 3. Zone sizes or MICs for reference organisms must be within established limits before reporting patient results.
 4. Each day tests are performed, the laboratory must use the appropriate control organism(s) to check the procedure.

II. REQUIREMENTS OF ACCREDITING AGENCIES FOR QUALITY CONTROL OF ANTIMICROBIAL SUSCEPTIBILITY TESTS
(continued)

5. Labs that follow NCCLS standards can go to weekly QC. Labs that do not follow NCCLS standards must do daily QC. (*Note:* Methods utilized with Food and Drug Administration [FDA]-cleared commercial systems are comparable to NCCLS standards.)
- C. JCAHO ([630] 792-5785; <http://www.jcaho.org/accredited+organizations/laboratory+services/index.htm>)
 1. Requirements stated in standard 8.1 (2).
 2. Follows NCCLS guidelines.
- D. Some states have specific requirements for QC of antimicrobial susceptibility testing. Obtain information from state laboratory directors.

III. MICROORGANISMS SUGGESTED FOR QUALITY CONTROL OF ANTIMICROBIAL SUSCEPTIBILITY TESTS

- A. See Appendix 5.13–1 for a listing of QC strains generally used for antimicrobial susceptibility tests as recommended by the NCCLS (3, 4).
- B. Specific notes for the standard aerobic bacterial QC strains
 1. *Pseudomonas aeruginosa* ATCC 27853
 - a. Decreased susceptibility to aminoglycosides as concentrations of Ca^{2+} and Mg^{2+} increase
 - b. May spontaneously mutate and become increasingly resistant to *Pseudomonas*-active penicillins (e.g., carbenicillin) if repeatedly subcultured.
 - c. May produce double zone around imipenem disk which is probably due to Mueller-Hinton medium; this is often corrected by using a new lot of medium.
 2. *Escherichia coli* ATCC 35218
 - a. Include when testing beta-lactam–beta-lactamase inhibitor combination agents (amoxicillin-clavulanic acid, ampicillin-sulbactam, ticarcillin-clavulanic acid, piperacillin-tazobactam).
 - b. This is a beta-lactamase-producing strain (in contrast to *E. coli* ATCC 25922).
 3. *Enterococcus faecalis* ATCC 29212
 - a. Test to make certain medium is sufficiently low in thymidine.
 - (1) Increased amounts of thymidine interfere with the activity of sulfonamides, trimethoprim, and trimethoprim-sulfamethoxazole, which act by interrupting folate synthesis in bacteria (isolates may appear falsely resistant to these agents).
 - (2) Enterococci have a unique ability to utilize exogenous thymine (product resulting from enzymatic action of thymidine phosphorylase on thymidine) and can escape the antibacterial action of these drugs, thus appearing resistant if a significant amount of thymidine or thymine is present in medium.
 - b. Media with blood components (except horse blood, which contains thymidine phosphorylase) contain increased concentrations of thymidine which can result in false resistance for sulfonamides, trimethoprim, and trimethoprim-sulfamethoxazole.
- C. When possible, select and test QC organism(s) that most closely resembles the patient isolates to be tested.
- D. When performing MIC tests, optimally use QC strains with on-scale endpoints for drugs tested (*see* example in Appendix 5.13–2).
- E. When using a commercial antimicrobial susceptibility test system, follow the manufacturer’s instructions for QC.

IV. SOURCES OF QUALITY CONTROL STRAINS

- A. Obtain directly from the ATCC (<http://www.atcc.org/>).
- B. Obtain from commercial company that sells lyophilized vials (or swabs) containing standard QC strains, such as the following.
 - 1. Becton Dickinson Microbiology Systems (BBL QualiSwab) (<http://www.bd.com>)
 - 2. MicroBioLogics (LYFO-DISK and KWIK-STIK) (<http://www.microbiologics.com/>)
 - 3. Remel (Bacti disks) (<http://www.remel.com/>)
- C. Obtain from manufacturer of commercial system used (e.g., Vitek, MicroScan).

V. MAINTENANCE OF QUALITY CONTROL AEROBIC BACTERIAL STRAINS

- A. For maintenance of anaerobic bacteria, see section 4.
- B. Permanent stock cultures—freezing for long-term storage
 - 1. Materials
 - a. Media and reagents
 - (1) Stock bacterial strain obtained from the ATCC or other reliable source. Do not prepare stock cultures from isolates that have been repeatedly subcultured or for which the source is unknown. Store as suggested by the manufacturer.
 - (2) Brucella broth containing 15% glycerol
 - (a) Prepare 100 ml of brucella broth according to manufacturer's directions.
 - (b) Add 15 ml of glycerol to 85 ml of broth and mix well.
 - (c) Dispense into 250-ml flasks and autoclave according to the manufacturer's directions for brucella broth.
 - (d) Store at 2 to 8°C.
 - (3) BAP, CHOC, or other nonselective agar plates
Store at 2 to 8°C.
 - b. Supplies
 - (1) Freezer-safe (–60 to –70°C) 1-dram (1 fluidram = 3.697 ml) glass screw-cap vials
 - (2) Permanent adhesive labels, rectangles (1 by 0.75 in.) and dots (0.5-in. diameter)
 - (3) Cellophane tape
 - (4) Sterile cotton-tipped swabs
 - (5) Sterile polystyrene capped tubes (17 by 100 mm)
 - c. Equipment
 - (1) Vortex mixer
 - (2) –60°C or lower freezer
 - 2. Procedure
 - a. Subculture stock bacterial strain to a BAP (or other nonselective agar plate), and incubate overnight at 35°C. Subculture for isolation to check purity; subculture a second time.
 - b. Prepare rectangular label with identification of stock strain and date of preparation of stock culture.
 - c. Affix rectangular labels to side of vials and cover with cellophane tape.
 - d. Prepare dot labels with abbreviated stock culture identification.
 - e. Affix dot labels to lids of vials.
 - f. Dispense approximately 10 ml of sterile brucella broth with 15% glycerol into 10-ml polystyrene tube.
 - g. Using a cotton-tipped swab, transfer growth from agar plate to brucella broth containing 15% glycerol, and disperse well, making a heavy suspension.

VI. CONTROLLING ANTIMICROBIAL SUSCEPTIBILITY TESTS WITH RECOMMENDED QUALITY CONTROL STRAINS AND LIMITATIONS OF USING THESE STRAINS (*continued*)

3. Incubation conditions (temperature, atmosphere)
 4. Standardization of inoculum and inoculation technique
 5. Batch contamination of media or supplies
 6. Instrument functioning
 7. Measurement of endpoints
- B.** Some of the test variables not readily controlled are as follows.
1. Individual antimicrobial agent-organism test problem (empty, dry, overfilled, or underfilled disk, well, or tube)
 2. Sporadic contamination of broth systems (with MIC tests, purity plate helps avoid problems)
 3. Sporadic instrument malfunction
 4. NaCl content for oxacillin broth tests with staphylococci
 5. Subjective reading of “difficult” endpoints, (e.g., “trailing” or “skipped wells”)
 6. Interpretation of results, use of appropriate interpretive criteria
 7. Transcription errors
 8. Individual technical errors
 9. Patient isolates that are considerably different from the recommended QC strains whereby testing of these is only modestly controlled by performance testing of the NCCLS-suggested QC reference strains. Some of these include the following.
 - a. Organisms with “unusual” growth characteristics (muroid *P. aeruginosa* or dwarf *E. coli*)
 - b. Organisms with unusual resistance characteristics (e.g., organisms with inducible resistance)
- C.** Because satisfactory performance of the QC strains does not guarantee accurate results for patient isolates, it is important to have additional mechanisms in place to verify individual results obtained from testing bacteria isolated from patient specimens.

VII. VERIFICATION OF SUSCEPTIBILITY RESULTS FOR BACTERIA ISOLATED FROM PATIENT SPECIMENS

- A.** The antibiogram is the overall antimicrobial susceptibility profile of a bacterial isolate to a battery of antimicrobial agents. Some bacteria have typical profiles, which can be used to do the following.
1. Verify antimicrobial results
 2. Verify organism identification
- B.** In developing an antibiogram check program to aid technologists in consistently identifying atypical (and potentially erroneous) results, provide the following.
1. Descriptions of typical antibiograms for given species (e.g., a common profile for a *Staphylococcus aureus* isolate is resistance to penicillin and susceptibility to clindamycin, erythromycin, oxacillin, and vancomycin). General antibiograms for commonly encountered bacteria are shown in Appendixes 5.13–4a to 5.13–4d.
 2. Descriptions of the relatedness of drugs tested (e.g., activity hierarchy). For example, the activity hierarchy of the four generations of cephalosporins against the *Enterobacteriaceae* is fourth > third > second > first.
 3. Information on exceptions to “hierarchy” rules such as the following.
 - a. Occasional gram-negative bacilli may possess extended-spectrum beta-lactamases (ESBLs) that selectively inactivate cephalosporins.
 - (1) **Example:** Occasional *E. coli* organisms may appear susceptible in vitro to cefazolin (first-generation cephalosporin) but resistant to ceftazidime (third-generation cephalosporin).

VII. VERIFICATION OF SUSCEPTIBILITY RESULTS FOR BACTERIA ISOLATED FROM PATIENT SPECIMENS (*continued*)

- (2) When this occurs, report all cephalosporin results so clinicians do not extrapolate that the isolate is susceptible to all cephalosporins because the isolate is susceptible to cefazolin. For organisms with ESBLs, follow standard reporting rules and report as resistant to all cephalosporins.
 - b. Occasional gram-negative bacilli (e.g., *Acinetobacter baumannii*) may possess aminoglycoside-inactivating enzymes that inactivate gentamicin, tobramycin, and amikacin, but not netilmicin. When this occurs, report all aminoglycoside results.
 4. Informal updates to advise staff of the prevalence of a particular “atypical” antibiogram at a given time (e.g., increased incidence of nosocomial infections due to gentamicin-resistant *Providencia rettgeri*).
 5. Descriptions of the types of antimicrobial resistance (or susceptibility) that when reported (or missed) are likely to impact on patient care. The following are examples.
 - a. *P. aeruginosa* resistant to amikacin, gentamicin, and tobramycin
 - b. Oxacillin-resistant *S. aureus*
 - c. Ceftriaxone-resistant *S. pneumoniae* (particularly from CSF)
 - C. To verify atypical antibiograms, proceed as follows.
 1. Check for transcription errors.
 2. Reexamine disk diffusion plate, MIC tray, purity plate, etc., to make certain growth was adequate and appears to represent a pure culture, the test was not misread, and results were correctly interpreted.
 - a. Subtle problems may not always be detected upon initial examination of the test.
 - b. Gross examination of test panel (including panels used with automated systems) may reveal blocked or empty well, etc.
 - c. Too-light growth (e.g., 1 to 2+ in broth system or scanty growth on disk diffusion plate) may result in false-susceptible results.
 - d. On blood-supplemented Mueller-Hinton agar plates, measure zone of inhibition of growth, *not* zone of inhibition of hemolysis.
 - e. In broth dilution systems, individually assess each “skipped well or tube” situation and determine whether this can be ignored (versus repeat testing).
 3. Check previous reports on the patient: was atypical antibiogram noted and verified previously?
 4. Repeat susceptibility tests, identification tests, or both. It may be helpful to use an alternative test method to verify unusual results.
 5. Send isolate to a reference lab for confirmation testing using an NCCLS dilution reference method to verify highly atypical results or results that have not been previously reported (e.g., vancomycin-intermediate or -resistant *S. aureus*, cefotaxime-resistant *Haemophilus influenzae*). Consult with the local public health department when highly significant (from a public health perspective) resistance is noted (e.g., vancomycin-intermediate or -resistant *S. aureus*). *Save the isolate.*
 - D. Examples of results that warrant verification before reporting are listed in Appendix 5.13–5.

VIII. COMPETENCY ASSESSMENT IN ANTIMICROBIAL SUSCEPTIBILITY TESTING

Competency assessment is regulated by CLIA '88 as outlined in the Code of Federal Regulations. Competency assessment of employees should be done within the first 6 months of employment of new personnel and at least annually thereafter.

- A. Competency assessment for antimicrobial susceptibility testing should include the following areas.
 - 1. Testing and reporting of appropriate organisms with appropriate antimicrobial agents
 - 2. Utilization of correct procedures for testing patient and QC organisms
 - 3. Verification of antimicrobial susceptibility profiles on patients' organisms
 - 4. Investigations into abnormal results or profiles
 - 5. Appropriate documentation of all testing
 - 6. Appropriate maintenance of instruments utilized for testing
- B. Tools that can be utilized to measure and document competency include, but are not limited to, the following.
 - 1. Direct observation of routine patient testing
 - 2. Monitoring the recording and reporting of test results
 - 3. Review of interim results (worksheets, QC, proficiency testing, and preventive maintenance records)
 - 4. Direct observation of instrument maintenance and function checks
 - 5. Assessment of problem-solving skills
- C. Competency assessment should focus on results that are likely to impact patient care and avoid medical errors.
- D. An example of a competency assessment checklist is shown in Appendix 5.13–6.

IX. CUMULATIVE ANTIMICROBIAL SUSCEPTIBILITY TEST DATA REPORTS

Most laboratories analyze results for all routine antimicrobial susceptibility tests and generate a report that presents these cumulative data in a table. The data presented include the percentage of isolates susceptible to specific antimicrobial agents. For example, the report would indicate the percentage of *S. aureus* organisms that are susceptible to oxacillin.

- A. The NCCLS has recently published a guideline, *Analysis and Presentation of Cumulative Antimicrobial Susceptibility Test Data* (NCCLS M39-A), that suggests how to prepare this report (5). The goal of this is to provide antibiogram data to be used by doctors for empiric therapy guidelines.
- B. Suggested report format in M39-A
 - 1. Prepare report annually.
 - 2. Include species for which there are at least 10 isolates.
 - 3. For analysis, include only the first isolate/patient/analysis period (irrespective of body site or susceptibility profile) to eliminate duplicate results that may skew the data.
 - a. This will not identify a very unusual phenotype if this is not the “first” isolate from the patient; however, such unusual phenotypes should be identified during daily supervisory review activities.
 - b. Laboratories can search entire database without excluding results when it is necessary to review isolates rather than patients.
 - 4. Exclude surveillance isolates such as those obtained during vancomycin-resistant enterococcus (VRE) or methicillin-resistant *S. aureus* (MRSA) surveillance activities.
 - 5. Include drugs routinely tested.

**IX. CUMULATIVE
ANTIMICROBIAL
SUSCEPTIBILITY TEST DATA
REPORTS** *(continued)*

6. Do not examine subset of results that are obtained only in certain circumstances (e.g., if imipenem is tested only on cefepime-resistant *Enterobacteriaceae*, do not compare imipenem to drugs routinely tested; imipenem results will be skewed [more resistant]).
7. Calculate and present data for percentage susceptible, except for the following.
 - a. *S. pneumoniae*: calculate percent susceptible and percent intermediate for penicillin
 - b. *S. pneumoniae*: calculate percent susceptible for meningitis and nonmeningitis for cefotaxime and ceftriaxone
 - c. Viridans group streptococci: calculate percent susceptible and percent intermediate for penicillin
 - d. *S. aureus*: calculate results from all isolates
 - e. *S. aureus*: calculate results from the MRSA subset

APPENDIX 5.13–1

Suggested QC strains for antimicrobial susceptibility tests^a

QC strain	Test(s), for which strain is primarily used
<i>Escherichia coli</i> ATCC 25922 (beta-lactamase negative)	Disk diffusion, MIC (Gram – drugs)
<i>Escherichia coli</i> ATCC 35218 (beta-lactamase positive)	Disk diffusion, MIC for beta-lactam–beta-lactamase inhibitor combination drugs
<i>Klebsiella pneumoniae</i> ATCC 700603 (ESBL producer)	ESBL screen and confirmatory tests
<i>Pseudomonas aeruginosa</i> ATCC 27853	Disk diffusion, MIC for aminoglycosides (and other drugs)
<i>Enterococcus faecalis</i> ATCC 29212	MIC (Gram + drugs); vancomycin agar screen; high-level aminoglycoside resistance screen; checking that medium is acceptable for testing sulfonamides, trimethoprim, and trimethoprim-sulfamethoxazole
<i>Enterococcus faecalis</i> ATCC 51299 (resistant to vancomycin and high levels of aminoglycoside)	Vancomycin agar screen; high-level aminoglycoside resistance screen
<i>Staphylococcus aureus</i> ATCC 25923 (beta-lactamase negative)	Disk diffusion (Gram + drugs)
<i>Staphylococcus aureus</i> ATCC 29213 (beta-lactamase positive)	MIC (Gram + drugs)
<i>Staphylococcus aureus</i> ATCC 43300 (oxacillin resistant)	Oxacillin-salt agar screen
<i>Haemophilus influenzae</i> ATCC 49247 (BLNAR)	Disk diffusion, MIC for <i>Haemophilus</i> spp.
<i>Haemophilus influenzae</i> ATCC 49766 (beta-lactamase positive).	Disk diffusion, MIC for <i>Haemophilus</i> spp. with selected cephalosporins
<i>Haemophilus influenzae</i> ATCC 10211	Checking growth capabilities of medium used for disk diffusion and MIC tests for <i>Haemophilus</i> spp.; beta-lactamase
<i>Neisseria gonorrhoeae</i> ATCC 49226 (CMRNG)	Disk diffusion, MIC for <i>Neisseria gonorrhoeae</i>
<i>Streptococcus pneumoniae</i> ATCC 49619 (penicillin intermediate)	Disk diffusion, MIC for <i>Streptococcus pneumoniae</i> and <i>Streptococcus</i> spp.
<i>Bacteroides fragilis</i> ATCC 25285	MIC for anaerobes
<i>Bacteroides thetaiotaomicron</i> ATCC 29741	MIC for anaerobes
<i>Eubacterium lentum</i> ATCC 43055	MIC for anaerobes

^a BLNAR, beta-lactamase negative, ampicillin resistant; CMRNG, chromosomally mediated (penicillin) resistant *N. gonorrhoeae*.

APPENDIX 5.13–2

Example for Use of QC Strains with “On-Scale” Endpoint

For QC of ciprofloxacin on gram-negative MIC panel

- A. Routinely test *E. coli* ATCC 25922 and *P. aeruginosa* ATCC 27853.
 B. Acceptable QC ranges
 1. *E. coli* ATCC 25922: 0.004 to 0.016 µg/ml
 2. *P. aeruginosa* ATCC 27853: 0.25 to 1 µg/ml
 C. For a panel that includes test concentrations of 0.12 to 4 µg/ml, *P. aeruginosa* ATCC 27853 has an on-scale endpoint, whereas *E. coli* ATCC 25922 does not.

QC strain	Range of concns tested and acceptable result (µg/ml) for QC strain					
	0.12	0.25	0.5	1.0	2.0	4.0
<i>E. coli</i> ATCC 25922	× ^a					
<i>P. aeruginosa</i> ATCC 27853		× ^b	× ^b	× ^b		

^a Off-scale endpoint.^b On-scale endpoint.

APPENDIX 5.13–3

Primary variables that must be controlled when performing routine disk diffusion and broth microdilution MIC tests^a

Variable	Standard	Comments
Inoculum	Disk diffusion: 1.5×10^8 CFU/ml Broth microdilution: final concn, 5×10^5 CFU/ml (range, 3×10^5 – 7×10^5)	Use “adequate” McFarland turbidity standard (0.5 for disk diffusion) or adequate standardizing device; when preparing direct suspensions (without incubation), do not use growth from plates >1 day old.
Media		
Formulation	Mueller-Hinton	Prepare in-house or purchase from reliable source; perform QC to verify acceptability prior to (or concurrent with) testing patient isolates.
Ca ²⁺ and Mg ²⁺ content	25 mg of Ca ²⁺ and 12.5 mg of Mg ²⁺ /liter	Increased concentrations result in decreased activity of aminoglycosides against <i>P. aeruginosa</i> and decreased activity of tetracyclines against all organisms (decreased concentrations have the opposite effect).
Thymidine content	Minimal or absent	Excessive concentrations can result in false resistance to sulfonamides and trimethoprim.
pH	7.2–7.4	Decreased pH can lead to decreased appearance of potency in aminoglycosides, erythromycin, clindamycin, and quinolones and increased activity of tetracyclines and penicillins (increased pH has the opposite effect).
Agar depth (disk diffusion)	Approximately 4 mm	Possibility for false susceptibility if <3 mm and false resistance if >5 mm
Antimicrobial agents		
Disks	Use disks containing appropriate FDA- or NCCLS-defined concentration of drug Proper storage Proper placement on agar	Check NCCLS publication or FDA package insert (accompanying disks) for specifications Long-term storage in non-frost-free freezer at ≤ –20°C in tightly sealed, desiccated container; short-term storage (≤1 week) at 2–8°C in tightly sealed desiccated container; allow to warm to room temp before opening container ≤12 disks/150-mm plate; ≤5 disks/100-mm plate (no overlap zones)
Solutions	Prepare from reference standard powders Proper storage	Pharmacy-grade antimicrobial agents are unacceptable: they may not show antimicrobial activity in vitro. Store in non-frost-free freezer optimally at ≤ –60°C; never refreeze.

(continued)

APPENDIX 5.13–3 (continued)

Primary variables that must be controlled when performing routine disk diffusion and broth microdilution MIC tests^a (continued)

Variable	Standard	Comments
Incubation		
Atmosphere	Humidified ambient air (unless CO ₂ specified)	CO ₂ incubation decreases pH, which can lead to decreased activity of aminoglycosides, erythromycin, and clindamycin and increased activity of tetracyclines and penicillins.
Temp	35°C	Some MRSA organisms may go undetected if >35°C.
Length	Disk diffusion: 16–18 h. Broth microdilution: 16–20 h (24 h for staphylococci with vancomycin and with oxacillin ^b and for enterococci with vancomycin and high-level gentamicin dilution tests; 48 h for enterococci and high-level streptomycin dilution tests; 20–24 h sometimes needed for fastidious bacteria).	Some MRSA and VISA organisms and VRE and gentamicin HLR enterococci may go undetected if <24 h; some streptomycin HLR enterococci may go undetected if <48 h (dilution tests).
Endpoint measurement		
Disk diffusion	Use reflected light (except for staphylococci and oxacillin ^b and vancomycin and enterococci and vancomycin) and hold plate against or a few inches above a black background; measure zones from back of plate; for opaque plates (e.g., blood-supplemented MHA, remove lid and read from top of plate).	Lawn must be confluent or almost confluent; ignore faint growth of tiny colonies at zone edge. Trimethoprim and sulfonamides: endpoint at ≥80% inhibition; ignore swarm within obvious zone for swarming <i>Proteus</i> spp.; retest when colonies seen within zone (except staphylococci and oxacillin ^b and enterococci and vancomycin). For hemolytic organisms on blood-supplemented MHA, measure zone of inhibition of growth and not zone of inhibition of hemolysis.
	Use transmitted light for staphylococci and oxacillin ^b and vancomycin and enterococci and vancomycin	Call resistant if <i>any</i> growth within zone (unless possibly artifactual or contaminated).
Broth microdilution	Use adequate lighting/reading device.	Reproducibility within ±2 mm MIC = lowest concentration that inhibits growth (turbidity, haze or pellet); sulfonamides and trimethoprim may trail (ignore trailing <2-mm buttons). Justify “skip wells” or repeat. Staphylococci and penicillin: perform induced beta-lactamase test if MIC is 0.06–0.12 µg/ml. Reproducibility within ±1 two-fold dilution

^a See J. A. Hindler and L. M. Mann. 1992. Principles and practices for the laboratory guidance of antimicrobial therapy, p. 548. In R. Tilton (ed.), *Clinical Laboratory Medicine*. The C. V. Mosby Co., St. Louis, Mo. Reprinted with permission of Elsevier. Abbreviations: HLR, high-level resistance; VISA, vancomycin-intermediate *S. aureus*; MHA, Mueller-Hinton agar.

^b Includes all penicillinase-stable penicillins (oxacillin, methicillin, nafcillin).

APPENDIX 5.13–4c

Gram-positive bacterium antibiograms^a

^a These antibiograms should serve as guidelines only; exceptions will occur. Abbreviations: CEFS, narrow-, extended-, and broad-spectrum cepheps (including cephalosporins); β-LAC, beta-lactamase; AMOX-CLAV, amoxicillin-clavulanic acid. For other abbreviations, see Table 5.13–4a, footnote *a*. Symbols: +, positive; –, negative.

^b Standard NCCLS interpretive criteria not available; data based on various publications.

^c Also resistant to oxacillin and clindamycin and susceptible to aminoglycosides.

^d Also resistant to clindamycin.

^e Also resistant to oxacillin and aminoglycosides.

APPENDIX 5.13–5

Suggested Conditions Requiring Verification of Identification and/or Antimicrobial Susceptibility Results

- A. Verify by repeat testing—unless patient had some isolate from another recent culture (1).
 1. *S. aureus*
 - a. Linezolid nonsusceptible (NS)
 - b. Oxacillin resistant (R)
 - c. Quinupristin-dalfopristin intermediate (I) or R
 - d. Vancomycin I or R
 2. Coagulase-negative staphylococci
 - a. Linezolid NS
 - b. Vancomycin I or R
 3. Any *Enterococcus* spp.: linezolid R
 4. *E. faecalis*
 - a. Ampicillin or penicillin R
 - b. Quinupristin-dalfopristin susceptible (S)
 5. *Enterococcus faecium*: quinupristin-dalfopristin R
 6. *S. pneumoniae*
 - a. Fluoroquinolone I or R
 - b. Linezolid NS
 - c. Vancomycin NS
 7. Viridans group *Streptococcus* spp.
 - a. Linezolid NS
 - b. Vancomycin NS

APPENDIX 5.13–5 (continued)

8. *Streptococcus*, beta-hemolytic
 - a. Ampicillin or penicillin NS
 - b. Third-generation cephalosporin NS
 - c. Linezolid NS
 - d. Vancomycin NS
 9. Other gram-positive organisms: vancomycin I or R (except *Lactobacillus* spp., *Leuconostoc* spp., *Pediococcus* spp., or *Erysipelothrix rhusiopathiae*)
 10. Any *Enterobacteriaceae*: carbapenem I or R (except *Proteus* spp.)
 11. Other *Enterobacteriaceae*
 - a. ESBL-producing *Klebsiella* spp. or *E. coli*
 - b. Ampicillin-, cefazolin-, or cephalothin-S *Enterobacter* spp., *Citrobacter freundii*, or *Serratia marcescens*
 - c. Ampicillin-S *Klebsiella* spp., *Proteus vulgaris*, or *Providencia* spp.
 - d. Third-generation cephalosporin-I or -R *Salmonella* spp.
 - e. Fluoroquinolone-I or -R *Salmonella* spp.
 12. *Stenotrophomonas maltophilia*
 - a. Trimethoprim-sulfamethoxazole R
 - b. Carbapenem S
 13. *H. influenzae*
 - a. Third-generation cephalosporin NS
 - b. Ampicillin I or R (beta-lactamase negative) or amoxicillin-clavulanic acid I or R
 - c. Aztreonam NS
 - d. Carbapenem NS
 - e. Fluoroquinolone NS
 14. *N. gonorrhoeae*
 - a. Third-generation cephalosporin R
 - b. Fluoroquinolone I or R
 15. Other
 - a. Isolate resistant to all drugs routinely reported.
 - b. Isolate for which results for related drugs do not correlate (e.g., resistance to third-generation cephalosporin and susceptible to first-generation cephalosporin in *Enterobacteriaceae*)
- B. Verify by reexamination of test and, if necessary, repeat testing—unless patient had same isolate from another recent culture (1).
1. *Enterococcus* spp
 - a. Gentamicin high-level aminoglycoside R; sterile body site isolates
 - b. Vancomycin R
 2. *S. pneumoniae*: penicillin I or R
 3. Viridans group *Streptococcus* spp.: penicillin I or R
 4. *Enterobacteriaceae*
 - a. Amikacin R
 - b. Fluoroquinolone R
 5. Non-*Enterobacteriaceae*: gentamicin, tobramycin, and amikacin R (except *Burkholderia cepacia*, *S. maltophilia*)

APPENDIX 5.13-6

Competency Assessment Checklist—Antimicrobial Susceptibility Testing

Competency Period: Initial (6 mos) _____ Annual _____ (please check one)

EMPLOYEE: _____ DEPT #: _____

TITLE: Medical Technologist

VALIDATOR: _____ DEPT #: _____

TITLE: Supervisor

NOTE: This is a sampling of the competencies necessary for safe, effective performance.

KEYS	HOW COMPETENCY MEASURED A. Direct observation of routine patient testing B. Monitoring the recording & reporting of test results C. Review of interim results (worksheets, QC, PT & PM records) D. Direct observation of instrument maintenance & function checks E. Assessment of problem solving skills	_____ Employee Signature/Date POSSESSES AND DEMONSTRATES THE ABILITIES NECESSARY FOR THE QUALITY PERFORMANCE OF THIS JOB	LEVEL OF COMPETENCE 1. Little or no experience 2. Some experience (may require practice and/or assistance) 3. Competent and can perform independently 4. Competent and can perform independently, and is able to assess the competency of others.
-------------	---	---	--

DATE	HOW MEASURED	VALIDATOR INITIALS/COMMENTS	COMPETENCIES	LEVEL OF COMPETENCE
	A and/or B		Appropriately determines which organisms require testing	
	A		Utilizes appropriate inoculum preparation method for organism and AST procedure	
	A		Prepares inoculum correctly	
	A and/or B		Tests antimicrobial agents or panel appropriate for the organism	
	A		Inoculates test correctly	
	A		Incubates tests correctly	
	A		Confirms purity of test prior to reading and recording results	
	A and B		Reads, records, and interprets results correctly	
	B		Verifies antimicrobial susceptibility profile and organism identification prior to reporting	
	A and/or B		Takes appropriate action to confirm any unusual or atypical results	
	B		Reports appropriate antimicrobial agent(s) and comment(s) for the organism and specimen	
	A and B		Utilizes computer appropriately for reporting process	

A and/or B	Notifies supervisor, infection control, physician, etc., as appropriate for confirmed atypical and/or noteworthy results
A and/or B	Reviews AST reports from previous day's work
A and/or B	Consults with physicians on special AST requests
A and/or B	Handles STAT AST requests and testing
A and/or E	Handles AST problems with microbiology staff members
A	Trains new microbiology staff, medical staff and students in AST
A	Maintains and subcultures QC strains appropriately
A and/or C	Runs appropriate daily or weekly QC with AST
B and/or C	Reads and documents QC results appropriately
E	Identifies and troubleshoots out-of-control results
C and E	Takes and documents appropriate corrective action for out-of-control results
E	Performs problem solving in AST
C	Maintains appropriate inventory of supplies needed for AST
A and/or B	Handles all testing materials appropriately
D	Performs/documents AST instrument maintenance
A and/or B	Locates the current NCCLS standards

NA = not applicable

5.14.1

McFarland Standards

I. PRINCIPLE

McFarland turbidity standards are used to standardize the approximate number of bacteria in a liquid suspension by visually comparing the turbidity of a test suspension with the turbidity of a McFarland standard. McFarland standards are prepared by adding barium chloride to sulfuric acid to obtain a barium sulfate pre-

cipitate. By adjusting the volumes of these two reagents, standards of varying degrees of turbidity can be prepared to represent several different concentrations of bacteria. The standard most commonly used in the clinical microbiology laboratory for routine antimicrobial susceptibility tests (1, 2) is 0.5, which represents 1.5×10^8

(generally, range is 1.0×10^8 to 2.0×10^8) bacteria/ml. McFarland standards are commercially available from several sources. As an alternative to the traditional barium sulfate standards, McFarland standards prepared from latex particles have recently become commercially available.

II. MATERIALS

Include QC information on reagent container and in QC records.

A. Reagents

1. Sulfuric acid, 1% (vol/vol) (H_2SO_4)
 - a. Add approximately 90 ml of deionized water to a 100-ml volumetric flask.
 - b. Using a 1.0-ml volumetric pipette, add 1.0 ml of concentrated H_2SO_4 to the flask.
 - c. Bring to 100 ml with deionized water, and mix.
 - d. Store in a screw-cap glass bottle for up to 1 year at 25°C.
2. Barium chloride, 1.175% (wt/vol) ($\text{BaCl}_2 \cdot 2\text{H}_2\text{O}$)
 - a. Weigh out 1.175 g of $\text{BaCl}_2 \cdot 2\text{H}_2\text{O}$ and place in a 100-ml volumetric flask.
 - b. Add approximately 50 ml of deionized water, and mix well to dissolve.
 - c. Bring to 100 ml with deionized water, and mix.
 - d. Store in a screw-cap glass bottle for up to 1 year at 25°C.

3. Sterile deionized reagent-grade water

Store in a screw-cap glass bottle for up to 1 year at 25°C.

B. Supplies

1. Sterile 1.0-liter and 10.0-ml serological pipettes and pipette bulb
2. Acid-washed glass screw-cap tubes of a diameter comparable to that used for inoculum preparation (e.g., 13 by 100 mm)
3. Parafilm or paraffin

C. Equipment

1. 100-ml volumetric flasks
2. 0.5- and 1.0-ml volumetric pipettes for 0.5 standards
See Appendix 5.14.1–1 for sizes of volumetric pipettes needed for preparation of other standards. $\text{BaCl}_2 \cdot 2\text{H}_2\text{O}$ should be dispensed with a volumetric pipette.
3. Magnetic stirrer and stirring rod
4. Vortex
5. Spectrophotometer

III. QUALITY CONTROL**A. At time of preparation of standards**

Check optical density of McFarland standard at wavelength of 625 nm and record results. The acceptable range for a McFarland 0.5 standard is 0.08 to 0.10. For standards other than 0.5, establish acceptable ranges in-house.

III. QUALITY CONTROL (continued)

B. Additional checks

1. Check in-use standards with each use for visible evidence of clumping, and periodically compare in-use standard with a standard that has not been in use. If clumping is apparent, discard the standard.
2. Check standards for any evidence of evaporation. This can be accomplished by drawing a line on the tube at the meniscus when the tubes are filled. A drop in liquid level below this line indicates that evaporation has occurred. If evaporation is evident, discard the standard.
3. Check the optical density of a representative standard (that has not been in use) at 3 months to make certain that the optical density of the lot is still within control limits. If in control, the shelf life of the lot can be extended for another month.
4. Repeat optical density check monthly. If in control, shelf life can be extended for another month for up to 12 months.

IV. PROCEDURE

A. Refer to Appendix 5.14.1–1 for volumes of 1% H₂SO₄ and 1.175% BaCl₂ · 2H₂O needed to prepare different grades of McFarland standards (representing various concentrations of bacteria), and substitute these volumes into the procedure below when preparing standards other than 0.5.

B. To prepare McFarland 0.5 standards

1. Add approximately 85 ml of 1% H₂SO₄ to a 100-ml volumetric flask.
2. Using a 0.5-ml volumetric pipette, add 0.5 ml of 1.175% BaCl₂ · 2H₂O dropwise to the H₂SO₄ while constantly swirling the flask.
3. Bring to 100 ml with 1% H₂SO₄.
4. Place magnetic stirring bar in flask and place on magnetic stirrer for approximately 3 to 5 min.
5. Examine solution visually to make certain it appears homogeneous and free of visible clumps; check optical density and record on QC sheet.
6. Providing QC is acceptable, dispense 2- to 7-ml volume (depending on volume routinely used in inoculum suspension preparation) into each tube.
7. Cap tubes tightly.
8. Seal with Parafilm or paraffin.
9. Store in the dark at room temperature for 3 months or longer (*see* item III above).

V. USE OF MCFARLAND STANDARDS

A. Mix McFarland standard and test suspension well on a vortex mixer prior to examination.

B. In the presence of good lighting, visually compare turbidity of test suspension to the McFarland standard.

1. Hold both tubes in front of a Wickerham card (Appendix 5.14.1–2).
2. If it is more difficult to see lines on Wickerham card through test suspension than through the McFarland standard, the suspension is too dense and must be diluted.
3. If dilution is necessary, use a sterile pipette to add additional sterile broth or saline to the tube to obtain turbidity comparable to that of the McFarland standard.
4. Before subsequent examinations, vortex test suspension and McFarland standard well.
5. If test suspension is too light, inoculate with additional organisms or reincubate suspension (depending on inoculum preparation protocol) until turbidity reaches that of the standard.

VI. PROCEDURE NOTES

- A. Test suspension and McFarland standard should be contained in tubes of the same diameter.
- B. McFarland standards are more likely to clump and evaporate if exposed to air. Thus, it is imperative that caps be tightly sealed with Parafilm or paraffin.
- C. Standards in use clump and evaporate more rapidly than those in storage, and in-use standards must be examined regularly. Discard standards with evidence of clumping or evaporation regardless of stated shelf life.
- D. When glass tubes are used, acid washing helps minimize clumping.
- E. A practical storage container for the McFarland standards is a test tube mailing container. Alternatively, wrap tube in aluminum foil.
- F. An alternative to using a spectrophotometer to QC McFarland standards is performing colony counts on bacterial suspensions (e.g., *Escherichia coli* ATCC 25922) that have been standardized against a particular lot of standards.
 - 1. Prepare six successive 10-fold dilutions of test suspension in 0.85% NaCl (the first dilution tube is labeled 10^{-2} ; plating 0.1 ml from the suspension standardized to the McFarland 0.5 would yield the 10^{-1} dilution). (TNTC, too numerous to count.)

Dilution	Expected no. of colonies (with 0.1-ml aliquots)
10^{-1}	TNTC
10^{-2}	TNTC
10^{-3}	TNTC
10^{-4}	TNTC
10^{-5}	TNTC
10^{-6}	150
10^{-7}	15

- 2. Plate 0.1-ml aliquots of dilutions expected to yield approximately 30 to 300 colonies (in this example, plate 10^{-6} and 10^{-7}) to BAP (in duplicate) and spread evenly to distribute using a loop or sterile “hockey stick.”
- 3. Colony counts should fall within 10% of expected numbers.
- G. Actual numbers of viable bacteria present in McFarland standardized-suspensions may vary depending on size, viability, and clumping of the particular bacteria tested.
- H. When using commercially available McFarland standards prepared from latex particles, follow manufacturer’s directions for use and storage.
- I. Other devices are satisfactory for standardizing bacterial suspensions. These include the following:
 - 1. Wand-type inoculum devices that pick up a standardized volume of cell paste (from colonies grown overnight on an agar plate) that is subsequently suspended in a standardized volume of liquid (BBL Prompt inoculation system, [Becton Dickinson Microbiology Systems, Sparks, Md., or Dade MicroScan, West Sacramento, Calif.].)
 - 2. Photometers or colorimeters such as the following
 - a. Vitek colorimeter (bioMérieux Vitek, Inc., Durham, N.C.)
 - b. MicroScan turbidity meter (Dade MicroScan)

VII. LIMITATIONS

Suspensions standardized to McFarland standards will contain the estimated number of bacteria only if high-quality McFarland standards are used. Standards that have clumped or evaporated will yield unsatisfactory results.

5.14.2

Antimicrobial Stock Solutions

I. PRINCIPLE

Aliquots of antimicrobial stock solutions are incorporated into broth or agar medium for antimicrobial susceptibility tests. Stock solutions are prepared from laboratory reference standard-grade antimicrobial powders. These are assayed for the amount of active agent present, and this is expressed as activity or potency. Potency

or activity is usually defined in terms of micrograms of active drug per milligram (e.g., 912 $\mu\text{g}/\text{mg}$) or percentage of active drug (e.g., 91.2%). The activities of some drugs are expressed as international units per milligram of powder. *Pharmacy-grade preparations should not be used, as these often contain stabilizers or blocking*

agents which render them inactive until metabolized in vivo. An analytical balance is used to weigh out an appropriate amount of antimicrobial powder, which is dissolved in a solvent specific for that powder and subsequently diluted with water or buffer. Antimicrobial stock solutions are optimally stored at -70°C or lower.

II. MATERIALS

Include QC information on reagent container and in QC records.

A. Reagents

1. Antimicrobial reference standard powders
 - a. Obtain from the U.S. Pharmacopeia, chemical supplier, or pharmaceutical company that manufactures that drug.
 - b. Store according to manufacturer's specifications. Opened vials or any nonvacuum vials must be stored in a desiccator (preferably in a vacuum).
 - c. Potency (activity), lot number, and expiration date must be specified. If they are not, contact the supplier.
2. Solvents and diluents (*see* Appendix 5.14.2-1)
 - a. Sterile deionized water
 - b. Saturated sodium bicarbonate powder
 - c. Sodium carbonate powder
 - d. 95% Ethanol
 - e. 100% Methanol
 - f. Sodium hydroxide (various normalities)
 - g. Hydrochloric acid (various normalities)
 - h. Phosphate buffers
 - i. Dimethyl sulfoxide

B. Supplies

1. Sterile polypropylene, polystyrene, or polyethylene capped tubes (12 by 75 mm and 16 by 100 mm) appropriate for freezing
 2. Sterile 1-, 2-, 5-, and 10.0-ml serological pipettes and pipette bulb
 3. Weigh boats or weighing papers
 4. Spatulas
 5. Sterile volumetric flasks (50, 100, 250 ml)
 6. Sterile Erlenmeyer flasks (50, 100, 250 ml)
 7. Adhesive labels, 1 by 0.75 in. (that withstand -70°C storage)
- ☑ **NOTE:** All glassware should be acid washed.

C. Equipment

1. Calibrated analytical balance sensitive to 0.0001 g
2. Refrigerator (2 to 8°C) (if part of refrigerator-freezer combination, must not be self-defrosting)
3. Forceps
4. -20°C non-frost-free freezer
5. -70°C (or lower) freezer
6. Vortex
7. Desiccator and desiccant

III. QUALITY CONTROL

- A. Record stock solution preparation information in QC log. Include preparation date, technologist's initials, concentration of solution, and expiration date of solution. For the powder, record manufacturer, lot number, potency, and expiration date. See Appendix 5.14.2–2.
- B. Perform QC of stock solutions by testing the particular stock solution in the test system with reference bacterial strains with known susceptibility profiles.
- C. Other methods for QC of stock solution, such as antimicrobial assay by high-pressure liquid chromatography, may be indicated in some situations (e.g., when stock solution is used in preparing controls for assay of antimicrobial agent in patient serum).

IV. PROCEDURE

- A. Remove desiccator from refrigerator or freezer, and allow it to warm to room temperature before opening to avoid condensation of water.
- B. Plan stock solution preparation (*see* Appendix 5.14.2–3).
 1. Determine concentration (in micrograms per milliliter) of stock solution needed.
 2. Determine volume of stock solution needed.
 3. Calculate amount of powder and diluent (including solvent) needed. Prepare stock solution at 1,000 µg/ml or more.
 4. Obtain information from the manufacturer, and check NCCLS tables (1) for appropriate solvent and diluent.
- C. Weighing the powder
 1. Using a forceps, place a piece of weigh paper or a weigh boat on analytical balance pan and tare.
 2. Using a spatula for transferring powder, weigh out powder.
 3. Transfer powder to flask, and rinse weigh paper or weigh boat with a small amount of solvent.
 - a. If a set amount of powder is weighed and the final volume of solution is predetermined, use a volumetric flask, if one is available.
 - b. If a variable amount of powder is weighed and the amount of solvent and diluent will be adjusted to that weight, use an Erlenmeyer flask.
- D. Dissolve and dilute the powder.
 1. Add just enough solvent to dissolve powder (will generally require a few drops to a few milliliters).
 2. Use solvent to remove every speck of powder from weigh paper or weigh boat.
 3. Add diluent to obtain desired final volume.
 4. Mix well.
- E. Dispense and store stock solutions.
 1. Prepare label to specify antimicrobial agent's name, concentration, preparation date, expiration date, and technologist's initials. Affix label to tube.
 2. Dispense stock solution in tubes at volumes appropriate for subsequent use.
 3. Cap tubes tightly, and store at -70°C or lower.
 4. Most antimicrobial stock solutions are stable for 6 months at -70°C or lower. *Exceptions include imipenem, clavulanic acid, cefaclor, and rifampin, which are very labile and should not be stored longer than 1 month (at -70°C or lower).* Contact the manufacturer of the antimicrobial agent for additional preparation and stability information.
- F. Use stock solutions.
 1. Allow stock solution to thaw at room temperature. Thawing can be expedited by placing tube of frozen stock solution in a beaker of tap water (not hot). Do not allow water to reach the cap of the tube.
 2. Never refreeze a stock solution after it has been thawed.

V. PROCEDURE NOTES**A. Antimicrobial powders (1, 2)**

1. The activity or potency of an antimicrobial powder may vary from lot to lot.
2. Some powders may have >100% potency. For example, vancomycin powder is now produced in a purer form than the reference standard powder initially characterized many years ago. Consequently, on a weight basis, current preparations are often more active (>100% potency) than the original reference standard powder.
3. Some powders will have a retest date in lieu of an expiration date. The retest date indicates when the manufacturer will reassay the powder to see if it has maintained potency. If the powder has maintained potency, the manufacturer will extend the expiration date (sometimes a manufacturer gives a powder a second retest date).
4. Moisture considerations
 - a. Moisture becomes a greater problem and poses a greater risk of water condensation on the powders at lower storage temperatures. Do not store powders at temperatures lower than that specified by the manufacturer.
 - b. It is not necessary to dry standard reference-grade powders unless specifically recommended by the manufacturer.
 - c. If possible, remove moist air within desiccators that have been in a refrigerator or freezer by evacuation.
 - d. Aminoglycoside powders are very stable at room temperature but are very hygroscopic. Consequently, some recommend that they be stored at room temperature in a desiccator.

B. Procedure

1. Whenever possible, weigh >100 mg of powder.
2. It is best to weigh out slightly more powder than is required. Then calculate the volume of diluent needed. This avoids multiple adjustments of the powder and minimizes exposure to moisture.
3. It is best to weigh out a precalculated amount of powder if an organic solvent is used.
4. Rifampin may deteriorate following exposure to sunlight and should be stored in the dark.
5. It is best to prepare stock solutions that are 10 times or more the highest concentration tested and at concentrations of 1,000 µg/ml or greater.
6. Make volume measurements point to point on a pipette. When appropriate, use a volumetric flask.
7. To avoid stock solution storage tubes from cracking at -70°C , place filled tubes at -20°C for 4 to 5 h before transferring them to -70°C . Polystyrene tubes are more likely to crack than polypropylene tubes.
8. It is usually unnecessary to filter stock solutions prepared at high concentrations, since the antimicrobial should sterilize the solution. As a precaution, however, use sterile materials (e.g., glassware, solvents and diluents, etc.) in preparing stock solutions, whenever possible. *If filter sterilization is necessary, use membrane filters only. Other types of filters (e.g., asbestos, glass, paper) may absorb antimicrobial agent and must not be used.* Assay all filtered solutions prior to use.

C. Antimicrobial stock solutions

1. Imipenem stock solutions are very unstable and must be stored at -70°C or lower. Other more labile antimicrobial solutions include clavulanic acid, ceftazidime, and rifampin. The beta-lactam agents in general tend to be more temperature labile.
2. Some stock solutions such as ampicillin, trimethoprim, and others prepared in phosphate buffers may precipitate during storage. To get drug back in solution, vortex well.

VI. LIMITATIONS

- A. Stock solutions at high concentrations (e.g., 12,800 µg/ml) can be satisfactorily prepared for most antimicrobial agents, although there are some drugs (e.g., chloramphenicol) that will not go into solution at high concentrations.
- B. Stock solutions will maintain the specified potency when prepared and stored according to the manufacturer's directions.

APPENDIX 5.14.2–1

Preparation of Solvents and Diluents

- A. Obtain dimethyl sulfoxide, anhydrous sodium carbonate, and methanol from chemical suppliers.
- B. 1 N HCl
 - 1. Add 8.33 ml of concentrated HCl to a 100-ml volumetric flask containing approximately 90 ml of deionized water and bring to 100 ml with deionized water.
 - 2. Mix well.
 - 3. Dispense into a screw-cap bottle.
 - 4. Store at 25°C for up to 1 year.
- 5. 0.04 N HCl
 - a. Add 4.0 ml of 1 N HCl to a 100-ml volumetric flask containing approximately 90 ml of deionized water and bring to 100 ml with deionized water.
 - b. Mix well.
 - c. Dispense into a screw-cap bottle.
 - d. Store at 25°C for up to 1 year.
- 6. 0.05 N HCl
 - a. Add 5.0 ml of 1 N HCl to a 100-ml volumetric flask containing approximately 90 ml of deionized water and bring to 100 ml with deionized water.
 - b. Mix well.
 - c. Dispense into a screw-cap bottle.
 - d. Store at 25°C for up to 1 year.
- C. 1 N NaOH
 - 1. Add 4 g of NaOH pellets to a 100-ml volumetric flask containing approximately 50 ml of deionized water, mix to dissolve, and bring to 100 ml with deionized water.
 - 2. Mix well.
 - 3. Dispense into a screw-cap bottle.
 - 4. Store at 25°C for up to 1 year.
- D. 0.1 N NaOH
 - 1. Add 10.0 ml of 1 N NaOH to a 100-ml volumetric flask containing approximately 90 ml of deionized water and bring to 100 ml with deionized water.
 - 2. Mix well.
 - 3. Dispense into a screw-cap bottle.
 - 4. Store at 25°C for up to 1 year.
- E. 2.5 N NaOH
 - 1. Add 10 g of NaOH pellets to a 100-ml volumetric flask containing approximately 50 ml of deionized water, mix to dissolve, and bring to 100 ml with deionized water.
 - 2. Mix well.
 - 3. Dispense into a screw-cap bottle.
 - 4. Store at 25°C for up to 1 year.
- F. 95% Ethanol
 - 1. Add 95 ml of absolute ethanol to a 100-ml volumetric flask and bring to 100 ml with deionized water.
 - 2. Mix well.
 - 3. Dispense into a screw-cap bottle.
 - 4. Store at 25°C for up to 1 year.

APPENDIX 5.14.2-1 (continued)

- G. Saturated sodium bicarbonate (Na_2HCO_3)
1. Add 100 ml of water to a small beaker, place magnetic stirring bar in beaker, and place beaker on stirring unit.
 2. Gradually add sodium bicarbonate powder to water while stirring constantly.
 3. Continue adding powder until it no longer goes into solution.
 4. Dispense into a screw-cap bottle.
 5. Autoclave for 15 min at 121°C (alternatively, filter through a 0.22- μm -pore-size membrane filter).
 6. Store at 25°C for up to 1 year.
- H. 0.1 M sodium bicarbonate (Na_2HCO_3)
1. Add 2.1 g of Na_2HCO_3 to a beaker.
 2. Add 250 ml of water, place magnetic stirring bar in beaker, and place beaker on stirring unit.
 3. Mix until dissolved.
 4. Dispense into a screw-cap bottle.
 5. Autoclave for 15 min at 121°C (alternatively, filter through a 0.22- μm -pore-size membrane filter).
 6. Store at 25°C for up to 1 year.
- I. Phosphate buffers
1. Prepare stock buffers (1).
 - a. Stock buffer A: KH_2PO_4 (0.2 M)
 - (1) Add 27.22 g of KH_2PO_4 (0.2 mol) (monobasic potassium phosphate, anhydrous) to a 1,000-ml volumetric flask.
 - (2) Add approximately 200 ml of deionized water.
 - (3) Shake to dissolve.
 - (4) Bring to 1,000 ml with deionized water.
 - (5) Dispense into 500-ml screw-cap bottles.
 - (6) Autoclave for 15 min at 121°C (alternatively, filter through a 0.22- μm -pore-size membrane filter).
 - b. Stock buffer B: K_2HPO_4 (0.2 M)
 - (1) Add 45.64 g of $\text{K}_2\text{HPO}_4 \cdot 3\text{H}_2\text{O}$ (0.2 mol) (dibasic potassium phosphate) to a 1,000-ml volumetric flask.
 - (2) Add approximately 200 ml of deionized water.
 - (3) Shake to dissolve.
 - (4) Bring to 1,000 ml with deionized water.
 - (5) Dispense into 500-ml screw-cap bottles.
 - (6) Autoclave for 15 min at 121°C (alternatively, filter through a 0.22- μm -pore-size membrane filter).
 - c. Store sterile stock buffers at 2 to 8°C for up to 1 year.
 2. Prepare 0.1 M phosphate working buffers by adding the following volumes of stock buffers A and B to 100-ml volumetric flasks to prepare working buffer at respective pHs.

pH	Stock buffer A (ml)	Stock buffer B (ml)
6.0	43.85	6.15
7.0	19.5	30.5
8.0	2.65	47.35

3. Bring to 100 ml with deionized water.
4. Check pH with a pH meter. It should be close to desired value. If necessary, adjust with 1 N NaOH or 0.1 M phosphoric acid (if more than a few drops of base or acid are necessary to adjust pH, remake buffer).
5. To prepare 0.01 M phosphate buffer (pH 7.0), make a 1:10 dilution of the 0.1 M buffer.
6. Dispense approximately 150 ml into screw-cap bottles.
7. Autoclave for 15 min at 121°C (alternatively, filter through a 0.22- μm -pore-size membrane filter).
8. Store sterile working buffers at 25°C for up to 1 year.

APPENDIX 5.14.2–2

Worksheet for antimicrobial stock solution QC (see p. 5.14.2.7)

APPENDIX 5.14.2–3

Formulas for Preparation of Antimicrobial Stock Solutions

A.

$$\text{weight (mg)} = \frac{\text{volume (ml)} \times \text{concentration } (\mu\text{g/ml})}{\text{assay potency } (\mu\text{g/mg})}$$

B.

$$\text{volume (ml)} = \frac{\text{weight (mg)} \times \text{assay potency } (\mu\text{g/mg})}{\text{concentration } (\mu\text{g/ml})}$$

C. Definitions

1. Assay potency (micrograms per milligram) is the activity or potency specified by manufacturer of reference standard powder (usually appears on the label).
2. Concentration (micrograms per milliliter) is the desired concentration of stock solution.
3. Volume (milliliters) is the desired volume of stock solution.
4. Weight (milligrams) is the weight of powder needed to prepare the desired volume of stock solution at the desired concentration.

D. Example using formula A

1. Apply when weighing an exact amount of powder.

Antimicrobial:	cephalothin
Desired concentration:	1,280 $\mu\text{g/ml}$
Desired volume:	100 ml
Assay potency:	931 $\mu\text{g/mg}$

$$x \text{ mg} = \frac{100 \text{ ml} \times 1,280 \mu\text{g/ml}}{931 \mu\text{g/mg}} = 137.5 \text{ mg}$$

2. Weigh exactly 137.5 mg (0.1375 g) and place it in a 100-ml volumetric flask.
3. Dissolve in approximately 2 ml of phosphate buffer (0.1 M pH 6.0), and bring to 100 ml with sterile deionized water.

E. Example using formula B

1. Use when weighing powder to a weight slightly in excess of that needed. Then calculate the exact volume of diluent needed to obtain the concentration desired.

Antimicrobial:	cephalothin
Desired concentration:	1,280 $\mu\text{g/ml}$
Desired volume:	approximately 50 ml
Assay potency:	931 $\mu\text{g/mg}$
Approximate amount to weigh:	>140 mg (approximately 141 to 160 mg)

$$x \text{ ml} = \frac{142.4 \text{ mg} \times 931 \mu\text{g/mg}}{1,280 \mu\text{g/ml}} = 103.57 \text{ ml}$$

2. Weigh approximately 141 to 160 mg (0.141 to 0.160 g). For example purposes, this weight is 142.4 mg (0.1424 g). Place in a 125-ml Erlenmeyer flask.
3. Dissolve in exactly 2 ml of phosphate buffer (0.1 M, pH 6.0) and add exactly 101.57 ml of sterile deionized water.

5.14.3

Preparation of Agar and Broth Media Used in Routine Antimicrobial Susceptibility Tests

I. PRINCIPLE

Specific agar and broth media (generally Mueller-Hinton with or without supplements) used for routine disk diffusion (1), agar dilution, and broth dilution (2) susceptibility tests are prepared from commercially available dehydrated compo-

nents. Although these media have shown fairly good reproducibility through many years of testing, they are undefined media, and there may be subtle performance differences among batches and lots.

II. MATERIALS

Include QC information on reagent container and in QC records.

A. Media and reagents

1. Distilled (or deionized) water
Store at 25°C.
2. Dehydrated Mueller-Hinton agar (sometimes referred to as Mueller-Hinton medium)
Store at 25°C.
3. Dehydrated Mueller-Hinton broth
Store at 25°C.
4. Dehydrated GC agar base
Store at 25°C.
5. Additives or supplements (*see* specific media to determine which of these are needed, and *see* Appendix 5.14.3-1 for preparation)
 - a. Defibrinated sheep blood
Store at 2 to 8°C.
 - b. Defibrinated horse blood
Store at 2 to 8°C.
 - c. NaCl
Store at 25°C.
 - d. Thymidine phosphorylase (Sigma-Aldrich, St. Louis, Mo.)
Store at 2 to 8°C.
 - e. Bovine hematin, *not* hemin (Sigma Chemical Co., St. Louis, Mo.)
Store at 2 to 8°C.
 - f. Yeast extract powder
Store at 25°C.
 - g. β -NAD solution powder
Store at 25°C.
 - h. GC agar supplement
Store at 2 to 8°C.

- i. Calcium chloride ($\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$)
Store at 2 to 8°C.
- j. Magnesium chloride ($\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$)
Store at 2 to 8°C.
- k. 1 N HCl
Store at 25°C.
- l. 1 N NaOH
Store at 25°C.

B. Supplies

1. Weigh paper or weigh boats
2. Spatulas or tongue depressors
3. Stoppers for flasks
4. Petri dishes (100 and 150 mm)
5. Tubes, flasks, or bottles of various sizes to contain prepared media
6. 1-, 5-, and 10-ml sterile serological pipettes and pipette bulb
7. Sterile tubes that withstand high centrifugal force, 12,000 $\times g$ (for preparation of lysed horse blood)
8. Membrane filters (0.22- and 0.45- μm pore size)

C. Equipment

1. Graduated cylinders
2. Erlenmeyer flasks
3. Volumetric flasks
4. Calibrated probe marked at 3, 4, and 5 mm (for checking agar depth)
5. Autoclave
6. 48 \pm 2°C water bath
7. Magnetic stirrer and stirring bars

II. MATERIALS (*continued*)

- | | |
|--|--|
| <ul style="list-style-type: none"> 8. Hot plate or other flat burner 9. Bunsen burner 10. Refrigerator (2 to 8 °C); <i>non-self-defrosting</i> if using refrigerator-freezer combination 11. Automated dispensing apparatus (optional) 12. 35 ± 2°C ambient-air incubator | <ul style="list-style-type: none"> 13. Analytical balance 14. pH meter 15. Large, flat, level surface for pouring plates 16. High-speed (12,000 × g) centrifuge (for preparation of lysed horse blood) |
|--|--|

III. QUALITY CONTROL

Perform the following checks when preparing media.

A. Sterility checks

1. Test medium for sterility by incubating a 5 to 10% sample from each newly prepared batch of media in ambient air at 35°C for 48 h.
2. Disregard sporadic contamination, e.g., one piece of medium.
3. Discard entire batch if significant contamination (≥10% of the medium incubated) is noted.
4. Discard all media used for sterility checks.

B. pH

1. Check the pH of each new lot of prepared media after it has cooled to room temperature.
2. Check the pH of agar by one of the following methods.
 - a. Use a surface electrode.
 - b. Macerate the medium in neutral distilled water, and use an immersion electrode.
 - c. Allow the agar to solidify around the electrodes of a pH meter.
3. For broth, place an immersion electrode into the liquid.
4. Acceptable range is 7.2 to 7.4 for Mueller-Hinton-based media and GC agar base.

C. Agar depth (for media used for the disk diffusion test)

1. Check the depths of two to five plates from each batch of plates.
2. Push a thin, sterile calibrated probe marked at 3, 4, and 5 mm into the agar to measure depth.
3. Acceptable range is 3 to 5 mm for disk diffusion testing.

D. Cation (Ca²⁺ and Mg²⁺) content

1. For broth, measure the concentration of each of these divalent cations following completion of broth preparation (send an aliquot to the chemistry laboratory for analysis of calcium and magnesium content)
2. For agar and broth, do a performance check with *Pseudomonas aeruginosa* ATCC 27853 and aminoglycosides (*see* disk diffusion and broth microdilution MIC test procedures [procedures 5.1 and 5.2])
3. Acceptable ranges (atomic absorption method or equivalent) are as follows.
 - a. Ca²⁺, 20 to 25 mg/liter (equivalent to 2.0 to 2.5 mg/dl)
 - b. Mg²⁺, 10 to 12.5 mg/liter (equivalent to 0.83 to 1.04 meq/liter)

E. Thymidine content

See procedures 5.1 and 5.2 for descriptions of performance testing of *Enterococcus faecalis* ATCC 29212. Satisfactory performance of this isolate with trimethoprim-sulfamethoxazole indicates acceptable thymidine content (zone of ≥20 mm or MIC of ≤0.5/9.5 µg/ml).

F. NaCl content (cation-adjusted Mueller-Hinton broth [CAMHB] plus 2% NaCl)

1. Measure concentration of NaCl following completion of broth preparation (send an aliquot to the chemistry laboratory for analysis of sodium and/or chloride).

III. QUALITY CONTROL

(continued)

2. Acceptable range (ion selective electrode method) is 450 to 480 mmol of Na^+ and/or Cl^- . Sources of ions are from both the Mueller-Hinton broth (naturally occurring) and addition of NaCl (20 g/liter) to broth medium.

G. Growth-supporting capabilities and performance checks

Determine growth-supporting capabilities, antimicrobial compatibility, and performance by testing QC reference strains (*see* procedures 5.1 and 5.2 and Appendix 5.14.3–2)

H. Appearance (*see* Appendix 5.14.3–2)

Prior to each use, examine media for evidence of discoloration, drying or cracking (agar), insufficient volume, or other signs of deterioration. Do not use media that do not appear acceptable.

IV.A. PROCEDURE: AGAR

A. Mueller-Hinton agar

The following procedure describes preparation of 1 liter of Mueller-Hinton agar from commercially available dehydrated Mueller-Hinton agar (medium) powder; for other volumes, modify accordingly. Additionally, this procedure assumes that dehydrated powder contains acceptable concentrations of Ca^{2+} and Mg^{2+} . In establishing shelf life, *see* procedure 14.2.

1. Weigh appropriate amount of dehydrated Mueller-Hinton agar powder (follow manufacturer's instructions on bottle) and place in a 2-liter flask.
2. Add 1 liter of distilled water and swirl to disperse powder.
3. Place over a hot plate with magnetic stirrer (or other heating device) and heat until powder is dissolved (bring to a gentle boil). *Do not boil vigorously, and do not apply direct heat without stirring, as medium will burn.*
4. Carefully remove agar from heat and dispense in desired aliquots into containers of choice (e.g., dispense 250-ml volumes into 500-ml Erlenmeyer flasks).
5. Loosely cover containers (e.g., insert stopper into mouth of flask).
6. Autoclave at 121°C for 15 min.
7. Allow to cool in a 48°C water bath.
8. Arrange petri plates on a level surface.
9. For disk diffusion tests, pour accurately measured volumes of molten agar into plates.
 - a. 60 to 70 ml/150-mm plate
 - b. 25 to 30 ml/100-mm plate
10. Eliminate bubbles on the molten agar surface by quickly (and carefully) passing the flame from a Bunsen burner over the agar.
11. Allow plates to solidify at room temperature with plate lids slightly ajar.
12. Store prepared plates at 2 to 8°C in tightly sealed packages.

B. Sheep blood (5%)-supplemented Mueller-Hinton agar

1. Prepare 1 liter Mueller-Hinton agar as described above.
2. Add 50 ml of sterile defibrinated sheep blood to molten and cooled (48°C) agar.
3. Gently swirl to mix and pour plates as described above.
4. Store prepared plates at 2 to 8°C in tightly sealed packages.

C. Haemophilus test medium (agar)

1. Weigh appropriate amount of dehydrated Mueller-Hinton agar powder (follow manufacturer's instructions on bottle) and place in a 2-liter flask.
2. Add 5 g of yeast extract.
3. Add 967 ml of distilled water, and swirl to disperse powder.
4. Place over a hot plate with magnetic stirrer (or other heating device) and heat until powder is dissolved (bring to a gentle boil). *Do not boil vigorously, and do not apply direct heat without stirring because medium will burn.*

IV.A. PROCEDURE: AGAR*(continued)*

5. Add 30 ml of freshly prepared hematin stock solution and mix well.
6. Dispense and autoclave at 121°C for 15 min.
7. Allow to cool in a 48°C water bath.
8. Aseptically add 3 ml of sterile β -NAD stock solution and mix well.
9. Pour plates as described above.
10. Store prepared plates at 2 to 8°C in tightly sealed packages.

D. GC agar base with 1% defined supplement

1. Weigh out appropriate amount of dehydrated GC agar base powder (follow manufacturer's instructions on bottle) and place in a 2-liter flask.
2. Add 999 ml of distilled water and swirl to disperse powder.
3. Place over a hot plate with magnetic stirrer (or other heating device) and heat until powder is dissolved (bring to a gentle boil). *Do not boil vigorously, and do not apply direct heat without stirring, as medium will burn.*
4. Autoclave at 121°C for 15 min.
5. Allow to cool in a 48°C water bath.
6. Aseptically add 10 ml of sterile defined supplement solution, and mix well.
7. Pour plates as described above.
8. Store prepared plates at 2 to 8°C in tightly sealed packages.

IV.B. PROCEDURE: BROTH**A. CAMHB**

The following procedure describes preparation of 1 liter of CAMHB from commercially available dehydrated Mueller-Hinton broth powder; for other volumes, modify accordingly. In establishing shelf life, see procedure 14.2.

1. Weigh appropriate amount of dehydrated Mueller-Hinton broth powder (follow manufacturer's instructions on bottle) and place in a 2-liter flask.
2. Add 1 liter of distilled water and swirl to disperse powder.
3. Place over a hot plate with magnetic stirrer (or other heating device) and heat until powder is dissolved (bring to a gentle boil). *Do not boil vigorously, and do not apply direct heat without stirring because medium will burn.*
4. Carefully remove broth from heat and dispense in desired aliquots into containers of choice (e.g., dispense accurately measured 250-ml volumes into 500-ml Erlenmeyer flasks).
5. Loosely cover containers (e.g., insert stopper into mouth of flask).
6. Autoclave at 121°C for 15 min.
7. Allow to cool, and then chill at 2 to 8°C for several hours.
8. Check the cation content for the specific lot of medium that is printed on the label.
 - a. Calculate the amount of calcium stock solution needed.
 - b. The following is an example.
 - (1) Specified amount of calcium already present in medium = 10.0 mg/liter
 - (2) Desired amount per liter of broth = 22.5 mg (20 to 25.0 mg/liter)
 - (3) Add 0.1 ml of calcium stock solution per liter for each increment of 1 mg/liter needed to attain desired concentration.

$$\begin{array}{r}
 22.5 \text{ mg/liter} \\
 - 10.0 \text{ mg/liter (already present in broth)} \\
 \hline
 12.5 \text{ mg/liter needed to reach desired concentration} \\
 12.5 \times 0.1 \text{ ml/liter} = 1.25 \text{ ml}
 \end{array}$$

Add 1.25 ml of calcium stock solution to each liter of broth.

- c. Calculate the amount of magnesium stock solution needed.

IV.B. PROCEDURE: BROTH*(continued)*

d. The following is an example.

- (1) Specified amount of magnesium already present in medium = 7.0 mg/liter
- (2) Desired amount per liter of broth = 11.25 mg (10 to 12.5 mg/liter)
- (3) Add 0.1 ml of magnesium stock solution per liter for each increment of 1 mg/liter needed to attain desired concentration.

$$\begin{array}{r} 11.25 \text{ mg/liter} \\ - 7.0 \text{ mg/liter (already present in broth)} \\ \hline 4.25 \text{ mg/liter needed to reach desired concentration} \\ 4.25 \times 0.1 \text{ ml/liter} = 0.425 \text{ ml} \end{array}$$

Add 0.425 ml of magnesium stock solution to each liter of broth.

9. Remove flasks from the refrigerator, aseptically add the appropriate volume of each *sterile* cation stock solution to the chilled broth, and mix well (medium must be cold to prevent precipitation of the cations).
10. If testing sulfonamides or trimethoprim-sulfamethoxazole, add thymidine phosphorylase to obtain a final concentration of 0.2 IU/ml.
11. Store prepared CAMHB at 2 to 8°C in sealed containers.

B. CAMHB supplemented with 2% NaCl

To the flask containing the dehydrated powder (step IV.B.A.1 above), add 20 g of NaCl per liter. Follow remaining steps as given above.

C. CAMHB supplemented with 2 to 5% lysed horse blood

1. Prepare CAMHB as described above.
2. Aseptically add the appropriate volume of 50% lysed horse blood to CAMHB to obtain a final concentration of 2 to 5% lysed horse blood.
 - a. Add 4 to 10 ml of 50% lysed horse blood to obtain a final volume of 100 ml of CAMHB.
 - b. When supplementing broth microdilution panels, add 5 μ l (0.005 ml) of 50% lysed horse blood to each well containing 100 μ l (0.1 ml) of antimicrobial agent and broth.

D. *Haemophilus* test medium (broth)

1. Weigh appropriate amount of dehydrated Mueller-Hinton broth powder to prepare 1 liter of medium (follow manufacturer's instructions on bottle) and place in a 2-liter flask.
2. Add 5 g of yeast extract.
3. Add 967 ml of distilled water, and swirl to disperse powder.
4. Place on a hot plate with magnetic stirrer (or other heating device) and heat until powder is dissolved (bring to a gentle boil). *Do not boil vigorously, and do not apply direct heat without stirring because medium will burn.*
5. Add 30 ml of freshly prepared hematin stock solution, and mix well.
6. Dispense, and autoclave at 121°C for 15 min.
7. Allow to cool, and chill at 2 to 8°C for several hours or overnight.
8. Aseptically add the appropriate volume of each sterile cation solution to the chilled broth, and mix well (*see* item IV.B.A above).
9. Aseptically add 3 ml of sterile β -NAD stock solution (to 1 liter of broth), and mix well.
10. If testing sulfonamides or trimethoprim-sulfamethoxazole, add thymidine phosphorylase to obtain a final concentration of 0.2 IU/ml.
11. Store prepared broth at 2 to 8°C in sealed containers.

V. PROCEDURE NOTES**A. General**

1. Dehydrated media
 - a. Store bottles of dehydrated media tightly capped and in a cool, dry place to prevent the powder from hardening.
 - b. Read directions carefully, especially if a new lot of medium is received.
 - c. Add powder to flask, and then add water.
2. Water

Use only distilled or deionized water. Impurities in tap water may affect medium performance.
3. Glassware
 - a. All glassware should be clean and free of soap residue.
 - b. Rinse all glassware with distilled or deionized water after washing and prior to use.
4. Heating and autoclaving
 - a. Heat medium to a gentle boil to achieve an even solution.
 - b. When the medium begins to clear and runs in a sheet down the side of the flask when the flask is swirled, it is ready to be autoclaved.
 - c. Do not autoclave medium longer or at higher temperatures than specified by the manufacturer.
5. When using prepared media, it is expected that the manufacturer has performed extensive QC to include but not be limited to the following.
 - a. Sterility checks
 - b. Measurement of pH
 - c. Measurement of some specific components (e.g., Ca^{2+} , Mg^{2+})
 - d. Measurements of fill (volume, depth, etc.)
 - e. Performance checks
 - f. Shelf life studies

B. Agar

1. Mueller-Hinton agar
 - a. The NCCLS has developed a protocol to assist manufacturers of commercially prepared Mueller-Hinton agar in producing a product that performs reliably (3).
 - b. The correct depth of plated medium for disk diffusion testing is critical. Failure to dispense accurate volumes may result in agar that is too thin (often yielding false-susceptible results) or too thick (often yielding false-resistant results).
2. In the preparation of GC agar with 1% supplement, do not use supplements containing cysteine because cysteine may inactivate newer beta-lactam antimicrobial agents. A chemically defined "XV-like" supplement without cysteine is recommended. This supplement is most like BBL IsoVitaleX but has no cysteine and is composed of (per liter of medium) 1.1 g of L-cystine, 0.03 g of guanine HCl, 3 mg of thiamine HCl, 13 mg of *p*-aminobenzoic acid, 0.01 g of vitamin B₁₂, 0.1 g of cocarboxylase, 0.25 g of NAD, 1.0 g of adenine, 10 g of L-glutamine, 100 g of glucose, and 0.02 g of ferric nitrate.

C. Mueller-Hinton broth

1. The NCCLS has developed a protocol to assist manufacturers of commercially prepared Mueller-Hinton agar in producing a product that performs reliably (4).
2. Cations (Ca^{2+} and Mg^{2+})
 - a. The following alternative procedure is satisfactory for the addition of cations (adding cations prior to autoclaving).
 - (1) Dissolve Mueller-Hinton broth powder as described above.
 - (2) As soon as broth has cooled slightly (approximately 15 min), chill in a refrigerator at 2 to 8°C (or in an ice bath). Small volumes (500 ml)

V. PROCEDURE NOTES

(continued)

- will be sufficiently cool after 4 to 6 h; larger volumes may require overnight chilling.
- (3) Add appropriate volumes of cation solutions as described above.
 - (4) Dispense into desired containers, and autoclave as described above.
 - (5) If water is sufficiently pure, precipitation does not occur. Although some do not feel that it is acceptable to hold medium for more than a few hours prior to autoclaving (even if refrigerated), one of us has been holding medium overnight at 2 to 8°C (for preparation of CAMHB), without problems, during 20 years of testing.
- b.** The addition of cations to Mueller-Hinton broth primarily affects activities of aminoglycosides and *P. aeruginosa* (isolates appear more resistant to aminoglycosides as cation content increases). Similarly, the activity of tetracycline against all isolates decreases as cation content increases.
- 3.** CAMHB supplemented with 2% NaCl is limited to testing staphylococci with the penicillinase-stable penicillins (oxacillin, methicillin, and nafcillin).
 - 4.** Thymidine content
 - a.** Most currently manufactured dehydrated Mueller-Hinton broth and agar powders are relatively free of thymidine.
 - 1.** Excessive concentrations of thymidine will interfere with testing of sulfonamides, trimethoprim, and trimethoprim-sulfamethoxazole (isolates will appear more resistant).
 - 2.** If the MIC of trimethoprim-sulfamethoxazole for *E. faecalis* ATCC 29212 is $\leq 0.5/9.5$ $\mu\text{g/ml}$ and/or the inhibition zone is ≥ 20 mm and free of fine colonies, the medium is sufficiently free of thymidine and acceptable for use (1, 2).
 - b.** Thymidine phosphorylase enzyme can be added to CAMHB to eliminate thymidine. Add sufficient volumes of sterile solution to autoclaved broth to obtain a final concentration of 0.2 U/ml.
 - 5.** The pH of Mueller-Hinton broth increases slightly (approximately 0.1 to 0.2 pH units) following autoclaving. Adjusting the preautoclave pH to approximately 7.1 results in a final pH within the acceptable range of 7.2 to 7.4. Adjust pH with 1 N HCl or 1 N NaOH. It generally takes approximately 0.5 ml of 1 N HCl to decrease the pH of 1 liter of broth by 0.1 pH unit. However, this will vary with different lots of medium and water.
 - 6.** Lysed horse blood
 - a.** Successful use of lysed horse blood relates to clarity of the lysed horse blood preparation. Only a high-speed centrifuge adequately precipitates cell debris. Repeated centrifugation or passage of supernatant through a filter may be necessary to obtain a clear solution.
 - b.** When performing a broth dilution test using CAMHB with lysed horse blood, always include an uninoculated negative control tube (or well) of CAMHB with lysed horse blood to use for comparison with inoculated solutions.
 - c.** Always check durability of tubes by centrifugation of a sample tube containing water prior to centrifugation of blood.

VI. LIMITATIONS

- A.** Not all clinically significant aerobic isolates that require antimicrobial susceptibility testing grow satisfactorily in the Mueller-Hinton agars or broths described here.

VI. LIMITATIONS (*continued*)

- B. Sometimes supplements may have an inactivating effect on the antimicrobial agents tested. Supplements that have not been extensively studied should be used with caution. Always test QC reference strains in the medium used for testing patient isolates. Results must fall into specified ranges for the test to be acceptable.
- C. There may be variations in performance of media obtained from different manufacturers or different lots from the same manufacturer.

APPENDIX 5.14.3-1

Preparation of Additives and Supplements

- A. Calcium stock solution (10 mg of Ca²⁺ per ml)
1. Add 3.68 g of CaCl₂ · 2H₂O to a 100-ml volumetric flask and bring to 100 ml with deionized water.
 2. Mix well to dissolve.
 3. Dispense into 100-ml screw-cap bottles (approximately 50 ml per bottle) and autoclave for 15 min at 121°C (or filter sterilize through a 0.22-µm-pore-size filter).
 4. Store at 2 to 8°C for up to 1 year.
- B. Magnesium stock solution (10 mg of Mg²⁺ per ml)
1. Add 8.36 g of MgCl₂ · 6H₂O to a 100-ml volumetric flask and bring to 100 ml with deionized water.
 2. Mix well to dissolve.
 3. Dispense into 100-ml screw-cap bottles (approximately 50 ml per bottle) and autoclave for 15 min at 121°C (or filter sterilize through a 0.22-µm-pore-size filter).
 4. Store at 2 to 8°C for up to 1 year.
- C. 1 N HCl
1. Add 8.33 ml of concentrated HCl to a 100-ml volumetric flask containing approximately 90 ml of deionized water and bring to 100 ml with deionized water.
 2. Mix well.
 3. Dispense into a screw-cap bottle.
 4. Store at 25°C for up to 1 year.
- D. 1 N NaOH (and 0.01 N NaOH)
1. Add 4 g of NaOH pellets to a 100-ml volumetric flask containing approximately 50 ml of deionized water, mix to dissolve, and bring to 100 ml with deionized water.
 2. Mix well.
 3. Dispense into a screw-cap bottle.
 4. Store at 25°C for up to 1 year.
 5. For preparation of 0.01 N NaOH, add 1.0 ml of 1 N NaOH to a volumetric flask and bring to 100 ml with deionized water.
- E. Hematin stock solution
Do not use hemin.
1. Add 50 mg of bovine hematin powder and 100 ml of 0.01 N NaOH to a 250-ml Erlenmeyer flask.
 2. Add magnetic stirring bar, and place over low heat on a hot plate until dissolved (takes about 15 min).
 3. Prepare fresh each time of use, and discard any unused reagent.
- F. β-NAD stock solution
1. Add 50 mg of β-NAD powder and 10 ml of deionized water to a 25-ml Erlenmeyer flask.
 2. Mix well to dissolve.
 3. Filter sterilize by passing solution through a 0.22-µm-pore-size membrane filter.

APPENDIX 5.14.3-1 (continued)

4. Dispense into a sterile screw-cap tube.
 5. Store at 2 to 8°C for up to 1 month.
- G. Lysed horse blood
1. Dispense defibrinated horse blood into freezer-safe tubes, and freeze-thaw a minimum of three times until the RBCs are completely lysed. Freezing at -20°C is preferred because this temperature disrupts RBCs more efficiently than -70°C . Thaw at room temperature.
 2. Add equal volumes of lysed blood and sterile deionized water (e.g., 5 ml of blood and 5 ml of water; solution is now 50% lysed horse blood).
 3. Dispense into tubes that will safely withstand the centrifugal force and centrifuge at $12,000 \times g$ for 20 min.
 4. Decant supernatant into another sterile tube, and discard the sediment.
 5. Centrifuge supernatant to further remove cell debris, if necessary.
 6. Decant supernatant into another sterile tube, and discard the sediment.
 7. Sometimes it may be helpful to pass solution through a 0.22- or 0.45- μm -pore-size membrane filter to clarify it further. However, this is usually unnecessary if centrifugation is satisfactory.
 8. Store at -20°C for up to 6 months.

5.15

Preparation of Broth Microdilution MIC Trays

I. PRINCIPLE

Broth microdilution MIC trays may be prepared in-house for performance of quantitative antimicrobial susceptibility studies. If large numbers of trays are required, dilutions of the antimicrobial agents are made in large volumes and generally dispensed in 0.1-ml amounts into microdilution trays by using a commercial dispensing apparatus. For individual test trays, dilutions of the required antimicrobial agents may be accomplished with an

eight-channel micropipette. The procedure described here is based on 96-well trays containing 0.1 ml per well. Not every aspect of broth microdilution tray preparation has been standardized, and for some steps, there are multiple ways of accomplishing identical results. The method presented here conforms closely to that described by the NCCLS (2) and is the procedure that has been successfully used with a Quick Spense (Sandy Springs In-

strument Co.) dispenser at the clinical microbiology laboratories of the University of California—Los Angeles for nearly two decades. It assumes that the layout of the tray in terms of positioning respective concentrations of each antimicrobial agent has been previously determined. The method is detailed for preparation of approximately 1,900 trays, but recommendations for preparing fewer trays are included.

II. MATERIALS

Include QC information on reagent container and in QC records.

See procedure 5.2 for materials required for QC.

A. Media and reagents

1. Cation-adjusted Mueller-Hinton broth (CAMHB) and CAMHB supplemented with 2% NaCl for penicillinase-stable penicillins (e.g., oxacillin, nafcillin) (*see* procedure 5.14 and Appendix 5.15–1)
Store at 2 to 8°C.
2. Antimicrobial stock solutions (*see* procedure 5.14)
Store at –70°C.
3. Thymidine phosphorylase, if trimethoprim-sulfamethoxazole, trimethoprim, or a sulfonamide is included
Store at 2 to 8°C.
4. Sterile deionized water
Store at 25°C.
5. Dye solution
 - a. 1% phenol red for gram-negative bacteria trays
 - (1) Dissolve the following.

phenol red	
powder0.5 g
0.1 N NaOH 14 ml
 - (2) Add 36 ml of deionized water.

- (3) Filter sterilize through a 0.45- μ m-pore-size filter, and store in a glass bottle.
- (4) For use as a marker in the MIC trays, add 1.0 ml of this solution per 200 ml of CAMHB.
Store at 25°C.
- b. 1.6% Bromocresol purple for gram-positive bacteria trays
 - (1) Dissolve the following.

bromocresol	
purple0.8 g
0.1 N NaOH 14.8 ml
 - (2) Add 35.2 ml of 95% ethanol.
 - (3) Filter sterilize through a 0.45- μ m-pore-size filter, and store in a glass bottle.
 - (4) For use as a marker in the MIC trays, add 0.2 ml of this solution per 200 ml of CAMHB.
Store at 25°C.

B. Supplies

1. Large containers (e.g., 12-liter Florence flasks or stainless steel pots to hold 12 liters of broth)

II. MATERIALS (*continued*)

2. 250-ml Erlenmeyer flasks (approximately 20)
3. Foam plugs to fit 250-ml Erlenmeyer flasks
4. Sterile serological pipettes (1.0, 2.0, 5.0, 10, and 25 [or 50] ml) and pipette bulb
5. Sterile plastic capped tubes (16 by 100 mm)
6. Round labels, 0.5-in. diameter
7. Two or three large sterile towels or drapes (approximately 24 by 48 in.)
8. Sterile 96-well polystyrene U-bottom broth microdilution trays
9. Microdilution tray plate sealers
10. Plastic storage bags with seals, 10 by 13 in.
11. 100-mm petri plates or other sterile reservoir (for preparation of individual trays)
12. 0.45- μ m-pore-size filter

C. Equipment

1. Commercial microdilution tray dispensing apparatus (Appendix 5.15–2)
 - a. Large reservoir tubes with volumetric gradations (to fit dispensing apparatus) that have been acid washed
 - b. Two large racks that each hold 96 large reservoir tubes in a format identical to that of the microdilution tray (12 columns by 8 rows)
2. pH meter
3. Vortex mixer
4. Analytical balance (sensitive to 0.1 g)
5. -70°C freezer
6. Multichannel micropipette and sterile tips (for preparation of individual trays)

III. QUALITY CONTROL

Document all QC results (*see* example forms in Appendixes 5.15–3 and 5.15–4). See procedure 5.14 also.

- A. Check sterility and pH of CAMHB. Also check Ca^{2+} and Mg^{2+} concentrations by sending representative samples of broth to the chemistry laboratory for analysis.
 1. Sterility

Incubate one flask and one tube of CAMHB at 35°C for 48 h (preferably prior to performing the run).
 2. pH: acceptable range, 7.2 to 7.4 at room temperature
 3. Ca^{2+} (atomic absorption method or equivalent): acceptable range is 20 to 25 mg/liter (equivalent to 2.0 to 2.5 mg/dl)
 4. Mg^{2+} (atomic absorption method or equivalent): acceptable range is 10 to 12.5 mg/liter (equivalent to 0.83 to 1.04 meq/liter)
- B. Check potency of all antimicrobial stock solutions prior to their use in the preparation of MIC trays by performing MIC tests with appropriate NCCLS-recommended ATCC reference strains.
 1. Prepare dilutions of stock antimicrobial agent encompassing acceptable MIC ranges as illustrated in Appendix 5.15–4.
 2. Perform a MIC test for each drug with a QC organism that has an on-scale MIC endpoint (*see* procedure 5.2).
- C. Confirm the sterility of the dispensing apparatus by using an approved autoclave indicator.
- D. Check the accuracy of the dispensed volume (must be within 10% of ideal volume or weight) as follows.
 1. Volume check by volume

Perform at beginning, middle, and end of run.

 - a. Dispense three “shots” of solution into a single tray. (Each shot should contain approximately 0.1 ml.)
 - b. Visually inspect menisci, checking for an even fill.
 - c. Using a 1.0-ml serological pipette, aspirate the entire contents of the well showing the lowest fill, and note volume.

III. QUALITY CONTROL

(continued)

- d. Repeat step III.D.1.c for well showing the highest fill.
 - e. Acceptable volume reading = 0.3 ± 0.03 ml
 2. Volume check by weight
 - Perform at beginning of run and after every 100 trays dispensed.
 - a. Using the analytical balance, tare in the weight of an empty tray.
 - b. Fill the tray with one shot of solution, and weigh.
 - c. Acceptable weight = 9.6 ± 0.5 g
 - E. Check sterility of prepared trays by incubating five trays each from the beginning and end of the run at 35°C for 48 h.
 - F. Performance testing using QC strains
 1. Test each new lot of prepared trays in duplicate and in parallel with an old lot of trays by using the recommended ATCC reference strains. It is desirable to use strains with on-scale endpoints. See sample listing of drugs in Appendix 5.15–5 and the recommended ATCC reference strains that have on-scale endpoints for the drug concentrations included (Appendix 5.15–6).
 2. Test additional organisms (usually in-house-selected strains) that would complement the ATCC reference strains in controlling preparation of the trays. The number of additional control organisms included depends on the number and variety of antimicrobial agents included in the tray.
 3. In selecting supplemental QC strains
 - a. Include strains to control antimicrobial agents for which none of the ATCC strains have on-scale endpoints (e.g., in example in Appendix 5.15–6, trimethoprim-sulfamethoxazole).
 - b. Include strains that control significant antimicrobial concentrations that may not be optimally controlled by the ATCC strains (e.g., include an isolate for which the gentamicin MIC is near the breakpoint of susceptibility [MIC, 4 to 8 µg/ml]).
 - c. Include strains that detect types of resistance that may not be detected with the ATCC reference strains, such as the following.
 - (1) Oxacillin-resistant *Staphylococcus aureus*
 - (2) Erythromycin-resistant *S. aureus*
 - (3) Aminoglycoside-resistant *Pseudomonas aeruginosa*
 - (4) Cefotaxime-resistant *Enterobacter* spp.
 4. For handling and testing of QC organisms and additional QC information, see procedure 5.13.

IV. PROCEDURE

This procedure is for preparation of 500 to 2,000 trays using a 200-ml capacity dispenser. For preparation of trays using a smaller automated dispensing apparatus (e.g., one that is designed for preparation of up to 200 trays), see Appendix 5.15–7. For preparation of a small number of individual trays, see Appendix 5.15–8. See procedure 5.14 for alternative methods for preparation of CAMHB.

- A. Fill reservoir tubes with CAMHB (96 of the tubes should be positioned in a 96-tube rack).
 1. Dispense an amount of prepared (but not autoclaved) CAMHB just short of the required volume into calibrated screw-cap reagent tubes supplied with the dispensing apparatus. Cap tubes loosely, and place in 96-tube rack supplied for use with the dispensing apparatus.
 2. Dispense remaining broth (in approximately 150-ml amounts) into 250-ml Erlenmeyer flasks. Plug flasks.
 3. Autoclave filled tubes and flasks for 15 min at 121°C.
 4. Allow broth to cool to room temperature. Tighten caps.

IV. PROCEDURE (*continued*)

- B.** Label trays, storage bags, and CAMHB reservoir tubes.
1. Label the required numbers of empty broth microdilution trays and plastic storage bags with lot number and preparation date. A quick and efficient way to do so is to arrange the trays in stacks of 30 and run a permanent-ink marking pen down one side. This colored stripe(s) (“code”) is referenced on the plastic storage bag and on the QC sheets with the preparation date. The preparation date serves as the lot number.
 2. For each CAMHB reservoir tube, prepare a label that indicates the antimicrobial agent, concentration of antimicrobial solution required, and volume of antimicrobial solution to add (*see* Appendix 5.15–7).
 3. Place labels on caps of the appropriate tubes containing CAMHB, and make certain that all tubes are positioned in the rack in the exact order required for the antimicrobial tray layout.
- C.** Add antimicrobial agents. (All measurements made must be point to point when using serological pipettes.)
1. Prepare intermediate dilutions of antimicrobial stock solutions (*see* Appendix 5.15–7). If using scheme in Table 5.15–A1, use sterile deionized water as the diluent. If using scheme in Table 5.15–A2, use CAMHB as the diluent.
 2. If thymidine phosphorylase is required (trimethoprim, sulfonamides, or trimethoprim-sulfamethoxazole), add the required amount to the appropriate tube(s) to achieve a final concentration of 0.2 IU/ml.
 3. Dispense the exact volume of the indicated concentration of antimicrobial solution into the appropriate tube of CAMHB.
 4. Mix by inverting the tube several times.
 5. Following the addition of antimicrobial solution, transfer each tube to a separate rack, making certain that the tube maintains the same position it held in the first rack.
 6. Continue with one tube at a time until all antimicrobial solutions have been added. Note that negative and positive control tubes will not contain antimicrobial agent.
 7. If used, add indicator dye to dye marker tube (volume may vary depending on the dye).
 8. Fill all tubes to final volumes by using the CAMHB in Erlenmeyer flasks.
 9. Invert each tube several times to mix.
 10. To ensure that the contents of each tube have been thoroughly mixed, transfer filled tubes back to the original rack following mixing, and make certain that they are replaced in their appropriate positions.
- D.** Fill trays.
1. Place rack of filled tubes into the dispensing apparatus, and assemble and prime according to manufacturer’s instructions.
 2. Insert first empty tray into dispensing apparatus, and fill with one shot of solution. Continue filling additional trays.
 3. Set aside the first five and last five trays filled to serve as sterility checks. Seal the top tray of each stack of five trays with a plate sealer (either sealing tape or empty tray), and incubate at 35°C for 72 h. Examine daily.
 4. Stack filled trays five high, and place in plastic bags (four stacks of five per bag). (The numbers of trays stacked and placed in a bag will depend on the bag dimensions.)
 5. Freeze at –70°C as rapidly as possible. *Note:* Storage of trays at –20°C may be acceptable for some antimicrobial agents. *Imipenem and combinations containing clavulanic acid must be stored at –70°C or lower. It is preferable to store all beta-lactams at –70°C or lower.*

IV. PROCEDURE *(continued)*

6. Perform weight checks approximately every 100 trays. Perform volume checks at beginning, middle, and end of run.
7. At completion of run, flush and clean dispensing apparatus according to manufacturer's instructions.
 - a. Flush a minimum of 40 liters of hot water ($\approx 95^{\circ}\text{C}$) through the tubing. (*Flushing with hot water is essential to prevent carryover of agents such as quinolones.*)
 - b. Rinse all tubes and caps thoroughly (five or six times) with distilled water. *Do not use soap. Acid wash tubes or use equivalent cleaning procedure, and rinse them with distilled water.*

V. VALIDATION OF PRODUCT

- A. The finished product is valid for use for routine testing providing that all QC parameters have been met.
- B. Broth microdilution MIC trays containing antimicrobial agents currently in use in routine clinical laboratories have a minimum shelf life of 1 year when stored at -70°C (1, 3). (For additional information, obtain drug stability data from the manufacturer of the drug.) *Never refreeze trays following thawing.*

VI. PROCEDURE NOTES

- A. Materials
 1. CAMHB is recommended for susceptibility testing of commonly isolated rapidly growing nonfastidious bacteria. It has demonstrated fairly good batch-to-batch reproducibility for susceptibility testing; is low in sulfonamide, trimethoprim, and tetracycline inhibitors; and yields satisfactory growth of most pathogens (2). CAMHB may be supplemented to support the growth of fastidious organisms (*see* procedure 5.2).
 2. Test penicillinase-stable penicillins (e.g., oxacillin, methicillin, nafcillin, and dicloxacillin) in CAMHB supplemented with 2% NaCl.
 3. Antimicrobial stock solutions may be prepared in advance, frozen at -70°C , and used within 1 week of preparation. They should be quality controlled prior to use. Fresh solutions can be used, but the potency cannot be validated prior to use in tray preparation.
 4. The pH of CAMHB tends to increase after autoclaving. A preautoclave pH of 7.1 to 7.15 usually results in a pH of 7.2 to 7.4 after autoclaving.
 5. Dispense several extra tubes of broth so that in the event of an error (e.g., incorrect amount or wrong drug added, broken tube), materials to easily rectify the situation are on hand.
 6. If high concentrations of aminoglycosides (e.g., gentamicin and streptomycin at 500 or 1,000 $\mu\text{g/ml}$) are included, add weighed antimicrobial powder directly to the broth tubes. It is important to maintain dedicated tubes for these high concentrations of antimicrobial agents to avoid any possibility of carryover of the antimicrobial agents from one run to the next.
- B. Labeling
 1. The use of a dye marker in one well (without antimicrobial agent) is helpful in distinguishing one type of MIC tray from another if several types are prepared in the laboratory. This also helps orient positioning of antimicrobial dilutions in trays.
 2. Food colors can be used as dye markers.
 3. Small round stickers containing information on antimicrobial agent, concentration, and volume of antimicrobial solution to add are convenient for labeling the caps of large 200-ml tubes. In addition, these labels may be saved on a plastic sheet protector for future use.

VI. PROCEDURE NOTES*(continued)***C. QC**

1. The maximum acceptable weight allowance of liquid in the 96-well MIC tray (containing 0.1 ml per well) is generally 9.6 ± 0.5 g if the 10% error rule is used (2), and this can be easily accomplished.
2. A second person to act as a spotter, who observes the critical steps of the procedure (e.g., all measuring steps), may be helpful in ensuring that the MIC trays have been prepared properly.
3. A practical supplemental method for QC of high concentrations of aminoglycosides (i.e., gentamicin or streptomycin at 500 or 1,000 $\mu\text{g/ml}$) is assay by a chemical or immunoassay method (performed in many clinical chemistry laboratories). Dilute the sample so that the expected concentration is within the limits of detection.
4. An on-scale endpoint will have a defined MIC within the range of concentrations tested (*not* less than or equal to the lowest concentration and not more than the highest concentration). For example, if 0.5, 1.0, 2.0, 4.0, 8.0, 16, and 32 $\mu\text{g/ml}$ are tested, on-scale endpoints would be 1.0, 2.0, 4.0, 8.0, 16, and 32.
5. CAMHB containing 2% NaCl will yield 450 to 480 mmol of Na^+ and/or Cl^- when assayed by the ion-selective electrode method. The sources of the ions are both the Mueller-Hinton broth (naturally occurring) and the NaCl (20 g/liter) added to the broth medium.

D. Storage

1. Fill standard -70°C freezers no more than 25% full (or less, depending on the particular freezer) with bagged MIC trays. It may be less stressful on the freezer if panels are cooled in a refrigerator or -20°C freezer for a short time before they are transferred to the -70°C freezer. Specifically designed freezers (those containing a double cooling system) that can accommodate the thermal load are optimal.
 2. Storage of trays at -20°C may be acceptable for some antimicrobial agents. Imipenem is unstable at -20°C . Imipenem and combinations containing clavulanic acid must be stored at -70°C or lower. It is preferable to store all beta-lactams at -70°C or lower (1, 3).
 3. It is important to use non-frost-free freezers for storage of antimicrobial solutions and prepared trays. Dehydration of liquid caused by frost-free freezers adversely affects antimicrobial solution volumes and concentrations.
- E.** Refer to microdilution tray layout blank form and examples in Appendix 5.15–9 when designing tray layout.
- F.** Refer to Appendix 5.15–10 for a quick checklist of required tasks for preparation of broth microdilution MIC trays and the appropriate times to perform them.

VII. LIMITATIONS

The procedure described has been shown to work successfully with the Quick Spense but may require some modification if other dispensing apparatus is used.

128.0	10,000	0.26	0.64	1.28	1.92	2.56
256.0	10,000	0.51	1.28	2.56	3.84	5.12
512.0	10,000	1.02	2.56	5.12	7.68	10.24

^a Sufficient volumes for preparation of trays: 20 ml for approximately 150 trays (0.1 ml per well), 50 ml for 400 trays, 100 ml for 900 trays, 150 ml for 1,400 trays, and 200 ml for 1,900 trays.

Table 5.15-A2 Preparation of antimicrobial dilutions: alternate scheme^a

Concn ($\mu\text{g/ml}$) of antimicrobial solution ^b	Vol of ^c :		Concn ($\mu\text{g/ml}$) of intermediate antimicrobial solution	Final concn ($\mu\text{g/ml}$) ^e
	Antimicrobial solution	CAMHB ^d		
5,120	1	1	2,560	256
5,120	1	3	1,280	128
5,120	1	7	640	64
640	1	1	320	32
640	1	3	160	16
640	1	7	80	8
80	1	1	40	4
80	1	3	20	2
80	1	7	10	1
10	1	1	5	0.5
10	1	3	2.5	0.25
10	1	7	1.25	0.125

^a Data are based on information in NCCLS. 2003. *Methods for Dilution Antimicrobial Susceptibility Tests for Bacteria That Grow Aerobically*, 6th ed. Approved standard M7-A6. NCCLS, Wayne, Pa.

^b 5.12 ml of 10,000- $\mu\text{g/ml}$ antimicrobial solution + 4.88 ml of CAMHB = 5,120 $\mu\text{g/ml}$.

^c Use multiples of these figures to obtain desired volumes of intermediate antimicrobial solutions.

^d Use CAMHB rather than deionized water (as in Table 5.15-A1) as diluent to avoid the diluting effect of large volumes of water in CAMHB.

^e Add intermediate solution and CAMHB to achieve final concentrations in reservoir tube as follows.

Vol (ml) of:		
Final antimicrobial solution	Intermediate antimicrobial solution	CAMHB
20	2	18
50	5	45
100	10	90
150	15	135
200	20	180

APPENDIX 5.15–8**Preparation of Individual Broth Microdilution MIC Trays**

- A. Prepare 1.0-ml amounts of antimicrobial agent solutions at the highest concentrations to be tested.
- B. Using a repeating or multichannel pipette, dispense 0.1 ml of CAMHB or other appropriate broth medium into each well of a U-bottom microdilution tray except for wells in the first column.
- C. Test concentrations from 128 to 0.25 $\mu\text{g/ml}$ (or other concentrations as needed). Include two wells without antimicrobial agent to serve as positive and negative controls.
- D. Add 0.1 ml of each antimicrobial agent at 128 $\mu\text{g/ml}$ to the first two wells (labeled 128 and 64 $\mu\text{g/ml}$) of each row.
- E. Using a multichannel pipette, aspirate the contents of the second well in each row up and down several times to mix well.
- F. Transfer 0.1 ml from the second well in each row to the third well in each row.
- G. Continue mixing and serially transferring the antimicrobial solutions until the last desired concentrations are achieved.
- H. Discard 0.1 ml from the last well in each row.
- I. Prepare additional trays as needed for QC.
- J. Inoculate trays as outlined in procedure 5.2.
- K. *Note:* For this particular procedure, it is not necessary to change tips between dilutions.

APPENDIX 5.15–9

Worksheet for microdilution MIC trays and sample sheet (*see* p. 5.15.17 and 5.15.18)

APPENDIX 5.15–10**Broth Microdilution MIC Tray Preparation Checklist**

- A. 3 weeks before run
 - Order empty microdilution trays from vendor.
- B. 2 weeks before run
 1. Prepare and QC antimicrobial stock solutions.
 2. Inform medium preparation area of scheduled tray preparation, and order media.
- C. 1 week before run
 1. Check with medium preparation area to verify schedule.
 2. All stock solutions should be quality controlled and ready for use.
 3. Acid wash large reservoir tubes.
 4. Label plastic bags for packaging of prepared trays. Include preparation date and color code.
- D. 3 days before run
 1. Get supplies in order.
 2. Prepare large flasks of media and refrigerate.
 3. Add Ca^{2+} and Mg^{2+} to cold Mueller-Hinton broth, and adjust pH.
 4. Dispense broth into tubes and flasks.
 5. Autoclave broth.
 6. Check final pH.
 7. Incubate one tube and one flask of broth for sterility check.
- E. 2 days before run
 1. Organize freezers for storage of prepared trays.
 2. Subculture QC organisms from frozen stocks.
 3. Send samples of broth to chemistry laboratory for Ca^{2+} , Mg^{2+} , and NaCl analysis.
- F. 1 day before run
 1. Label tubes, and dispense sterile water for intermediate antimicrobial dilutions.
 2. Subculture QC organisms a second time.
 3. Assemble and label materials for QC of new trays.
 4. Place dots (labels) on large reservoir tubes, and recheck tray layout.
 5. Weigh out gentamicin and streptomycin (for runs of gram-positive trays).
 6. Begin preparation of dispensing apparatus.

APPENDIX 5.15–10 *(continued)*

7. Assemble supplies for next morning (including sterile towels, which may require autoclaving).
 8. Unwrap, stack, and mark empty trays (open wells down). Cover with sterile towel to prevent contamination.
- G. Day of run
1. Disinfect all work areas.
 2. Remove stock solutions from freezer.
 3. Add thymidine phosphorylase to appropriate reservoir tubes.
 4. Prepare intermediate antimicrobial solution dilutions (in presence of spotter).
 5. Check positioning of tubes, and add antimicrobial solutions (in presence of spotter).
 6. Fill all tubes to final volume with CAMHB.
- H. Immediately before dispensing
1. Recheck positions of tubes.
 2. Prepare dispensing apparatus.
 3. Remove labels from caps.
 4. Remove caps from tubes.
 5. Place rack of tubes in reservoir, and finish assembling the dispensing apparatus.
 6. Proceed with volume and weight QC checks prior to filling trays.
 7. Place filled trays in freezers.
- I. After run
1. Clean dispensing apparatus according to manufacturer's instructions.
 2. Rinse large tubes and caps six to eight times with deionized (or distilled) water. Do not use soap of any kind on tubes or caps.
 3. Wash reservoir tubes with acid or use another equivalent cleaning procedure.

Broth Microdilution MIC Tray Preparation Medium Ordering

For 1,900-tray run:

Please prepare for _____ (date).

Color code _____

24.0 liters of CAMHB

1. Prepare MHB according to manufacturer's directions.
2. Dispense into two 12.0-liter volumes and chill to 2–8°C.
3. Add Ca²⁺ and Mg²⁺, adjust pH, and dispense broth as follows.

- a. If CAMHB–2% NaCl not required:

105 tubes to contain 195 ml

15 flasks to contain 150 ml

- b. If CAMHB–2% NaCl required (gram-positive run):

88 tubes to contain 195 ml of CAMHB

10 flasks to contain 150 ml of CAMHB

Add 60 g of NaCl to 3.0 liters of MHB during medium preparation step, add Ca²⁺ and Mg²⁺, adjust pH, and dispense broth as follows:

11 tubes to contain 195 ml of CAMHB–2% NaCl

2 flasks to contain 150 ml of CAMHB–2% NaCl

I. INTRODUCTION

Developing protocols for antimicrobial susceptibility testing and reporting is best done with input from the infectious disease service, infection control, and the pharmacy and therapeutics committee. The goals are to provide clinically relevant

information that will support cost-effective utilization of antimicrobial agents and to avoid reporting results that may adversely affect patient care. Because of differences in hospital formularies and laboratory functions, it is impossible to make

specific recommendations and the suggestions described herein can only serve as a guide to the decision making processes. A list of commonly used antibacterial agents is shown in Appendix 5.16-1.

II. BASIC STEPS IN DEVELOPING A TESTING AND REPORTING PROTOCOL

- A. Assess resources available (test system[s], numbers of drugs practically tested in respective system, laboratory reporting capabilities [e.g., computer reporting], manpower)
- B. Determine needs of the infectious disease service, pharmacy and therapeutics committee, infection control, and others.
- C. Determine which drugs are on the formulary.
- D. Determine which drugs will be included in routine testing “batteries.” Define, for example, batteries for the following.
 1. Gram-negative bacilli (e.g., *Enterobacteriaceae*)
 2. Gram-positive cocci (e.g., *Staphylococcus* spp., *Enterococcus* spp.)
 3. *Pseudomonas* spp.
 4. *Haemophilus* spp.
 5. *Streptococcus pneumoniae* and *Streptococcus* species
 6. Urine isolates
 7. Very resistant isolates (include “broad spectrum” battery and/or strategy for testing agents not routinely tested; this may involve use of a reference laboratory)
- E. Determine which drugs will be routinely reported for specific organisms and organism groups.
- F. Determine if selective reporting will be implemented.
- G. Develop a protocol for determining how to report test results obtained following special requests by physicians. For example, if a physician requests a drug be reported that is not reported routinely, qualify with a comment such as, “Drug X reported upon special request by Dr. Jones.”

III. PRIMARY RESOURCES

- A. Tables 1 and 1A in NCCLS documents M7-A6 and M2-A8 (3, 4), “Suggested Groupings of U.S. FDA-Approved Antimicrobial Agents That Should be Considered for Routine Testing and Reporting by Clinical Microbiology Laboratories”
- B. *The Medical Letter* (1) and *The Sanford Guide to Antimicrobial Chemotherapy* (2) provide recommendations for the drugs of first choice and alternative agents for treating infections caused by specific bacteria.
- C. Other medical publications that address antimicrobial prescribing choices

IV. SELECTIVE DRUG REPORTING (CASCADE REPORTING) OPTION

- A. Test first- and second-line drugs routinely.
- B. Base reporting on organism identification, overall antimicrobial susceptibility profile of the isolate, and site of infection.
- C. Report second-line agents only if first-line agents appear inappropriate (inactive, inappropriate for specific infection or infecting species, etc.)
- D. Make all results available for unusual clinical situations.
- E. Examples of selective reporting based on organism identification and overall antibiogram
 - 1. *Enterobacteriaceae*
 - a. If isolate is resistant to first-generation cephalosporins, *Then* report second-generation cephalosporins.
 - b. If isolate is resistant to gentamicin, *Then* report tobramycin or amikacin or both.
 - 2. *Pseudomonas aeruginosa*
If isolate is resistant to ceftazidime, piperacillin, and aminoglycosides, *Then* report imipenem.
- F. Examples of selective reporting according to body site
 - 1. Report results for drugs (e.g., cefotaxime, ceftriaxone) that cross the blood-brain barrier on CSF isolates, if appropriate for the organism group.
Do not report agents administered only by the oral route or aminoglycosides, first- and second-generation cephalosporins, clindamycin, fluoroquinolones, macrolides, or tetracyclines, as these are ineffective in treating meningitis.
 - 2. Report results for agents (e.g., nitrofurantoin, norfloxacin) that are used only for treating urinary tract infections on urine isolates only.
 - 3. Some antimicrobial agents are inappropriate for treatment of infections caused by certain bacteria, even if the in vitro results indicate that the isolate is susceptible. These include the following.
 - a. Beta-lactams (penicillins, cephalosporins, beta-lactam–beta-lactamase inhibitor combinations, imipenem) for methicillin-resistant staphylococci
 - b. Cephalosporins, aminoglycosides (except high-level screens), clindamycin, and trimethoprim-sulfamethoxazole for enterococci
 - c. Cephalosporins for *Listeria* spp.
 - d. First- or second-generation cephalosporins and aminoglycosides for *Salmonella* spp. and *Shigella* spp.
 - e. Penicillins, cephalosporins, and aztreonam on extended-spectrum beta-lactamase-producing *Escherichia coli* and *Klebsiella* spp.
- G. Selective reporting may not be practiced by institutions where there are other mechanisms in place to prevent physicians from prescribing antimicrobial agents inappropriately.

APPENDIX 5.16–1

Reference chart for commonly used antimicrobial agents^a

Drug family and generic name (route[s] of administration)	Product name(s) ^b	Primary spectrum of activity		Mode of action	Clinical use; comments
		Gram positive	Gram negative		
Penicillins					
Natural penicillins					
Penicillin G (i.m., i.v.)	Various product names	×		Inhibition of cell wall synthesis	Community-acquired meningitis in normal hosts due to pneumococci, meningococci, or <i>Listeria</i> spp.; serious streptococcal infection (e.g., endocarditis, bacteremia, and osteomyelitis), serious enterococcal infections (given in combination with gentamicin); anaerobic infections other than those caused by <i>Bacteroides fragilis</i> ; <i>Pasteurella</i> spp.
Penicillin V (p.o.)	Various product names	×		Inhibition of cell wall synthesis	Streptococcal pharyngitis/otitis, skin and soft tissue infections
Extended-spectrum penicillins					
Aminopenicillins					
Ampicillin (p.o., i.m., i.v.)	Various product names	×	×	Inhibition of cell wall synthesis	Same as penicillin G plus infections caused by <i>E. coli</i> , <i>Salmonella</i> spp., <i>Haemophilus influenzae</i> (beta-lactamase negative), and <i>Proteus mirabilis</i> ; amoxicillin is used for less serious infections.
Amoxicillin (p.o.)	Various product names				
Carboxypenicillins					
Carbenicillin (p.o., i.m., i.v.)	Geopen, Geocillin, Pyopen		×	Inhibition of cell wall synthesis	Used in combination with an aminoglycoside for serious infections due to susceptible <i>Enterobacteriaceae</i> (<i>Klebsiella</i> spp. are resistant) and <i>P. aeruginosa</i> ; oral carbenicillin is used exclusively for urinary tract infections.
Ticarcillin (i.m., i.v.)	Ticar				
Ureidopenicillins					
Azlocillin (i.v.)	Azlin		×	Inhibition of cell wall synthesis	Same as carboxypenicillins, with enhanced activity against <i>Enterobacteriaceae</i> (including <i>Klebsiella</i> spp.), <i>P. aeruginosa</i> , and <i>Bacteroides</i> spp.
Mezlocillin (i.m., i.v.)	Mezlin				
Piperacillin (i.m., i.v.)	Pipracil				
Penicillinase-stable penicillins					
Methicillin (i.m., i.v.)	Staphcillin	×		Inhibition of cell wall synthesis	Staphylococcal infections due to strains susceptible to penicillinase-stable penicillins; will cover most streptococci (but not enterococci); oral agents (cloxacillin, dicloxacillin) used for less serious infections.
Nafcillin (p.o., i.m., i.v.)	Nafcil, Nalipen, Unipen				
Isoxazolyl penicillins					
Oxacillin (p.o., i.m., i.v.)	Prostaphlin				
Cloxacillin (p.o.)	Tegopen				
Dicloxacillin (p.o.)	Dynapen, Pathocil				
Amidinopenicillin					
Mecillinam (p.o.)	CoActin		×	Inhibition of cell wall synthesis	Acute uncomplicated urinary tract infections

(continued)

APPENDIX 5.16–1 (continued)

Reference chart for commonly used antimicrobial agents^a (continued)

Drug family and generic name (route[s] of administration)	Product name(s) ^b	Primary spectrum of activity		Mode of action	Clinical use; comments
		Gram positive	Gram negative		
Beta-lactam–beta-lactamase inhibitor combinations		×	×	Inhibition of cell wall synthesis	Moderate to severe mixed infections due to aerobic and anaerobic bacteria (e.g., intra-abdominal and pelvic infections, aspiration pneumonia, etc.); amoxicillin-clavulanic acid is used for upper and lower respiratory tract infections due to <i>H. influenzae</i> , <i>Moraxella catarrhalis</i> , <i>Staphylococcus aureus</i> , and anaerobes; the beta-lactamase-inhibiting component facilitates activity against beta-lactamase-producing <i>Staphylococcus</i> spp. (methicillin susceptible), <i>H. influenzae</i> , and <i>Bacteroides</i> spp.
Amoxicillin-clavulanic acid (p.o.)	Augmentin				
Ticarcillin-clavulanic acid (i.v.)	Timentin				
Ampicillin-sulbactam (i.v.) Piperacillin-tazobactam (i.v.)	Unasyn Zosyn				
Cephems, ^d parenteral					
Cephalosporins					
Narrow spectrum (first generation)		×	×	Inhibition of cell wall synthesis	Surgical prophylaxis; community-acquired pulmonary, skin and soft tissue, and urinary tract infections; staphylococcal osteomyelitis and soft tissue infection; active against many gram-positive cocci other than methicillin-resistant staphylococci and enterococci; active against some <i>Enterobacteriaceae</i> , including many strains of <i>E. coli</i> , <i>P. mirabilis</i> , <i>Klebsiella</i> spp., and most anaerobes (other than <i>B. fragilis</i>).
Cefazolin (i.m., i.v.) Cephalothin (i.m., i.v.) Cephapirin (i.m., i.v.) Cephadrine (p.o., i.m., i.v.)	Kefzol, Zolicef Keflin Cefadyl Anspor, Velosef				
Extended spectrum (second generation)		×	×	Inhibition of cell wall synthesis	Community-acquired pulmonary, skin, and soft tissue infections, and exacerbations of chronic obstructive pulmonary disease; slightly more active than first-generation agents against <i>Enterobacteriaceae</i> (increased beta-lactamase stability) and less active against staphylococci
Cefamandole (i.m., i.v.) Cefuroxime-sodium (i.m., i.v.) Cefonicid (i.m., i.v.) Cephameycins ^f Cefotetan (i.v.) Cefoxitin (i.m., i.v.) Cefmetazole (i.v.)	Mandol Zinacef, Kefurox Monocid Cefotan Mefoxin Zefazone				
Extended spectrum (third generation)		×	×	Inhibition of cell wall synthesis	The cephamycins are used for mild to moderate mixed infections (e.g., intra-abdominal and pelvic infections, aspiration pneumonia, etc.) and surgical prophylaxis in gastrointestinal, obstetric, and gynecological procedures. The cephamycins have good activity against <i>B. fragilis</i> . Used in combination with aminoglycoside for serious infections caused by susceptible <i>Enterobacteriaceae</i> and <i>P. aeruginosa</i> ; used alone for childhood meningitis due to <i>H. influenzae</i> and gram-negative bacillary meningitis. Ceftriaxone is used for gonorrhea and Lyme disease. Have greatly increased activity against gram-negative bacilli because of increased beta-lactamase stability. Compared to other cepheems, most have activity against <i>P. aeruginosa</i> (particularly ceftazidime) and CSF penetration; however, they are not as active against staphylococci.
Cefoperazone (i.m., i.v.)	Cefobid				
Cefotaxime (i.m., i.v.)	Claforan				
Ceftizoxime (i.m., i.v.)	Cefizox				
Ceftriaxone (i.m., i.v.)	Rocephin				
Ceftazidime (i.m., i.v.)	Fortaz, Tazicef, Tazidime				

APPENDIX 5.16–1 (continued)

Drug family and generic name (route[s] of administration)	Product name(s) ^b	Primary spectrum of activity		Mode of action	Clinical use; comments
		Gram positive	Gram negative		
Extended spectrum (fourth generation) Cefepime (i.v.)	Maxipime	×	×	Inhibition of cell wall synthesis	Similar to third-generation cephalosporins, with enhanced activity against organisms that produce inducible beta-lactamases (e.g., <i>Enterobacter cloacae</i>); activity against gram-positive bacteria is similar to that of cefotaxime and activity against gram-negative bacteria is similar to that of ceftazidime, to include good antipseudomonal activity.
Cephems, p.o. Cephalosporins Cefaclor Cefadroxil Cefdinir Cefditoren Cefixime Cefpodoxime Cefprozil Cefuroxime-axetil Cephalexin Cephadrine Ceftibuten Carbacephem Loracarbef	Ceclor Duricef, Ultracef Omnicef Spectracef Suprax Vantin Cefzil Ceftin Keflex, Biocef Anspor, Velosef Cedax Lorabid	×	×	Inhibition of cell wall synthesis	Community-acquired upper respiratory tract, ear, urinary tract, skin, and soft tissue infections; cefaclor, loracarbef, cefprozil, and cefuroxime are more active than the others against <i>Haemophilus</i> spp. and <i>M. catarrhalis</i> .
Monobactam Aztreonam (i.v.)	Azactam		×	Inhibition of cell wall synthesis	Infections caused by aerobic gram-negative bacilli in patients allergic to other beta-lactams; activity is comparable to that of third-generation cephalosporins against <i>P. aeruginosa</i> and <i>Enterobacteriaceae</i> , inactive against gram-positive organisms and anaerobes.
Carbapenems Ertapenem (i.m., i.v.) Imipenem (i.v.) Meropenem (i.v.)	Invanz Primaxin Merrem	×	×	Inhibition of cell wall synthesis	Imipenem and meropenem are used for severe mixed infections (e.g., intra-abdominal and pelvic infections and aspiration pneumonia) and infections caused by multiply resistant gram-negative bacilli, including <i>P. aeruginosa</i> ; highly active against most gram-positive organisms (but not against methicillin-resistant staphylococci, <i>Enterococcus faecium</i> , or diphtheroids); and the most active beta-lactams against <i>Enterobacteriaceae</i> and <i>P. aeruginosa</i> . Like the cephalosporins, carbapenems have poor activity against <i>Stenotrophomonas maltophilia</i> and <i>Burkholderia cepacia</i> ; active against <i>B. fragilis</i> . Ertapenem has no activity against <i>P. aeruginosa</i> and slightly less activity against the other organisms mentioned above; is primarily for intra-abdominal and pelvic infections.

(continued)

APPENDIX 5.16–1 (continued)

Reference chart for commonly used antimicrobial agents^a (continued)

Drug family and generic name (route[s] of administration)	Product name(s) ^b	Primary spectrum of activity		Mode of action	Clinical use; comments
		Gram positive	Gram negative		
Aminocyclitols ^c Spectinomycin (i.m.) Trospectinomycin (i.m., i.v.)	Trobicin			Interference with protein synthesis at the 30S ribosomal subunit	Gonorrhea only; however, largely replaced by ceftriaxone or a quinolone
Aminoglycosides Gentamicin (i.m., i.v.)	Garamycin, Genticin	×	×	Interference with protein synthesis at the 30S ribosomal subunit	Moderate to severe infections caused by aerobic gram-negative bacilli; often used in combination with a beta-lactam agent, e.g., in combination with ampicillin or penicillin (or sometimes vancomycin) for synergistic killing of enterococci, streptococci, and staphylococci causing endocarditis.
Tobramycin (i.m., i.v.)	Nebcin, Tobrex				Gram-negative infections, indications similar to those for gentamicin; compared with gentamicin, has slightly increased activity against <i>P. aeruginosa</i> and sometimes decreased activity against <i>Serratia marcescens</i> .
Amikacin (i.m., i.v.)	Amikin				Gram-negative infections, indications similar to those for gentamicin; has increased activity against gentamicin- and tobramycin-resistant isolates.
Netilmicin (i.m., i.v.)	Netromycin				Gram-negative infections, indications similar to those for gentamicin; slightly less active than other aminoglycosides against <i>P. aeruginosa</i> and <i>S. marcescens</i> .
Neomycin (p.o., topical)	Mycifradin, Neobiotic				Oral and topical use only for gastrointestinal tract decontamination and superficial infections, respectively
Kanamycin (p.o.)	Kantrex, Klebcil				Oral and topical use, similar to neomycin; parenteral forms infrequently used
Streptomycin (i.m., i.v.)	Streptomycin				Used in combination with ampicillin or penicillin (or sometimes vancomycin) for synergistic killing of enterococci or streptococci causing endocarditis.
Ansamycin Rifampin (p.o., i.v.)	Rifadin, Rimactane	×		Inhibition of DNA transcription	Used in combination with antistaphylococcal agents to enhance antibacterial activity, especially in osteomyelitis and endocarditis; first-line agent for tuberculosis in combination with isoniazid; prophylaxis for meningococcal disease; rifabutin for mycobacterial infections only
Quinolones (narrow spectrum) Cinoxacin (p.o.) Garenoxacin (p.o., i.v.) ^c Nalidixic acid (p.o.)	Cinobac NegGram	×	×	Inhibition of DNA gyrase activity	Cinoxacin and nalidixic acid, lower urinary tract infection only; are inactive against <i>P. aeruginosa</i> and have limited activity against gram-positive bacteria. Garenoxacin is like fluoroquinolones in its spectrum against respiratory pathogens; is active against <i>Enterobacteriaceae</i> and has some activity against <i>P. aeruginosa</i> .

APPENDIX 5.16–1 (continued)

Drug family and generic name (route[s] of administration)	Product name(s) ^b	Primary spectrum of activity		Mode of action	Clinical use; comments
		Gram positive	Gram negative		
Fluoroquinolones (broader spectrum)		×	×	Inhibition of DNA gyrase activity	Norfloxacin and ofloxacin, uncomplicated and complicated urinary tract infections, gonorrhea, and prostatitis. Ciprofloxacin, moderate to severe infections caused by gram-negative bacilli (especially pulmonary, bone, and joint infections); has limited activity against gram-positive bacteria; is active against <i>P. aeruginosa</i> . The other drugs have enhanced activity against gram-positive bacteria; used for respiratory tract infections, including acute exacerbations of chronic bronchitis caused by common respiratory pathogens (<i>H. influenzae</i> , <i>M. catarrhalis</i> , and <i>S. pneumoniae</i>) and also atypical organisms (<i>Legionella</i> spp., <i>Mycoplasma pneumoniae</i> , <i>Chlamydia pneumoniae</i>); have little activity against <i>P. aeruginosa</i> (except levofloxacin, which is also active against gram-negative bacteria)
Norfloxacin (p.o.)	Noroxin				
Ofloxacin (p.o., i.v.)	Floxin				
Ciprofloxacin (p.o., i.v.)	Cipro				
Gatifloxacin (p.o., i.v.)	Tequin				
Levofloxacin (p.o., i.v.)	Levaquin				
Lomefloxacin (p.o.)	Maxaquin				
Moxifloxacin (p.o., i.v.)	Avelox				
Folate pathway inhibitors					
Sulfonamides (p.o., i.v.)	Various product names	×	×	Competitive inhibition of folic acid synthesis	Uncomplicated lower urinary tract infections and nocardiosis
Trimethoprim-sulfamethoxazole (p.o., i.v.)	Bactrim, Septra		×	Competitive inhibition of folic acid synthesis	Acute and chronic urinary tract infections; bacterial diarrhea; infections caused by <i>Enterobacteriaceae</i> ; acute and chronic community-acquired upper respiratory tract infections; also used to treat <i>Pneumocystis carinii</i> infections.
Trimethoprim (p.o.)	Proloprim, Trimplex		×	Inhibition of folic acid synthesis	Uncomplicated lower urinary tract infections and prophylaxis for recurrent urinary tract infections
Fosfomycin					
Fosfomycin (p.o.)	Monurol	×	×	Inhibition of pyruvyl transferase enzyme	Acute uncomplicated urinary tract infections due to <i>E. coli</i> and <i>Enterococcus faecalis</i>
Ketolide					
Telithromycin ^c (p.o.)	Ketek	×	×	Binds to 50S ribosomal subunit, blocking the initiation of peptide chains	Respiratory infections caused by common and atypical and intracellular or cell-associated respiratory pathogens, including those that are resistant to beta-lactam and/or macrolide-lincosamide-streptogramin B antimicrobials
Lincosamide					
Clindamycin (p.o., i.m., i.v.)	Cleocin	×		Binds to 50S ribosomal subunit, blocking the initiation of peptide chains	Anaerobic infections (including those caused by <i>B. fragilis</i>); gram-positive bone and joint infections in children

(continued)

APPENDIX 5.16–1 (continued)

Reference chart for commonly used antimicrobial agents^a (continued)

Drug family and generic name (route[s] of administration)	Product name(s) ^b	Primary spectrum of activity		Mode of action	Clinical use; comments
		Gram positive	Gram negative		
Lipopeptide Daptomycin ^c (i.v.)	Cidecin	×		Disruption of multiple aspects of bacterial plasma membrane function	Bacteremia, endocarditis, and skin and soft tissue infections caused by gram-positive bacteria; active against VRE and MRSA.
Macrolides Azithromycin (p.o., i.v.) Clarithromycin (p.o.) Erythromycin (p.o., i.v.) Dirithromycin ^c (p.o.)	Zithromax Biaxin Various product names Dynabac	×		Binds to 50S ribosomal subunit, blocking the initiation of peptide chains	Upper and lower respiratory tract infections caused by gram-positive organisms (pneumococci or group A streptococci) in penicillin-allergic patients; pertussis, <i>Campylobacter</i> , <i>M. pneumoniae</i> , <i>Chlamydia trachomatis</i> , <i>Legionella</i> spp., and <i>H. influenzae</i> (azithromycin and clarithromycin); less serious staphylococcal infections; clarithromycin is used in combination with other agents for some mycobacterial infections.
Nitrofurantoin (p.o.)	Furadantin, Macro-dantin	×	×	Inhibition of a variety of bacterial enzyme systems	Acute and chronic lower urinary tract infections; inactive against <i>S. marcescens</i> , <i>Proteus</i> spp., and <i>P. aeruginosa</i>
Nitroimidazole Metronidazole (p.o., i.v.)	Flagyl			Inhibition of DNA replication	Anaerobic infection; vaginitis caused by <i>Gardnerella vaginalis</i> and <i>Trichomonas vaginalis</i> ; <i>Clostridium difficile</i> toxin-associated diarrhea and colitis
Oxazolidinone Linezolid (p.o., i.v.)	Zyvox	×		Inhibition of initiation of bacterial protein synthesis	Complicated and uncomplicated skin and soft tissue infections; community- and hospital-acquired pneumonia; drug-resistant gram-positive infections (including MRSA and VRE)
Glycopeptides Vancomycin (p.o., i.v.) Teicoplanin ^c (i.m., i.v.) (lipoglycopeptide)	Vancocin Targocid	×		Inhibition of cell wall synthesis	Methicillin-resistant staphylococcal infection and gram-positive infection in penicillin-allergic patients; oral form for <i>C. difficile</i> toxin-associated diarrhea/colitis; is inactive against <i>Lactobacillus</i> spp., <i>Pediococcus</i> spp., <i>Leuconostoc</i> spp., and <i>Erysipelothrix</i> spp.
Phenicol Chloramphenicol (p.o., i.v.)	Chloromycetin	×	×	Prevents mRNA from attaching to ribosomes	Childhood meningitis (e.g., that caused by <i>S. pneumoniae</i> , <i>H. influenzae</i> , and <i>Neisseria meningitidis</i>); typhoid fever; anaerobic infections (especially brain abscesses); salmonellosis

APPENDIX 5.16–1 (continued)

Drug family and generic name (route[s] of administration)	Product name(s) ^b	Primary spectrum of activity		Mode of action	Clinical use; comments
		Gram positive	Gram negative		
Streptogramin Quinupristin-dalfopristin	Synercid	×		Inhibition of substrate attachment and inhibition of peptide chain elongation (50S ribosome)	Complicated skin and skin structure infections caused by <i>S. aureus</i> and group A streptococci; <i>E. faecium</i> (inactive against <i>E. faecalis</i>)
Tetracyclines Short-acting tetracycline Tetracycline (p.o., i.m., i.v.)	Various product names	×	×	Interference with protein synthesis at the 30S ribosomal subunit	Not often used as directed therapy for common bacterial infections; however, used for brucellosis and chlamydial, mycoplasmal, and rickettsial infections.
Long-acting tetracyclines Doxycycline (p.o., i.v.) Minocycline (p.o.)		Vibramycin Minocin, Vectrin			

^a i.m., intramuscularly; p.o., orally; i.v., intravenously; VRE, vancomycin-resistant enterococci; MRSA, methicillin-resistant *S. aureus*.

^b Denotes the product name(s) according to *Facts and Comparisons* or according to the manufacturer.

^c Investigational agent; not Food and Drug Administration approved as of January 2003.

^d Cephems have no activity against methicillin-resistant staphylococci, enterococci, or *Listeria* spp.

^e Active against *Neisseria gonorrhoeae*.

^f These agents are cepheems but *not* cephalosporins.

Evaluating Antimicrobial Susceptibility Test Systems

I. PRINCIPLE

A wide variety of antimicrobial susceptibility test systems are available to microbiologists today. This procedure provides guidance on evaluating and choosing a system or method appropriate for your laboratory. The primary focus should be on determination of the systems' capabilities, assessment of costs and work flow, and examination of performance data.

Obviously, not every laboratory has the resources for performing the detailed eval-

uation described here. When smaller laboratories are faced with decision making regarding a new antimicrobial test system, they must rely primarily on published data, information supplied by the manufacturer, and information supplied by other users of the system. However, every laboratory should undertake a limited study (at least 50 isolates of various spe-

cies, various antimicrobial susceptibility profiles, and NCCLS QC strains should be tested) so that performance can be assessed on a small scale and, more important, so that technologists and supervisory personnel can get a feel for how the system works and how it would fit into the laboratory's work flow.

II. MATERIALS

- A. Marketing literature from manufacturers
- B. Package inserts from systems being evaluated
- C. Pertinent scientific journal articles and abstracts
- D. QC organisms
- E. Clinical isolates
- F. Challenge isolates
- G. Media for storage of QC and test isolates (2) (*see* procedure 5.13)
- H. Appropriate agar media
Store at 2 to 8°C.
- I. McFarland standards (store at room temperature in the dark) or turbidity standard method recommended by the manufacturer (e.g., nephelometer or colorimeter)
- J. Materials necessary to set up reference system (usually agar dilution [2], broth microdilution [2], or disk diffusion)
- K. Materials necessary to set up each test system according to instructions in the package insert (e.g., cytochrome oxidase, sterile saline, disposable test tubes, coagulase test method)
- L. Required storage equipment for materials and disposables (e.g., -70°C freezer, -20°C non-frost-free freezer, 2 to 8°C refrigerator)

III. PROCEDURE

- A. Consider the following when choosing an antimicrobial susceptibility test system to evaluate.
 1. Performance
 - a. Examine independent evaluations in peer-reviewed journals. Note the following to determine validity of study.
 - (1) Number of isolates tested
 - (2) Specific organism-antimicrobial agent combinations tested
 - (3) Number of clinically significant resistant isolates included
 - (4) Number of institutions included in study
 - (5) Reference method used for comparison
 - (6) Method used for data correlation
 - (7) Date of study (Changes may have been made since study was performed.)
 - b. Examine recent data provided by manufacturer.
 - c. Abstracts may provide additional information on product performance, but these are not subjected to peer review, and methods are often sketchy.
 2. Cost
 - a. Capital equipment
 - b. Per test
 - c. Maintenance
 - d. Technical assistance (e.g., training)
 - e. Software updates
 3. Practical considerations
 - a. Space requirements
 - b. Electrical requirements
 - c. Instrument noise
 - d. Instrument capacity
 - e. Current customer satisfaction
 - f. Ease of use, personnel requirements
 - g. Biohazardous waste generated
 - h. Shelf lives of disposable materials
 - i. Storage requirements of disposable materials
 - j. Environmental requirements
 - (1) Temperature
 - (2) Humidity
 - k. Organism identification capabilities of system
 - l. Instrument downtime
 4. Software
 - a. Computer interface capabilities
 - b. Data management capabilities
 - c. Frequency of updates
 - d. Ease of updates
 - e. Availability of selective reporting
 5. Manufacturer's support
 - a. Service response time
 - b. Availability of technical assistance
 - c. Order response time
 6. Technical considerations
 - a. Range of dilutions reported per antimicrobial agent
 - b. Flexibility of antimicrobial agent selection
 - c. QC required
 - d. Response time for adding new antimicrobial agents

III. PROCEDURE*(continued)*

- e. Range of organisms tested by system (*Haemophilus* spp., other fastidious organisms, anaerobes, etc.)
 - f. Number and type of disclaimed antimicrobial agent-organism combinations
 - g. Compliance with NCCLS recommendations
 - h. Result reported
 - (1) Quantitative (MIC)
 - (2) Qualitative (breakpoint)
 - i. Food and Drug Administration cleared
 - j. Backup method requirement
 - k. Length of time before results can be reported
 - l. Compatibility with identification system
 - m. Number of antimicrobial agents available
7. Work flow considerations
- a. Inoculum
 - (1) Source
 - (a) Age of culture
 - (b) Medium
 - (2) Inoculation fluid
 - (3) Preincubation
 - (4) Standardization
 - (a) Visual
 - (b) Instrument assisted
 - (5) Inoculation process
 - (a) Manual
 - (b) Automated
 - (6) Same suspension for identification and susceptibility?
 - b. Labeling
 - (1) Manual
 - (2) Bar codes
 - (3) Other (e.g., computer keyboard entry)
 - c. Data-test entry
 - d. Time before reports become available
- B. Devise a strategy for evaluating antimicrobial susceptibility test systems.
1. Determine systems to be compared.
 2. Determine reference method.
 - a. NCCLS-approved standard method (2) (recommended)
 - b. Laboratory's current method or other test system with NCCLS-approved standard method to resolve discrepancies
 3. Review methods to be tested.
 4. Determine antimicrobial agents to be tested.
 5. Determine strains to be tested.
 - a. Test a minimum of 50 fresh and recent clinical isolates (1 isolate of a given species per patient) representing a wide variety of species. Fresh isolates are those which have never been frozen and have been on agar for less than 7 days.
 - b. Test a minimum of 50 challenge strains (organisms with varied resistance patterns for each antimicrobial agent to be evaluated).
 - (1) Beta-lactam antimicrobial agents
 - (a) Organisms resistant to extended-spectrum cephalosporins
 - i. *Enterobacter cloacae*
 - ii. *Enterobacter aerogenes*
 - iii. *Citrobacter freundii*
 - iv. *Serratia marcescens*

III. PROCEDURE*(continued)*

- v. *Pseudomonas aeruginosa*
- vi. Indole-positive *Proteaeae* (e.g., *Morganella morganii* and *Providencia* spp.)
- vii. Extended-spectrum beta-lactamase-producing *Klebsiella* spp. and *Escherichia coli*
- (b) Imipenem-resistant *P. aeruginosa*
- (c) Ampicillin-resistant *E. coli*
- (d) Piperacillin-resistant *Klebsiella* spp.
- (e) Methicillin-resistant staphylococci
 - i. *Staphylococcus aureus*
 - ii. Coagulase-negative staphylococci
- (f) Ampicillin-resistant *Enterococcus faecium*
- (2) Aminoglycosides
 - (a) Gentamicin-resistant organisms
 - i. Members of the family *Enterobacteriaceae*
 - ii. Staphylococci
 - iii. *P. aeruginosa*
 - (b) Amikacin-resistant organisms
 - i. *Enterobacteriaceae*
 - ii. *P. aeruginosa*
 - (c) Tobramycin-resistant *P. aeruginosa*
 - (d) High-level aminoglycoside-resistant enterococci
- (3) Fluoroquinolone-resistant organisms
 - (a) *Enterobacteriaceae*
 - (b) Staphylococci
 - (c) *P. aeruginosa*
- (4) Vancomycin-resistant enterococci
- (5) Clindamycin-resistant staphylococci
- (6) Erythromycin-resistant staphylococci
- (7) For fastidious organism panels
 - (a) *Streptococcus pneumoniae*
 - i. Penicillin resistant and intermediate
 - ii. Extended-spectrum cephalosporin resistant and intermediate
 - iii. Fluoroquinolone resistant
 - (b) *Streptococcus* species
 - i. Penicillin-resistant and -intermediate viridans group streptococci
 - ii. Macrolide-resistant *Streptococcus* species
 - iii. Clindamycin-resistant *Streptococcus* species
- c. The evaluation process may be improved if more than 50 to 100 isolates are tested. It is not unreasonable for a larger laboratory to test 100 to 300 isolates.
- d. Test a minimum of five strains in triplicate for 3 days to determine reproducibility of system.
 - (1) Choose a variety of species.
 - (2) Choose strains with a history of reproducible results by another method.
 - (3) Choose resistant isolates and isolates for which the MICs are on-scale.
- 6. Define procedural parameters.
 - a. General techniques
 - (1) Subculture stock isolates to nonselective media twice before testing.
 - (2) Pick one colony from the first subculture to make the second subculture.

III. PROCEDURE*(continued)*

- (3) Use fresh isolates (less than 24 h old).
 - (4) Run test system and reference method in parallel on the same day from the same inoculum if possible.
 - (5) Run recommended NCCLS QC strains (2) along with manufacturer's recommended QC strains daily.
 - (6) Plate inoculum to check purity.
 - (7) Save all isolates tested.
 - (a) For short-term storage (<2 weeks), use soybean casein digest agar slants at 2 to 8°C (2).
 - (b) For long-term storage, use brucella broth with 15% glycerol and freeze at -20°C or lower (preferably -70°C).
 - (8) Retest isolates with insufficient growth. Confirmed growth failures of >10% for any genus or species tested indicate that the system might be unreliable for that specific group.
- b.** Procedural techniques defined by each system
 - (1) Inoculum
 - (2) Storage of test kits
 - (3) Required reagents and media
 - (4) Acceptable organisms to test in specific system
 - (5) Proper incubation time and temperature
- C.** Compare test result with reference result (providing QC is acceptable).
- 1.** MIC (quantitative) comparison

A valid quantitative comparison can be made only when more than three consecutive twofold dilutions are tested (1)

 - a.** Essential agreement

Test result is ± 1 doubling dilution from reference result. For example, if the reference result is 2 $\mu\text{g/ml}$, the test result could be 1, 2, or 4 $\mu\text{g/ml}$ and be in essential agreement.
 - b.** Exact agreement

Test result and reference result have the same MIC.
 - 2.** Category (qualitative) comparison (*see* Appendix 5.17-1)
 - a.** Agreement

Category results are identical.
 - b.** Very major error

Test result shows susceptibility, and reference result shows resistance.
 - c.** Major error

Test result shows resistance, and reference result shows susceptibility.
 - d.** Minor error

Test result shows resistance or susceptibility and reference result shows intermediate, or test result shows intermediate and reference result shows resistance or susceptibility.
 - 3.** Essential versus category agreement (example)
 - a.** Breakpoints for tobramycin
 - (1) Susceptible = $\leq 4 \mu\text{g/ml}$
 - (2) Intermediate = 8 $\mu\text{g/ml}$
 - (3) Resistant = $\geq 16 \mu\text{g/ml}$
 - b.** Dilutions tested: 0.5, 1, 2, 4, 8, and 16 $\mu\text{g/ml}$
 - c.** Essential but not category agreement
 - (1) Reference = 8 $\mu\text{g/ml}$ (intermediate)
 - (2) Test = 4 $\mu\text{g/ml}$ (susceptible)
 - d.** Category but not essential agreement
 - (1) Reference = 4 $\mu\text{g/ml}$ (susceptible)
 - (2) Test = 0.5 $\mu\text{g/ml}$ (susceptible)

III. PROCEDURE*(continued)*

4. Resolution of discrepancies
 - a. Repeat all tests with major and very major errors in triplicate for both systems (1)
 - b. Repeat tests with significant minor errors.
 - (1) Antimicrobial agents with >10% minor errors
 - (2) Minor errors that may influence antimicrobial therapy
 - c. Repeat all tests with MIC errors (i.e., that do not have essential agreement or that are $> \pm 1$ doubling dilution from reference).
 - d. Use NCCLS standard method (2) to resolve discrepancies that exist after both methods have been repeated.
 - e. Use results obtained from retests to correlate data.
- D. Correlate data.
 1. Percent essential agreement =
$$\frac{\text{number of tests within } \pm 1 \text{ doubling dilution from reference}}{\text{number of organisms tested}} \times 100$$
 2. Calculate essential agreement for the following.
 - a. Overall (all organisms and all antimicrobial agents)
 - b. Each antimicrobial agent with all organisms
 - c. Each organism with all antimicrobial agents
 - d. Each antimicrobial agent for each group of organisms
 3. Percent category agreement =
$$\frac{\text{number of tests with no category errors}}{\text{number of organisms tested}} \times 100$$
 4. Calculate category agreement for the following.
 - a. Overall (all organisms and all antimicrobial agents)
 - b. Each antimicrobial agent with all organisms
 - c. Each organism with all antimicrobial agents
 - d. Each antimicrobial agent for each group of organisms
 5. Percent minor (or very major or major) errors =
$$\frac{\text{number of tests with minor (or very major or major) errors}}{\text{number of organisms tested}} \times 100$$
 6. Calculate minor (or very major or major) errors for the following.
 - a. Overall (all organisms and all antimicrobial agents)
 - b. Each antimicrobial agent with all organisms
 - c. Each organism with all antimicrobial agents
 - d. Each antimicrobial agent for each group of organisms
- E. Record results on display sheet that summarizes total performance of a single antimicrobial agent for the various organism groups, and include overall performance of the drug (Appendix 5.17-2).
- F. Record results on display sheet that summarizes essential and categoric agreement for each drug and each organism group, and include overall performance (Appendix 5.17-3).

IV. INTERPRETATION OF CORRELATIONS

- A. Essential agreement should be >90% for each organism group-antimicrobial agent combination (1).
- B. For reproducibility testing, results for each antimicrobial agent should be within ± 1 doubling dilution 95% of the time (1).
- C. Recommended acceptable category guidelines are as follows.

- 1. Food and Drug Administration guidelines for manufacturers (1)

- a. Very major errors

- (1) Very major errors must be $\leq 1.5\%$.
 - (2) Calculate very major errors from the number of resistant isolates.

$$\% \text{ very major errors} = \frac{\text{number of very major errors}}{\text{total number of resistant isolates}} \times 100$$

- (3) Test at least 20 resistant strains representing each known mechanism of resistance for each antimicrobial agent. For example, for methicillin-resistant staphylococci, test organisms with altered penicillin-binding proteins and test hyper-beta-lactamase producers.

- b. Major errors

- (1) Major errors must be $\leq 3.0\%$.
 - (2) Calculate major errors from the number of susceptible isolates.

$$\% \text{ major errors} = \frac{\text{number of major errors}}{\text{total number of susceptible isolates}} \times 100$$

- D. Significance of errors

- 1. Even though tolerance levels have been established for errors, examine all errors closely to identify any trends that may have a significant clinical impact. Some results may be more significant than others, depending on the particular medical community's needs.

- 2. Minor errors, examples

- a. Ceftriaxone versus *Enterobacter* species

- (1) Errors
 - (a) Very major, 0.2%
 - (b) Major, 0.1%
 - (c) Minor, 4%
 - (2) Example of minor error: reference = >32 $\mu\text{g/ml}$ (resistant) and test = 16 $\mu\text{g/ml}$ (intermediate)
 - (3) Concern

Laboratories servicing physicians involved in at-home intravenous antimicrobial therapy programs require reliable results with this agent. Therefore, if most of the errors are similar to the example, a 4% minor error rate might be unacceptable.

- b. Tobramycin versus *P. aeruginosa*

- (1) Errors
 - (a) Very major, 0.3%
 - (b) Major, 0.2%
 - (c) Minor, 3%
 - (2) Example of minor error: reference = 8 $\mu\text{g/ml}$ (intermediate) and test = 2 $\mu\text{g/ml}$ (susceptible)
 - (3) Other aminoglycoside results
 - (a) Amikacin = 8 $\mu\text{g/ml}$ (susceptible)
 - (b) Gentamicin = >16 $\mu\text{g/ml}$ (resistant)

IV. INTERPRETATION OF CORRELATIONS (continued)

- (4) Concern
A physician prescribing an aminoglycoside would select amikacin on the basis of reference results but tobramycin or amikacin on the basis of test results. If most minor errors are similar to the example, a 3% minor error rate might be unacceptable.
 3. Major errors, examples
 - a. Oxacillin versus *S. aureus*
 - (1) Errors
 - (a) Very major, 0.2%
 - (b) Major, 3%
 - (2) Example of major error: reference = 2 µg/ml (susceptible) and test = 8 µg/ml (resistant)
 - (3) Concern
A physician would select oxacillin on the basis of the reference result but probably vancomycin on the basis of the test result. This would result in increased patient care costs due to patient isolation and the expense of the antimicrobial agent. In this case, a 3% major error rate might be unacceptable.
 - b. Cefazolin versus *Klebsiella pneumoniae*
 - (1) Errors
 - (a) Very major, 0.5%
 - (b) Major, 2%
 - (2) Example of major error: reference = 4 µg/ml (susceptible) and test = 32 µg/ml (resistant)
 - (3) Concern
A physician may choose cefazolin on the basis of the reference result but an aminoglycoside or a broad-spectrum cephalosporin on the basis of the test result. This increases patient risk because of the toxic effects of aminoglycosides and also increases the cost of therapy.
 4. Very major errors, examples
Very major errors are the most significant type of error. With certain organism-antimicrobial agent combinations, some of these errors have a great impact on patient therapy and prognosis. This is especially true when the antimicrobial agent is the drug of choice and/or the infection is serious (e.g., endocarditis, osteomyelitis, septicemia). Examples of very major errors that have a high likelihood of resulting in clinical failure are as follows.
 - a. Oxacillin versus *S. aureus*
 - b. Tobramycin versus *P. aeruginosa*
 - c. Cefotaxime versus *Enterobacter* spp.
- E. Putting performance data in perspective
1. Some antimicrobial agents are not recommended for treatment of infections caused by certain organisms regardless of in vitro test results. Major and very major errors with these combinations may therefore not be as significant.
 - a. Trimethoprim-sulfamethoxazole versus enterococci
 - b. Ampicillin versus *P. aeruginosa*
 - c. Cephalothin versus methicillin-resistant *S. aureus*
 2. If most errors involve isolates that are not commonly encountered in your laboratory setting
 - a. Weigh the inconvenience and cost of using another method for those isolates against the overall advantages of the test system.
 - b. Utilize selective reporting of antimicrobial agent-organism combinations that have low correlations.

IV. INTERPRETATION OF CORRELATIONS (*continued*)

3. If small numbers of resistant or susceptible isolates are tested, correlations that do not reflect system performance may result. When reviewing percentages of major and very major errors, note the method of calculation. Major and very major errors calculated from the total test set may be misleading as opposed to errors calculated by using the numbers of susceptible and resistant isolates, respectively. The following represents an example.
 - a. Twenty-five ciprofloxacin-susceptible *E. coli* isolates are tested. No resistant isolates are tested.
 - b. Category correlation is 100% (0% very major errors, 0% major errors).
 - c. There are no very major errors, but the possibility for very major errors does not exist since no resistant isolates were included among the 25 test isolates.

V. PROCEDURE NOTES

- A. When reviewing journal articles
 1. Verify that the same category breakpoints are used for both the test and reference systems.
 2. Note the software version (if applicable) used on the test system. Manufacturers continually make data analysis modifications, and the software version used in the published study may not be the most current version available.
- B. During the evaluation, determine whether the system fits into the work flow. Changes to the work flow may be necessary if the new system is adopted by the laboratory.
- C. Personnel performing testing should become familiar with methods (both reference and test systems) to be used prior to the evaluation in order to limit errors due to technique.
- D. If feasible, use as many fresh, clinical, single-patient isolates as possible (up to 300) (Use single-patient isolates to avoid duplicate testing of the same organism.) Fewer isolates may be used, but this may result in less statistically significant correlations, especially when correlations are analyzed by organism group. In addition, two-thirds of the organisms tested for each antimicrobial agent should be representative of the drug's spectrum of activity. If a large-scale comparison to a reference method is not possible, at a minimum consider a comparison to the current testing system. Any differences between the two systems can be evaluated, and potential changes in the annual cumulative susceptibility report may be anticipated.
- E. It is important to verify that the system can detect clinically significant resistant isolates. This is especially relevant with rapid systems. If resistant isolates cannot be obtained for the evaluation, available literature should be reviewed to determine the system's capability of detecting resistance. As new resistance patterns emerge, it is important to further verify the system's performance.
- F. Isolates with insufficient growth should be retested to determine if the lack of growth is due to technique or to a limitation of the system.
- G. Contact the manufacturer for possible explanations of discrepant results. Be aware of factors that affect susceptibility results in both the reference and the test systems. For example, inoculum, time of incubation, pH, temperature, age of culture, etc., can affect results.
- H. If comparative data for specific organism-antimicrobial agent combinations fall significantly below acceptable limits, determine whether failure is due to system performance or low sample numbers. If low correlations are attributed to system performance, use an alternate method with proven performance.
- I. Do not confirm MIC discrepancies on nonfermenters other than *P. aeruginosa* and *Acinetobacter* spp. by disk diffusion. Use an alternate method (i.e., broth microdilution, broth macrodilution, or agar dilution).

V. PROCEDURE NOTES

(continued)

- J.** It may be difficult to obtain challenge organisms from within your institution. In that case, contact larger institutions or university hospitals for these isolates. A gram-positive challenge set composed of 100 organisms (catalog no. GP0100) and a gram-negative challenge set composed of 200 organisms (catalog no. GN0250) can be purchased through the CDC.
- K.** Run QC strains daily for verification of precision and accuracy of the test and the reference procedure. Do not use results from antimicrobial agents that do not meet established QC ranges.

VI. LIMITATIONS OF THE PROCEDURE

- A.** No system can be better than the system to which it is being compared, since it is assumed that the reference system is correct. Some discrepancies may require additional testing when standard methods are known to have limitations. For example, methicillin-resistant *S. aureus* may occasionally not be detected with disk diffusion and broth dilution. A screen plate containing Mueller-Hinton agar supplemented with 4% NaCl and 6 µg of oxacillin per ml has been suggested as an alternative method for confirming oxacillin resistance in *S. aureus* (2).
- B.** If a large number of the resistant isolates tested are from your institution, they may be multiple isolates of the same nosocomial strain.

5.18.1

Appendix 5.18.1–1—Sources of Supplies for Antimicrobial Susceptibility Tests

The list below is intended to provide guidance in acquiring materials for performing antimicrobial susceptibility tests as described in section 5. See procedure 3.1 for a listing of companies that supply media, reagents, QC strains, and other products necessary to perform the procedures.

Antimicrobial powders

Sigma Diagnostics
545 South Ewing Ave.
St. Louis, MO 63103
(314) 286-7880
<http://www.sigma-aldrich.co>

U.S. Pharmacopeia
12601 Twinbrook Parkway
Rockville, MD 20852
(800) 227-8772
<http://www.usp.org>

In addition, some pharmaceutical companies (generally in the medical department) provide reference-grade powders for antimicrobial agents that they manufacture. To determine the manufacturer, contact your pharmacy.

Antimicrobial disks

BD Diagnostic Systems
7 Loveton Circle
Sparks, MD 21152
(800) 638-8663
<http://www.bd.com>

Remel, Inc.
12076 Santa Fe Dr.
Lenexa, KS 66215
(800) 255-6730
<http://www.remelinc.com>

Hardy Diagnostics
1430 W. McCoy Ln.
Santa Maria, CA 93455
(800) 266-2222
<http://www.hardydiagnostics.com>

Microdilution dispensing system

Sandy Spring Technologies (Autospense IIe dispensing system)
21131 Georgia Ave.
Brookeville, MD 20833
(301) 260-1220

Microdilution testing supplies (disposable plastic trays)

Dynex
14340 Sullyfield Circle
Chantilly, VA 20151
(800) 336-4543
<http://www.dynex technologies.com>

Evergreen Scientific
2300 East 49th St.
P.O. Box 58248
Los Angeles, CA 90058
(800) 421-6261
<http://www.evergreensci.com>

Nunc
75 Panorama Creek Dr.
Rochester, NY 14625-2385
(585) 586-8800
<http://www.nuncbrand.com>

Petri plates, special (quadrant plates and square plates)

BD Falcon
1 Becton Dr.
Franklin Lakes, NJ 07417
(201) 847-6800
<http://www.bd.com>

Suppliers of antimicrobial susceptibility test systems (if used for diagnostic testing, make certain the product is Food and Drug Administration cleared)

AB Biodisk North America, Inc. (Etest)
200 Centennial Ave.
Piscataway, NJ 08854
(732) 457-0408
<http://www.abbiodisk.com>

PML Microbiologicals, Inc.
27120 S. W. 95th Ave.
Wilsonville, OR 97071
(800) 547-0659
<http://www.pmlmicro.com>

BD Diagnostic Systems (Pasco, Phoenix)
7 Loveton Circle
Sparks, MD 21152
(800) 638-8663
<http://www.bd.com>

Remel
12076 Santa Fe Dr.
Lenexa, KS 66215
(800) 255-6730
<http://www.remelinc.com>

bioMérieux, Inc. (Vitek and Vitek 2)
100 Rodolphe St.
Durham, NC 27717
(800) 682-2666
<http://www.biomerieux-vitek.com>

Trek Diagnostic Systems (Sensititre)
982 Keynote Circle, Suite 6
Cleveland, OH 44131
(800) 871-8909
<http://www.trekds.com>

Dade Behring (MicroScan)
MicroScan Microbiology Systems
1584 Enterprise Blvd.
West Sacramento, CA 95691
(800) 242-3233

6.1

Specimen Examination and Primary Isolation

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Aerobic actinomycetes cause a variety of infections in humans: respiratory, cutaneous (such as mycetoma, lymphocutaneous and superficial skin [abscess or cellulitis] infections, or secondary cutaneous involvement with disseminated disease), and disseminated, with a marked tropism to the central nervous system, from a primary pulmonary infection. See Appendix 6.3.1–1 at the end of this section for a list of etiologic agents and the sites most commonly associated with these infections.

Aerobic actinomycetes are often overlooked or missed unless there is a suspicion of these infections. Knowing which aerobic actinomycete has been isolated assists the physician in diagnosing the dis-

ease, in determining appropriate therapy for patients with these infections, and in determining the clinical significance.

This procedure outlines practical procedures that can be used to establish the presence of clinically important aerobic actinomycetes. These include members of several genera: *Actinomadura*, *Dermatophilus*, *Gordonia*, *Nocardia*, *Nocardiosis*, *Rhodococcus*, *Streptomyces*, *Tsukamurella*, and, to a lesser extent, *Amycolata*, *Amycolatopsis*, *Micromonospora*, *Saccharopolyspora*, *Saccharomonospora*, and *Thermoactinomyces*. The genera *Gordonia*, *Nocardia*, *Rhodococcus*, and *Tsukamurella*, and the microbiologically closely related genera *Mycobacterium* and

Corynebacterium, are collectively known as the mycolic acid-containing genera, or “mycolata,” and they have a set of chemical markers in common, i.e., the cell wall components *meso*-diaminopimelic acid, arabinose and galactose, mycolic acids, and cellular fatty acid. This combination of chemical markers is diagnostic for all members of the mycolic acid-containing genera. The major characteristics used for the identification of the mycolata and the amycolata, the non-mycolic acid-containing genera, to the genus level and their separation from *Mycobacterium* and *Corynebacterium* are given in Table 6.1–1 and Fig. 6.2–1.

II. LEVELS OF LABORATORY SERVICE FOR AEROBIC ACTINOMYCETES

The concept of levels of laboratory service is based on the infrequency of isolation of the aerobic actinomycetes and the lack of capabilities in small and medium-size hospitals (Table 6.1–2). Laboratory service is classified into two levels (I and II).

III. MATERIALS

A. Stain reagents

See individual stain procedures below.

B. Media

See Appendix 6.3.2–1 at the end of this section for suppliers.

1. Enriched medium at 35°C
 - a. Heart infusion agar with rabbit blood (BAP)
 - b. Lowenstein-Jensen slant
2. Minimal medium at 25°C
Sabouraud dextrose agar (SDA)
3. Liquid medium at 35°C
 - a. Thioglycolate (incubated under microaerobic and anaerobic conditions)

b. Tryptic soy broth (TSB)

c. Radiometric (BACTEC 12B) blood culture system

4. Selective enrichment broth at 35°C
 - a. TSB with and without inhibitor 5% NaCl
 - b. TSB without dextrose with and without pretreatment (HCl-KCl [pH 2.2 ± 0.1])

Table 6.1–1 Results of tests used for presumptive identification of aerobic actinomycetes to genus level^{a,b}

Genus	Test results										
	Vegetative filaments		Conidia	Acid-fast nature	Presence ^c in whole cells of:		Mycolic acids	Metabolism of glucose	Growth at 50°C	Arylsulfatase	Growth in lysozyme
	Substrate	Aerial			DAP	Sugars					
<i>Actinomadura</i>	+	V	V	–	meso	Mad	–	O	–	–	–
<i>Amycolata</i>	+	+	V	–	meso	Arab, gal	–	O	–	–	–
<i>Amycolatopsis</i>	+	+	V	–	meso	Arab, gal	–	O	–	–	–

<i>Dermatophilus</i> ^d	+	–	–	–	meso	Mad	–	F	–	–	NT
<i>Gordonia</i>	+	–	–	W	meso	Arab, gal	+	O	–	–	V
<i>Micromonospora</i>	+	–	+	–	meso	Arab, xyl	–	O	–	–	–
<i>Mycobacterium</i>	+	–	–	+	meso	Arab, gal	+	O	–	+	–
<i>Nocardia</i>	+	+	V	W	meso	Arab, gal	+	O	–	–	+
<i>Nocardiosis</i>	+	+	+	–	meso	None	–	O	–	–	–
<i>Rhodococcus</i>	+	–	–	W	meso	Arab, gal	+	O	–	–	V
<i>Saccharomonospora</i>	+	+	+	–	meso	Arab, gal	–	O	+	–	–
<i>Saccharopolyspora</i>	+	+	+	–	meso	Arab, gal	–	O	+	–	V
<i>Streptomyces</i>	+	+	+	–	L	None	–	O	–	–	–
<i>Thermoactinomyces</i>	+	+	+	–	meso	Arab, gal	–	O	+	–	+
<i>Tsukamurella</i>	+	–	–	W	meso	Arab, gal	+	O	–	–	+

^a Data adapted from McNeil and Brown (4).

^b +, 90% or more of strains are positive; –, 90% or more of strains are negative; V, 11 to 89% of strains are positive; O, oxidative; F, fermentative; NT, not tested; DAP, diaminopimelic acid; Mad, madurose; Arab, arabinose; gal, galactose; xyl, xylose; W, weakly or partially acid-fast.

^c As determined by the methodology of Becker et al. (1) for whole-cell DAP and sugars.

^d Genus is motile.

III. MATERIALS (continued)

5. Selective enrichment agar at 35°C
 - a. Buffered charcoal yeast extract (BCYE)
 - (1) BCYE with anisomycin (40 U/ml), polymyxin B (80 µg/ml), and vancomycin (0.5 µg/ml)
 - (2) BCYE without antibiotics
 - b. Modified Thayer-Martin agar with colistin (7.5 µg/ml), nystatin (12,500 µg/ml), and vancomycin (4 µg/ml)

C. Other supplies

Petri dishes, pipettes, loops, inoculating needles, slides, coverslips, scissors, mortar and pestle, filtration equipment with 0.45-µm-pore-size disposable filters, lysis-centrifugation system, centrifuge and centrifuge tubes, microscope, methanol, sulfuric acid, and potassium hydroxide solution.

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

Include QC information on reagent container and in QC records.

- A. All media and reagents should have recorded arrival date, date put into use, and expiration date, the last appearing on the label.
- B. Reagents should be examined regularly for signs of contamination or extraneous material.
- C. Organisms with known staining reaction
 1. For Gram stain, use QC smears as given in section 3 of this handbook.
 2. For acid-fast stain, use a smear containing an acid-fast-positive microorganism (*Mycobacterium fortuitum* ATCC 6841), which stains red (retains the carbol fuchsin), and an acid-fast-negative microorganism (*Staphylococcus aureus* ATCC 25923), which stains blue.

V. SPECIMEN EXAMINATION

It is imperative that these cultures be handled in a biosafety hood.

Observe standard precautions.

Observe standard precautions.

Observe standard precautions.

A. Principle

In addition to the clinical picture, a definitive diagnosis depends upon demonstration of the organism in smears or sections from the original clinical material, along with the isolation and identification of the agent.

B. Preparation of specimen

1. Sputum, bronchial washings, and exudates (nonsterile sites)
 - a. Material should be spread out in a petri dish.
 - b. Selectively remove clumps or granules and crush between two glass slides in preparation for KOH mount.
2. Body fluids (e.g., blood or CSF)
 - a. Centrifuge at $3,000 \times g$ for 20 min.
 - b. Make smears with a thin suspension of sediment on clean glass slide.
 - c. Heat fix gently.
3. Tissue
 - a. Cut small portion of tissue with sterile scissors and grind with mortar and pestle or tissue homogenizer.
 - b. Add small amount of sterile water or broth, and make smears with a small portion of the homogenate on clean glass slide.
 - c. Heat fix gently.

C. Direct macroscopic examination of specimen

Observe for clumps of microorganisms or granules with a stereomicroscope (magnification, $\times 100$).

D. Microscopic examination of culture material

1. Gram stain (*see* Gram stain procedure in section 3 of this handbook)
2. Acid-fast stain for aerobic actinomycetes (modified Kinyoun method) (2)

Modified Kinyoun acid-fast stain is a cold method of staining for acid fastness. Acid-fast bacilli are difficult to stain because of the long-chain fatty acids (mycolic acids) in the cell wall. The exact nature of this unique staining reaction is not completely understood, but it is believed that the phenol dissolves the lipid sufficiently to allow penetration of the primary stain. The cell wall retains the primary stain even after exposure to the decolorizing agent, aqueous 1% sulfuric acid. Resistance to 1% sulfuric acid is required for the organism to be termed acid-fast. A counterstain is employed to highlight the stained organisms. This method of staining for acid fastness is preferred because it is more sensitive in the staining of *Gordonia* species, *Nocardia* species, *Rhodococcus* species, and *Tsukamurella* species that are usually negative with the classical Ziehl-Neelsen stain.

 - a. Materials and preparation method are given in Appendix 6.3.3–1 item II at the end of this section.

Table 6.1–2 Laboratory level I and II qualifying procedures

Procedure ^a	Level	
	I	II
Microscopic examination of clinical material		
Gram stain	Yes	Yes
Acid-fast stain (modified Kinyoun)	Yes	Yes
Isolation of aerobic actinomycetes	Yes	Yes
Identification of aerobic actinomycetes	No	Yes
Antimicrobial susceptibility tests	No	Yes

^a Procedures not performed by level I laboratories are referred to a level II laboratory or a recognized reference facility.

V. SPECIMEN EXAMINATION

(continued)

b. Procedure

- (1) Prepare and heat fix the smear on a clean glass slide.
- (2) Flood the smear with ~5 drops of Kinyoun fuchsin-phenol and allow to stain for 5 min. *Do not heat.*
- (3) Rinse with tap water and drain.
- (4) Flood the smear with aqueous 1% H₂SO₄ and destain for 3 min. Then, rinse with tap water and drain.
- (5) Flood the smear with methylene blue and then rinse, drain, and air dry.
- (6) Examine the smear under oil immersion at ×1,000 magnification.

3. KOH mount

- a.** KOH reagent (10%) allows the rapid observation of sulfur granules present in tissue by partially digesting the proteinaceous host cell components. *Actinomadura* species, *Nocardia* species, and *Streptomyces* species, when seen as etiologic agents of actinomycotic mycetoma, grow in the tissue as small, hard colonies known as granules.

b. Procedure

- (1) To an aliquot of specimen, add a drop of 10% KOH and place a coverslip over the preparation.
- (2) Hold the slide at room temperature for 5 to 30 min after the addition of 10% KOH to allow digestion to occur. If necessary, heat gently to enhance digestion.
- (3) Observe at ×1,000 magnification.

E. Histopathologic stains for microscopic examination of tissue

Histopathologic stains are useful in demonstrating host response and the microscopic structures of etiologic agents in tissue.

1. Hematoxylin and eosin (H&E)

H&E is the best stain for demonstrating host reaction in tissue and for studying the microscopic features of granules.

- a.** Gram-positive filaments are not seen.
- b.** Granules stain blue with hematoxylin, and the surface shows clavate eosinophilia.
- c.** Shows an infiltration of PMNs surrounding the granule but does not penetrate the interior.

2. Modified Gram stain (Brown-Brenn)

- a.** Demonstrates the presence of gram-positive branched filaments ($\leq 1.0 \mu\text{m}$ wide).
- b.** Demonstrates the gram positivity of filaments of the agents of nocardiosis and actinomycotic mycetoma.

3. Gomori methenamine-silver (GMS) stain

- a.** Stains aerobic actinomycetes and fungi.
 - (1) Filaments of aerobic actinomycetes are $\leq 1.0 \mu\text{m}$ wide.
 - (2) Filaments of fungi range from 2 to 6 μm wide.

VI. ISOLATION OF AEROBIC ACTINOMYCETES OF MEDICAL IMPORTANCE

Observe standard precautions.

■ **NOTE:** Fig. 6.1–1 shows an abbreviated flowchart for the isolation of aerobic actinomycetes.

The selection of media for the isolation of the aerobic actinomycetes depends primarily on the specimen type. Media should support the aerobic actinomycetes while inhibiting the growth of contaminating organisms. Specimens from normally sterile sites may be inoculated into less inhibitory media; specimens from nonsterile sites, such as respiratory specimens, must be inoculated onto selective media that are inhibitory to other bacteria present.

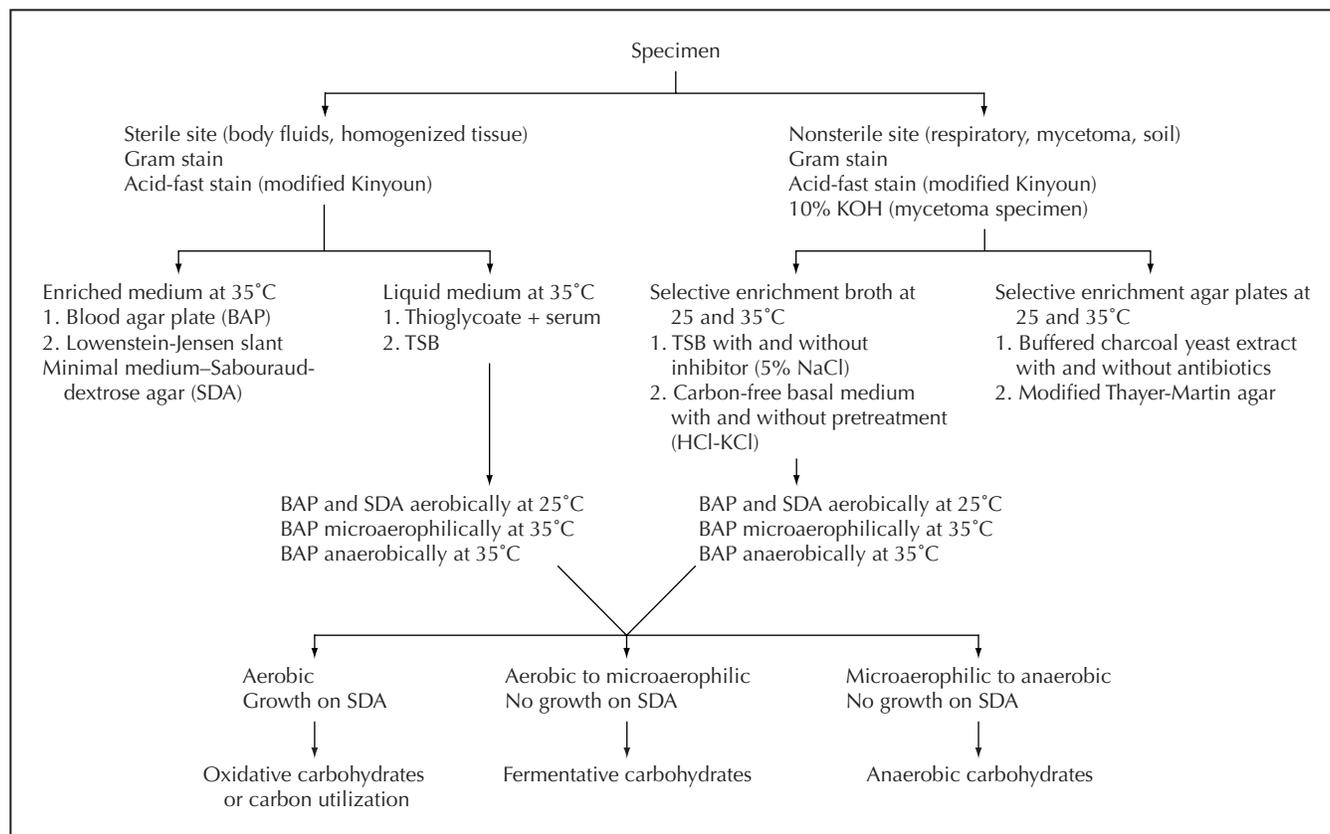

Figure 6.1–1 Abbreviated flowchart for isolation of aerobic actinomycetes.

VI. ISOLATION OF AEROBIC ACTINOMYCETES OF MEDICAL IMPORTANCE *(continued)*

A. Preparation of inoculum

1. Sterile sites

- a. Blood specimens concentrated by lysis-centrifugation system (Isolator) (*see* Appendix 6.3.2–1)
- b. Body fluids (CSF, joint fluid, and urine specimens processed by filtration) (3)
 - (1) Filter using a disposable plastic system with a 0.45- μ m-pore-size membrane.
 - (2) Use sterile forceps to remove membrane filter from apparatus and to place it onto an agar plate.

2. Nonsterile site (respiratory and mycetoma)

Pretreat with 1 ml of a low-pH (2.2) HCl-KCl solution (46.8 ml of 0.2 M HCl and 300 ml of 0.2 M KCl) per 10 ml of sample for 4 min prior to inoculation (5).

B. Isolation

1. Sterile sites (body fluids)

- a. Blood specimen—incubate up to 3 weeks aerobically and microaerobically at 35°C.
 - (1) Use automated radiometric (BACTEC) or nonradiometric culture method.
 - (2) Inoculate 10 to 50 μ l of specimen directly into THIO (supports aerobic growth, as well as growth of anaerobic actinomycetes) and TSB.

VI. ISOLATION OF AEROBIC ACTINOMYCETES OF MEDICAL IMPORTANCE (continued)

- b. Body fluids (CSF and urine) and homogenized tissue
 - (1) Inoculate into liquid broth at 35°C.
 - (2) CSF must be incubated for 2 weeks with frequent subcultures.
 - (3) Tissue specimens must be incubated for 3 weeks with frequent and terminal subcultures.

☑ **NOTE:** Sediment from lysis-centrifugation of blood, other body fluids, and homogenized tissue may be inoculated initially onto solid media; however, plates must be sealed with parafilm (Parafilm M; American Can Company, Greenwich, Conn.) to prevent dehydration during prolonged incubation.
2. Nonsterile sites
 - a. Respiratory-sample problems

It has been demonstrated that digestion-decontamination of respiratory-tract specimens with *N*-acetyl-L-cysteine, sodium hydroxide, and benzalkonium used for mycobacterial isolation is toxic to *Nocardia* species, and it has been shown that antibiotics in fungal culture media inhibit *Nocardia* species.
 - b. Respiratory, mycetoma, and soil samples
 - (1) Selective enrichment broth at 25 and 35°C
 - (a) TSB with and without inhibitor 5% NaCl
 - (b) Carbon-free basal medium with and without inhibitor
 - (2) Selective enrichment agar at 25 and 35°C
 - (a) BCYE with and without antibiotics
 - (b) Modified Thayer-Martin agar with and without antibiotics
3. After growth, all isolates must be subcultured to determine temperature, oxygen, and nutritional requirements.
 - a. Enriched medium (BAP) (aerobically and anaerobically at 25 and 35°C)
 - b. Minimal medium (SDA) at 25°C

POSTANALYTICAL CONSIDERATIONS

VII. INTERPRETATION OF TESTS

- A. Gram stain
 1. Interpretation of controls
 - a. Gram-positive organisms appear blue.
 - b. Gram-negative organisms appear red.
 2. Interpretation of structure and Gram reaction of aerobic actinomycetes
 - a. *Actinomadura* species are gram-positive, short bacilli (1 to 2 μm wide) that are rarely branched.
 - b. *Gordonia* species are gram-positive, thin, beaded coccobacilli (≤1 μm wide)
 - c. *Nocardia* species are gram-positive, branched filaments (≤1 μm wide) that may stain gram variable and usually fragment into bacillary forms.
 - d. *Rhodococcus* species may have many growth stages: some have a simple rod-coccus growth cycle similar to that of *R. equi*; others have a more complex hypha-rod-coccus cycle (*R. coprophilus*, *R. fascians*, *R. marinonascens*, and *R. ruber*). *R. coprophilus*, *R. erythropolis*, *R. globerulus*, *R. rhodnii*, and *R. rhodochrous* are differentiated further into elementary branched hypha-rod-coccus cyclic forms. The branched hyphae (≤1 μm wide) may be rudimentary, highly transitory, or extensive.
 - e. *Streptomyces* species are gram-variable branched filaments (1 to 2 μm wide). May produce chains of spores.
 - f. *Tsukamurella* species are gram-positive short-to-long bacilli. No branched forms are seen unless on minimal medium, such as tap water.

VII. INTERPRETATION OF TESTS (continued)**B. Modified Kinyoun stain**

1. Most *Nocardia* species are weakly or partially acid-fast (varies from 10 to 20% per oil immersion field).
2. *Streptomyces* species are usually negative. Occasionally the spores of some *Streptomyces* species are acid-fast.
3. *Tsukamurella* species vary from 20 to 100% per oil immersion field.
4. Both *Gordonia* and *Rhodococcus* species vary from no acid fastness to 10 to 20% per oil immersion field.
5. All *Mycobacterium* species tested in our laboratory have been 100% acid-fast by the modified Kinyoun method.

C. KOH preparation

1. Interpretation of results
 - a. Actinomycotic granule has beaded branched filaments (1.5 to 2.0 μm wide).
 - b. Eumycotic granule has hyphae from 4 to 7 μm wide (may be branched).
 - c. Granules seen in botryomycosis may have filaments (often in association with cocci).
2. Limitations
Observation of granules must be followed by isolation and identification of etiologic agent.

D. Interpretation of growth on different media and under different incubation conditions

1. Aerobic actinomycete
 - a. Grows aerobically.
 - b. Grows at 25 or 35°C.
 - c. Grows on SDA.
2. Fastidious aerobic actinomycete
 - a. Grows aerobically to microaerobically.
 - b. Grows at 35°C only.
 - c. Does not grow on SDA.
3. Anaerobic actinomycete
 - a. Grows microaerobically to anaerobically.
 - b. Grows at 35°C only.
 - c. Does not grow on SDA.

6.2

Media and Methods Used for the Identification of Aerobic Actinomycetes

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

After initial isolation, subcultures must be incubated at 25, 35, and 45°C to determine the optimal temperature for growth of the microorganisms. Most isolates of *Nocardia asteroides* grow best at 35°C, while most isolates of *Streptomyces* grow best at 25°C. Any specimen suspected of containing a thermophilic actinomycete must also be incubated at 50°C, since all thermophiles grow at this elevated temperature. The actinomycetes can be identified to the

genus level on the basis of a variety of conventional phenotypic characteristics (microscopic [Gram and acid-fast staining] and macroscopic morphologies, growth requirements, metabolism of glucose, arylsulfatase production, and growth in lysozyme) and chemotaxonomic characteristics (whole-cell isomers of diaminopimelic acid and mycolic acid composition) (Table 6.1–1, above). Some of

these tests are beyond the capabilities of most clinical laboratories. However, both microscopic and macroscopic morphologies combined with a few physiologic tests can give a presumptive identification to the genus or species level. A schematic flowchart for the tentative identification of medically important aerobic actinomycetes and related genera is given in Fig. 6.2–1.

II. MATERIALS

Include QC information on reagent container and in QC records.

- A. Refer to each procedure for the media to be used, and refer to the appendixes at the end of this section for composition and preparation and for commercial sources.
- B. Acetamide hydrolysis medium (*see* Appendix 6.3.3–1 item III)
- C. Arylsulfatase liquid medium (*see* Appendix 6.3.3–1 item IV)
- D. Carbohydrate basal medium—Gordon's oxidative agar slants (*see* Appendix 6.3.3–1 item V)
- E. Carbon utilization of carbohydrates—these tests use commercially available kits, which are listed in item IV.D below.
- F. Cell wall determination of diaminopimelic acid isomers—isolates are grown in Trypticase (or tryptic) soy broth (*see* Appendix 6.3.2–1). This procedure is described in Appendix 6.3.4–1.
- G. Citrate agar (*see* Appendix 6.3.3–1 item VI)
- H. Decomposition of substrates (*see* Appendix 6.3.3–1 item VII)
- I. Esculin hydrolysis medium (*see* Appendix 6.3.3–1 item VIII)
- J. Lysozyme test (*see* Appendix 6.3.3–1 item IX)

ANALYTICAL CONSIDERATIONS

III. QUALITY CONTROL

- A. Controls for acetamide hydrolysis
 1. A tube of uninoculated substrate medium (sterility)
 2. A tube of substrate medium inoculated with *Nocardia farcinica* (ATCC 3318) (positive)
 3. A tube of substrate medium inoculated with *Nocardia nova* (ATCC 33726) (negative)

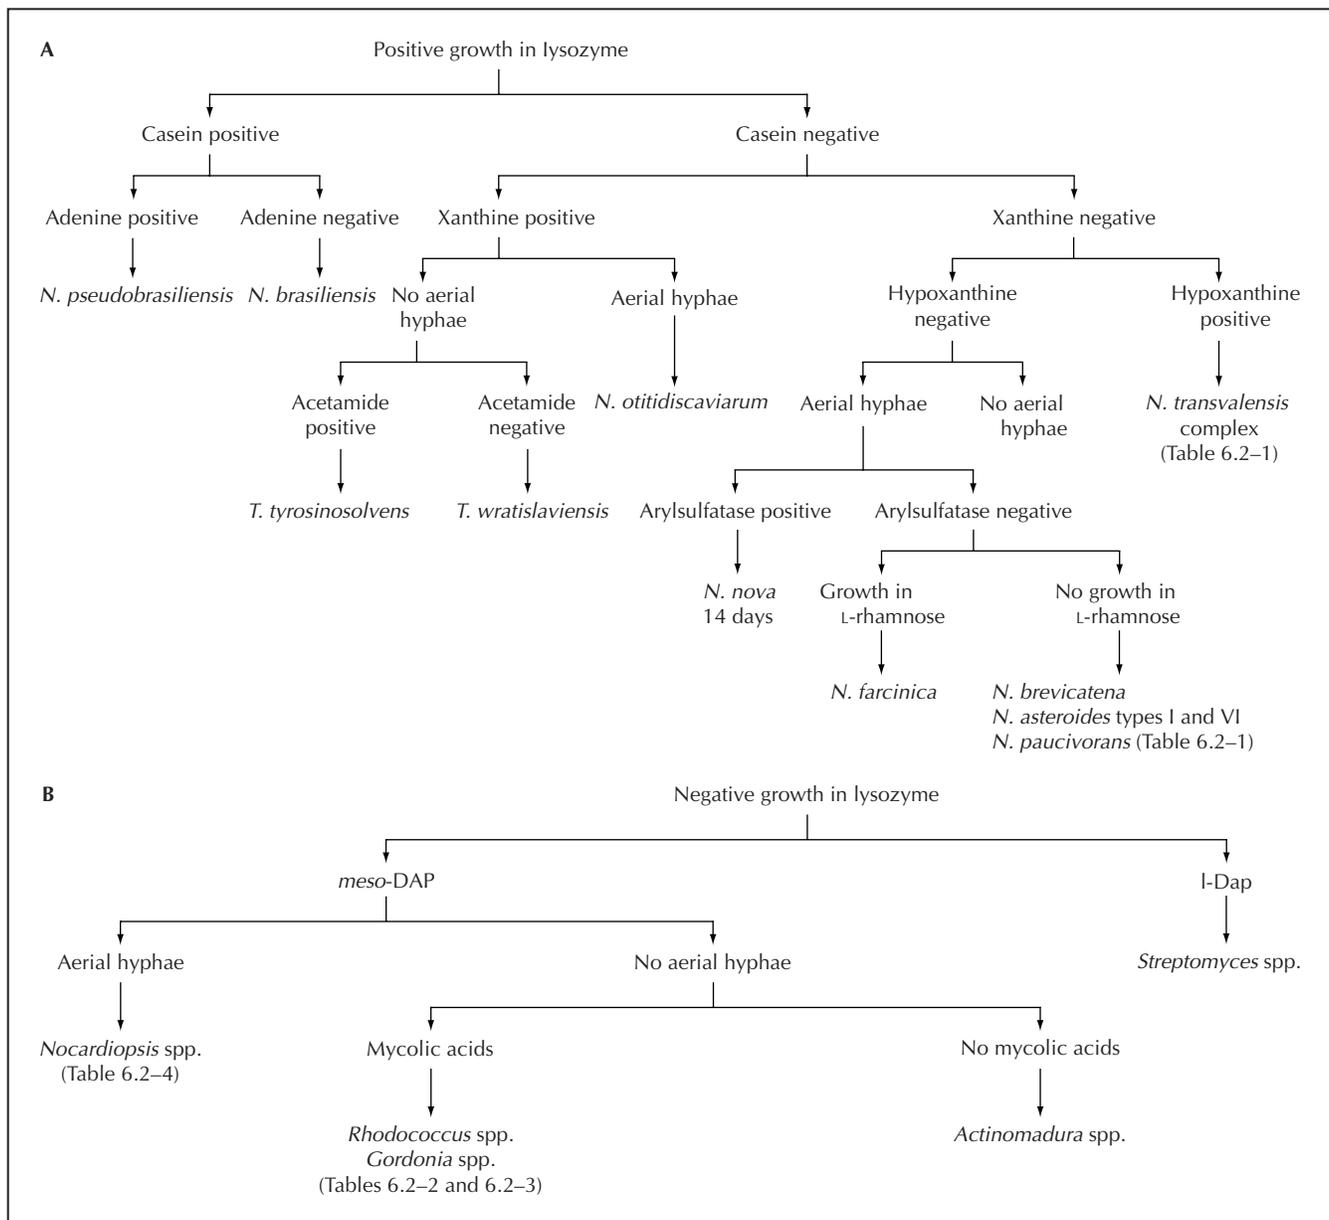

Figure 6.2-1 Schematic flowchart for tentative identification of medically important aerobic actinomycetes and related genera based on lysozyme resistance (A) or susceptibility (B).

III. QUALITY CONTROL (continued)

B. Controls for arylsulfatase liquid medium

1. A tube of uninoculated substrate medium (negative)
2. A tube of each substrate inoculated with *Mycobacterium fortuitum* (positive; 3 days) and *N. nova* (positive; 2 weeks)

C. Controls for carbohydrate basal medium—Gordon's slants

1. *N. nova* (W5593) produces oxidative acid from all carbohydrates except dulcitol, i-erythritol, and i-myoinositol.

III. QUALITY CONTROL*(continued)*

2. *N. farcinica* (ATCC 3318) produces oxidative acid from i-erythritol.
3. *Nocardia carnea* (W5643) produces oxidative acid from i-*myo*-inositol.
4. *Tsukamurella inchonensis* (ATCC 700082) produces oxidative acid from dulcitol.

D. Controls for citrate agar

Nocardia brasiliensis (ATCC 19296) (positive) and *N. nova* (ATCC 33726) (negative)

E. Controls for decomposition of substrates

1. *N. farcinica* ATCC 3318 does not hydrolyze adenine, casein, hypoxanthine, tyrosine, or xanthine-negative control.
2. *Nocardia pseudobrasiliensis* (ATCC 51512) hydrolyzes adenine.
3. *Nocardiopsis dassonvillei* (ATCC 23218) hydrolyzes casein, hypoxanthine, tyrosine, or xanthine-positive control.

F. Controls for esculin hydrolysis medium

N. farcinica ATCC 3318 (positive) and *N. nova* ATCC 33726 (negative)

G. Controls for lysozyme test

N. farcinica ATCC 3818 (positive) and *Streptomyces* species (negative)

IV. METHODS OF IDENTIFICATION OF ACTINOMYCETES

It is imperative that these cultures be handled in a biosafety hood.

A. Acetamide hydrolysis medium

1. Acylamidase is an enzyme that is capable of deamidating acetamide. This produces ammonia, which increases the pH of the medium, causing a corresponding change from yellow-orange to deep pink or magenta.
2. Procedure
 - a. Inoculate the acetamide agar slant with a loopful of culture emulsified in a broth or ~100 µl per slant from a culture grown in a broth.
 - b. Incubate inoculated slant for 21 days at 35°C before discarding as negative.
 - c. Observe weekly for a color change to deep pink or magenta.

B. Arylsulfatase liquid medium

1. Arylsulfatase is an enzyme capable of hydrolyzing the bond between sulfate and the aromatic ring in a compound such as potassium phenolphthalein disulfate. Free phenolphthalein can then be recognized by the formation of a deep pink color when an alkali is added. This medium is used in the differential identification of rapidly growing mycobacteria and of *N. asteroides* complex and *N. nova*.
2. Materials

Arylsulfatase broth and the reagent 1.2 N sodium carbonate (10.6 of anhydrous Na₂CO₃ in 100 ml of H₂O)
3. Procedure
 - a. Label tubes of substrate with specimen numbers.
 - b. Inoculate the tubes with 0.1 ml of a 1-day liquid culture of the organism to be tested.
 - c. Incubate at 35°C.
 - d. After 3 days of incubation of the 0.001 M substrate, remove test tubes from the incubator and add not more than 6 drops of 2 N sodium carbonate solution.
 - e. If negative at 3 days, test again in 2 weeks.

C. Carbohydrate basal medium—Gordon's oxidative agar slants

1. Oxidative acid production of carbohydrates is used as a differential characteristic to separate all members of the aerobic actinomycetes.
2. Materials

Slants containing basal medium and one of the following: D-glucose, D-mannose, D-mannitol, D-sorbitol, salicin, dulcitol, glycerol, raffinose, i-*myo*-inositol, adonitol, trehalose, i-erythritol, D-galactose, melibiose, lactose,

IV. METHODS OF IDENTIFICATION OF ACTINOMYCETES (continued)

starch, sucrose, D-fructose, maltose, cellobiose, xylose, L-arabinose, L-rhamnose

3. Procedure

- a. Inoculate ~10 µl of growth from a broth medium and incubate for 21 days at optimal growth temperature.
- b. Read change in color from purple to yellow as acid production.
- c. Read no change in color as negative for acid production.

D. Carbon utilization of carbohydrates

1. Carbon utilization of carbohydrates is used as a differential characteristic to separate all members of the aerobic actinomycetes. Growth of an organism occurs in each of the different carbohydrates in which the organism is able to utilize the carbohydrate as a sole carbon source.
2. Commercial tests that have carbon utilization of carbohydrates included in their panels (see Appendix 6.3.2–1 at the end of this section)
 - a. API 20C AUX system
 - b. API 50 CH system
 - c. Biotype-100

E. Citrate agar (Simmons)

1. Citrate agar is a medium consisting of inorganic salts in which ammonium salts are the only source of nitrogen and citrate is the carbon source. Organisms capable of utilizing ammonium dihydrogen phosphate and sodium citrate as the sole source of nitrogen and carbon, respectively, will grow on this medium and produce an alkaline reaction, as evidenced by a change in the color of bromthymol blue indicator from green (neutral) to blue (alkaline).
2. Procedure
Inoculate the agar slant lightly with a loop by using growth from an 18- to 24-h heart infusion agar slant, and incubate at 35°C for up to 7 days.

F. Decomposition of substrates

1. The ability or inability of the aerobic actinomycetes to hydrolyze adenine, casein, hypoxanthine, tyrosine, and xanthine continues to be a major and generally accepted criterion for the tentative identification of *N. brasiliensis*, *N. pseudobrasiliensis*, *Nocardia otitidiscaviarum*, *Nocardia transvalensis*, *Actinomadura* species, *Nocardioopsis* species, *Streptomyces* species, and *Tsukamurella* species.
2. Materials
Casein medium and basal medium with adenine, hypoxanthine, tyrosine, and xanthine
3. Procedure
Inoculate the unknown culture onto the surfaces of the casein, xanthine, hypoxanthine, and adenine decomposition test media using a quadrant of a plate for each culture. Incubate at optimal temperature (25 or 35°C). Observe xanthine, hypoxanthine, adenine, and tyrosine plates for clearing of the crystals at 7, 14, and 21 days.

G. Esculin hydrolysis medium

1. Esculin hydrolysis medium is used to determine whether an organism will hydrolyze the glycoside esculin, which produces esculetin and dextrose. The esculetin reacts with the iron salt (ferric ammonium citrate) contained in the medium to produce a dark-brown-to-black complex.
2. Procedure
 - a. Inoculate esculin agar slant with a loopful of culture emulsified in a broth or ~10 µl per slant from a culture grown in a broth.
 - b. Incubate inoculated slant for 14 days at 35°C before discarding as negative.

IV. METHODS OF IDENTIFICATION OF ACTINOMYCETES (continued)

Include QC information on reagent container and in QC records.

H. Lysozyme test

1. To determine an organism's ability to grow in the presence of lysozyme
2. Procedure
Inoculate tubes of the lysozyme-glycerol mixture and basal glycerol broth (control) with the unknown culture. After 2 to 4 weeks of incubation at 25°C, observe the unknown culture for signs of growth.

I. Identification using commercial biochemical or miniaturized test systems

In contrast to the use of conventional growth-dependent procedures for identifying bacteria, the use of chromogenic enzyme substrates can rapidly detect constitutive enzymes produced by microorganisms.

Kilian (10), in 1978, evaluated the API ZYM system (Société Analytab Products Inc., La Balme Les Grottes, France) for the rapid identification of members of the family *Actinomycetaceae* and related bacteria. In combination with the β -xylosidase test, catalase activity, and oxygen requirements, 12 of 19 enzymes screened proved to be of value for differentiating species of the family *Actinomycetaceae* and some related species within 4 h. In 1990, Boiron and Provost (4) further evaluated the API ZYM system for detection of constitutive enzymes by chromogenic substrates.

A related application of rapid chromogenic substrate tests is the fluorogenic enzyme method, described by Goodfellow and colleagues (6, 8), to study the numerical taxonomy of both *Rhodococcus* and *Streptococcus* species. Other miniaturized studies include two Dade MicroScan Inc. (West Sacramento, Calif.) products, Rapid Anaerobe Identification and *Haemophilus-Neisseria* panels that test for preformed enzymes; the ID 32C Yeast Identification System (bioMérieux Vitek, Inc., Marcy L'Etoile, France); and another system based on 273 phenotypic tests (2, 3, 12). However, the last approach, which uses numerous tests, is not applicable in the routine clinical laboratory and may be more suitable to specialized reference or research laboratories.

POSTANALYTICAL CONSIDERATIONS

V. INTERPRETATION OF RESULTS

A. Acetamide hydrolysis

Acetamide reaction is used as one way to differentiate among members of the genus *Nocardia*. *N. farcinica* is positive, and the other *Nocardia* spp. are negative.

B. Arylsulfatase detection

Positive is a color change to pink or red, and negative shows no color change.

☑ **NOTE:** Most *N. nova* isolates are positive in 14 days, and most *M. fortuitum* isolates are positive in 3 days.

C. Citrate agar

A positive reaction, denoting alkalization, is indicated by the development of a dark blue color. Growth without color change in the medium is considered a negative reaction.

D. Decomposition of substrates

1. Adenine, casein, hypoxanthine, tyrosine, and xanthine are useful differential characteristics to separate members of the genus *Nocardia* (Table 6.2-1).
2. Adenine and tyrosine are useful differential characteristics to separate members of the genus *Rhodococcus* (Table 6.2-2).
3. Hypoxanthine, tyrosine, and xanthine are useful differential characteristics to separate members of the genus *Tsukamurella* (Table 6.2-3).

Table 6.2–3 Differential characteristics of the genus *Tsukamurella*^{a,b}

Characteristic	Presence				
	<i>T. inchonensis</i>	<i>T. paurometabola</i>	<i>T. pulmonis</i>	<i>T. tyrosinosolvans</i>	<i>T. wratislaviensis</i>
Decomposition of:					
Hypoxanthine	+	–	–	+	+
Xanthine	–	–	–	+	+
Tyrosine	–	–	–	+	+
Utilization as sole carbon source:					
Cellobiose	+	–	–	–	–
Maltose	+	–	–	+	+
<i>i-myo</i> -Inositol	+	–	–	+	+
D-Mannitol	+	–	+	+	+
D-Sorbitol	+	–	+	+	+
Citrate	+	+	–	V	–
Utilization of acetamide as sole carbon and nitrogen source	+	–	+	+	–
Growth at 45°C	+	–	–	–	NT

^a Data adapted from references 14, 2–23, and 25.

^b +, positive; –, negative; V, variable; NT, not tested.

V. INTERPRETATION OF RESULTS (continued)

4. Adenine, hypoxanthine, tyrosine, and xanthine are useful differential characteristics to separate members of the genus *Nocardioopsis* (Table 6.2–4).

☑ **NOTE:** Isolates of *Dermatophilus congolensis* may take up to 7 days to decompose casein. Hypoxanthine, tyrosine, and xanthine are not decomposed. The thermophilic actinomycetes are separated by decomposition of the following substrates: adenine, casein, hypoxanthine, tyrosine, and xanthine. Most isolates of *Micromonospora* are strongly proteolytic; all isolates from human clinical specimens have decomposed casein, and 75% have decomposed tyrosine. No isolates decompose hypoxanthine or xanthine.

E. Esculin hydrolysis

Esculin fluoresces under the UV rays of a Wood's lamp; when esculin is hydrolyzed (a positive test), the medium turns reddish black and the esculin no longer fluoresces. An inoculated control tube of the medium without esculin may be useful in interpreting weak results. Esculin is useful in separating *Actinomadura madurae* (positive) from *Actinomadura pelletieri* (negative).

F. Lysozyme

1. The lysozyme test is considered positive if good growth is noted in both tubes, and negative if growth is good in the control tube but poor or absent in the tube containing the lysozyme.
2. Except for 35% of the isolates of the *Nocardia brevicatena* complex, all *Nocardia* species grow in the presence of lysozyme.
3. *Streptomyces* species are sensitive to lysozyme and are inhibited by its presence.

Table 6.2–4 Differential characteristics of the genus *Nocardioopsis*^{a,b}

Characteristic	Value						
	<i>N. alba</i>	<i>N. dassonvillei</i>	<i>N. halophila</i>	<i>N. listeri</i>	<i>N. lucen-tensis</i>	<i>N. pra-sina</i>	<i>N. synnema-taformans</i>
Species isolated from humans	–	+	–	–	–	–	+
Species implicated as cause of human disease	–	+	–	–	–	–	+
Color of substrate hyphae	Colorless	Yellow; orange to brown	Yellow to coral red	Colorless	Yellow to brown	Colorless	Deep pigment
Decomposition of:							
Adenine	+	+	+	+	+	–	+
Hypoxanthine	+	+	+	+	+	–	+
Tyrosine	+	+	–	+	+	+	+
Xanthine	+	+	–	+	–	+	+
Utilization as carbon source							
Cellobiose	+	+	NT	–	+	–	+
D-Galactose	+	+	–	–	–	–	+
D-Glucose	+	+	–	–	+	–	+
<i>i-myo</i> -Inositol	–	–	+	–	+	–	+
Maltose	+	–	+	–	+	–	+
D-Mannitol	–	+	+	–	+	–	+
Raffinose	–	–	–	–	+	–	–
L-Rhamnose	+	W	+	–	+	–	+
Sucrose	–	+	–	–	+	–	–
Trehalose	+	+	NT	–	+	–	–
D-Xylose	–	+	+	–	–	–	+

^a Data from references 1, 9, 20, and 24.

^b +, positive; –, negative; W, weakly positive; NT, not tested.

Table 6.2–5 Differential physiological characteristics of the medically important *Gordonia* species^{a,b}

Characteristic	<i>G. aichiensis</i>	<i>G. bronchialis</i>	<i>G. rubropertincta</i>	<i>G. sputi</i>	<i>G. terrae</i>
Species isolated from humans	+	+	+	+	+
Species implicated as cause of human infections	ND	+	+	+	+
Presence of synnemata ^c or rare microscopic hyphae	–	+	–	–	–
Utilization of carbon source ^d					
D-Galactose	+	–	+	+	+
<i>i-myo</i> -Inositol	–	+	–	–	–
D-Mannitol	–	–	+	+	+
Raffinose	–	–	–	+	+
L-Rhamnose	–	–	–	–	+
D-Sorbitol	–	–	+	+	+
Citrate	+	–	+	–	+

^a Data adapted from references 1a, 5, 11, and 13.

^b +, ≥90% of the strains are positive; –, ≥90% of the strains are negative; ND, not determined.

^c Group of erect conidiophores cemented together.

^d Concentration used to determine carbon source utilization was 1.0% except for growth on citrate, which was tested at 0.1%.

VI. LIMITATIONS

A. Carbohydrate basal medium—Gordon's oxidative agar slants

Cellobiose is easily reverted. Use 1 ml of 20% solution with a final concentration of 2%.

B. Decomposition of substrates

The tests for decomposition of substrates are not useful for separating *N. asteroides* sensu stricto, *N. farcinica*, *N. nova*, and *N. brevicatena* from each other or from the related genera *Corynebacterium*, *Gordonia* (Table 6.2–5), *Mycobacterium*, and *Rhodococcus*.

VII. IDENTIFICATION OF AEROBIC ACTINOMYCETES

All actinomycetes should be identified to the genus level and, in most cases, to the species level with the media and methods given in the previous section. Tables 6.2–1 through 6.2–5 serve as identification guides. Because of a rapidly evolving taxonomy, these tables may require modification as more new species are described. A schematic identification key is given in Fig. 6.2–1.

6.3.1

Appendix 6.3.1–1—Clinical Diseases in Humans Associated with Aerobic Actinomycetes

Actinomadura madurae—causative agent of mycetoma (rare in the United States but more common in tropical and subtropical countries) and nonmycetomic infections (very rare, but some reports of postoperative wound infections, pneumonia, and bacteremia)

Actinomadura pelletieri—causative agent of mycetoma (rare)

Dermatophilus congolensis—causative agent of dermatophilosis, particularly affecting workers in contact with infected animals (rare)

Gordonia bronchialis, *Gordonia sputi*, *Gordonia terrae*, and *Gordonia* spp.—causative agents of pulmonary disease (rare), bacteremia (rare), and postoperative infections (*Gordonia bronchialis*; rare)

Nocardia asteroides sensu stricto (types I and VI)—causative agents of nocardiosis (pulmonary and/or central nervous system [CNS] disease)

Nocardia brasiliensis—causative agent of nocardiosis (cutaneous and lymphocutaneous [rare] and mycetoma [rare in the United States but more common in South America, Mexico, and Australia])

Nocardia farcinica—causative agent of nocardiosis (pulmonary and/or CNS disease; postoperative infections [rare])

Nocardia nova—causative agent of nocardiosis (pulmonary and/or cutaneous disease)

Nocardia otitidiscaviarum—causative agent of nocardiosis (pulmonary and/or cutaneous disease) (rare)

Nocardia pseudobrasiliensis—causative agent of nocardiosis (pulmonary disease) (rare)

Nocardia transvalensis—causative agent of nocardiosis (pulmonary, disseminated, and mycetoma) (very rare)

Rhodococcus equi—causative agent of pulmonary disease (rare) and bacteremia (rare), particularly in human immunodeficiency virus-infected persons

Rhodococcus spp.—causative agents of invasive disease (very rare)

Streptomyces somaliensis—causative agent of mycetoma (very rare)

Tsukamurella inchonensis, *Tsukamurella pulmonis*, and *Tsukamurella tyrosinosolvans*—causative agents of pulmonary disease (rare), cutaneous disease (rare), and bacteremia (rare)

Appendix 6.3.3–1—Medium Composition and Preparation

I. GRAM STAIN

A. Crystal violet

1. Crystal violet powder (99% dye content)

Use 13.87 g (the amount of dye used is adjusted in proportion to the dye content of the powder, stated on the label) and add 200 ml of 95% ethanol.

2. Ammonium oxalate (8 g in 800 ml of distilled water)
3. Mix solutions 1 and 2 and allow to stand overnight or until the dye dissolves.
4. Filter through no. 2 Whatman filter paper.

B. Gram's iodine

iodine crystals 1.00 g
potassium iodide 2.00 g
distilled water 300 ml

Mix reagents 1 and 2 in a mortar and gradually add distilled water while emulsifying with a pestle. Store in a brown bottle at room temperature.

C. Decolorizing solution: 95% ethanol

D. Safranin-O counterstain

safranin-O 3.41 g
95% ethanol 100 ml
distilled water 900 ml

Safranin-O is dissolved in 100 ml of 95% ethanol, and the mixture is then combined with 900 ml of distilled water.

II. MODIFIED KINYOUN STAIN

A. Modified Kinyoun carbolfuchsin

1. Dissolve 4 g of basic fuchsin in 20 ml of 90 to 95% ethanol.
2. Dissolve 8 g of phenol crystals in 100 ml of distilled water.
3. Mix solutions 1 and 2.

B. Decolorizer (1% [vol/vol] H₂SO₄)

Add 1 ml of concentrated sulfuric acid to 99 ml of distilled water.

C. Methylene blue

Dissolve 2.5 g of methylene blue chloride in 100 ml of 95% ethyl alcohol.

III. ACETAMIDE HYDROLYSIS MEDIUM

Reagents

acetamide	10.000 g
sodium chloride	5.000 g
dipotassium phosphate	1.390 g
monopotassium phosphate	0.730 g
magnesium sulfate	0.500 g
phenol red	0.0120 g
agar	15.000 g
distilled water	1,000 ml

Prepare according to the manufacturer's instructions and place in 5-ml amounts into 12- by 125-mm tubes; autoclave at 121°C for 15 min and slant for cooling.

IV. ARYLSULFATASE LIQUID MEDIUM

A. Preparation of stock substrate

1. Dissolve 2.6 g of phenolphthalein disulfate, tripotassium salt, in 50 ml of distilled water; this is a 0.08 M solution.
2. Sterilize by membrane filtration (0.22- μ m-pore-size filter).
3. Store in refrigerator.
 - ☐ **NOTE:** Before use, the phenolphthalein disulfate should be tested for free phenolphthalein. Dissolve a small portion in a minimal amount of water, and add a few drops of 2 N sodium carbonate. If a pink color forms, this indicates free phenolphthalein, which will give false-positive reactions under actual test conditions. Sufficient purification of the product may be attained by dissolving 3 to 5 g of phenolphthalein disulfate in a minimal amount of water; this salt may be precipitated from solution (free of most phenolphthalein) by the addition of excess ethanol. The precipitated disulfate salt may be filtered off on a Buchner funnel, washed several

times with fresh ethanol, allowed to dry, and bottled for use in preparation of stock solution as described above.

B. Arylsulfatase broth

1. Aseptically add 2.5 ml of 0.08 M stock substrate to 200 ml of sterile Middlebrook 7H-9 broth. This provides 0.008 M substrate for the 3-day and 2-week tests.
2. Prepare two flasks, each with 200 ml of the sterile liquid medium.
3. Aseptically dispense each substrate in 2-ml amounts into sterile 16- by 125-mm screw cap test tubes.
4. The ready-to-use substrates may be stored at room temperature. As a QC check, add to a tube of each uninoculated substrate a few drops of sodium carbonate. The substrates should remain colorless. If the solution turns pink, discard the substrate and check the quality of the stock powder (as indicated in the note above) before preparing fresh substrate.

V. GORDON'S OXIDATIVE SLANTS

A. Basal medium

(NH ₄) ₂ HPO ₄	1.00 g
KCl	0.02 g
MgSO ₄ ·7H ₂ O	0.20 g
Agar	15.00 g
Distilled H ₂ O	1,000 ml

1. Add one salt at a time slowly.
2. Adjust the pH to 7.0.
3. Add 15 ml of 0.04% solution of bromcresol purple.

B. Autoclavable sugars

1. To a 100-ml aliquot of basal medium add 1 g of carbohydrate or 10 ml of 10% carbohydrate solution to 90 ml of basal medium. Autoclave for 10 min. Dispense 5 ml into 15- by 125-mm screw cap tubes and slant.

2. Autoclavable sugars

Basal medium (no carbohydrate)—control
D-Glucose
D-Mannitol
Salicin
Glycerol
i- <i>myo</i> -Inositol
Trehalose
D-Galactose
D-Mannose
D-Sorbitol
Dulcitol
Raffinose
Adonitol
i-Erythritol
Melibiose

V. GORDON'S OXIDATIVE SLANTS *(continued)*

C. Nonautoclavable sugars

1. Autoclave 90-ml aliquots of basal medium. Allow to cool to 45°C. Add aseptically 10 ml of 10% Seitz-filtered carbohydrate solution. Dispense 5 ml into 15- by 125-mm tubes and slant.

2. Seitz-filtered carbohydrates

- Lactose
- Sucrose
- Maltose
- Xylose
- L-Arabinose
- Starch
- D-Fructose
- Cellobiose
- L-Rhamnose

VI. CITRATE AGAR

- magnesium sulfate 0.02 g
- monoammonium phosphate 1.00 g
- dipotassium phosphate 1.00 g
- sodium citrate 2.00 g
- sodium chloride 5.00 g
- agar 15.00 g
- bromthymol blue 0.08 g
- distilled water 1,000 ml

Prepare according to the manufacturer's instructions and place in 5-ml amounts into 12- by 125-mm tubes; autoclave at 121°C for 15 min and slant for cooling.

VII. DECOMPOSITION OF SUBSTRATES

A. Media

1. Casein medium
 Prepare separately skim milk and agar.
 skim milk (dehydrated) 10 g
 distilled water 100 ml
 Autoclave at 15 lb/in² for 20 min at 121°C.
 agar 2.0 g
 distilled water 100 ml
 Cool both solutions to 45°C. Mix together and pour into quadrant Petri plates.
2. Basal medium for hypoxanthine, tyrosine, xanthine, and adenine nutrient agar
 peptone 5 g
 beef extract 3 g
 agar 15 g
 distilled water 1,000 ml
 Autoclave at 15-lb pressure for 20 min at 121°C. Adjust final pH to 7.0.

B. Addition of crystals

Suspend 0.4 g of xanthine, 0.4 g of tyrosine, 0.4 g of hypoxanthine, and 0.4 g of adenine in individual 10-ml amounts of distilled water and autoclave. When the agar has cooled to 45°C, mix the crystals and the basal medium and pour individual crystal suspensions into quadrant plates.

VIII. ESCULIN HYDROLYSIS MEDIUM

- esculin 1 g
- ferric citrate 0.5 g
- infusion agar 40.0 g
- distilled water 1,000 ml

Heat the ingredients to dissolve, and then cool to 55°C. Adjust the pH to 7.0. Pour the medium in 5-ml amounts into 15- by 125-mm tubes; autoclave at 121°C for 15 min and slant for cooling.

IX. LYSOZYME TEST**A. Basal glycerol broth**

peptone5.0 g
beef extract3.0 g
glycerol 70 ml
distilled water 1,000 ml
Autoclave at 15 lb/in² for 15 min at
121°C. Dispense 5 ml into test tubes
for control.

B. Lysozyme solution

lysozyme 100 mg
distilled water 100 ml
Sterilize by filtration. This stock solu-
tion should be stored at 4°C. Any stock
solution remaining after 2 months
should be discarded, since it deterio-
rates in that time. Mix 5 ml of the stock
lysozyme solution with 95 ml of basal
glycerol broth, and dispense 5-ml
quantities into test tubes.

6.3.4

Appendix 6.3.4–1—Cell Wall Determination of Diaminopimelic Acid Isomers

The cell wall of actinomycetes, like those of other bacteria, contains a murein layer that can be used as a criterion of taxonomic value. In the case of actinomycetes, it is possible to assign most strains to a cell

wall group with a crude whole-cell extraction and without the laborious task of making cell wall preparations (Table 6.3.4–A1). *Meso*-Diaminopimelic acid (DAP) is found in *Actinomadura* spp., *Corynebac-*

terium spp., *Gordonia* spp., *Mycobacterium* spp., *Nocardia* spp., *Nocardiopsis* spp., *Rhodococcus* spp., and *Tsukamurella* spp. as a major constituent of the cell wall; L-DAP is found in *Streptomyces* spp.

I. SUPPLIES

Include QC information on reagent container and in QC records.

A. General

1. Glassware—125-mm tubes; 250- and 500-ml flasks
2. Pipettes—10 and 100 μ l
3. Membrane filter; 0.22- μ m pore size

B. Chromatographic procedures

Ampoules, Pyrex chromatography tank (12 by 12 by 24 in) fitted with a glass rack for paper strips, Whatman chromatography paper no. 1 (46 by 57 mm and 4.24-cm diameter), oven, steam bath, fume cupboard

C. Control for detecting DAP isolates in cell walls

Control DAP (DL- α - ϵ -diaminopimelic acid [DL-2,6-diaminoheptanedoic acid])

Table 6.3.4–A1 Major constituents of cell walls of actinomycetes^a

Cell wall type	Species	Major constituents	Whole-cell sugar pattern	
			Type	Diagnostic sugar(s)
I	<i>Streptomyces</i> spp.	L-DAP; glycine	None	None
II	<i>Micromonospora</i> spp.	<i>meso</i> -DAP; glycine; hydroxy DAP may also be present	D	Xylose; arabinose
III	<i>Actinomadura</i> spp.	<i>meso</i> -DAP	B	Madurose ^b
	<i>Nocardiopsis</i> spp.	<i>meso</i> -DAP	C	None
IV	<i>Nocardia</i> spp.	<i>meso</i> -DAP; arabinose and galactose	A	Arabinose; galactose
	<i>Rhodococcus</i> spp.	<i>meso</i> -DAP; arabinose and galactose	A	Arabinose; galactose
	<i>Gordonia</i> spp.	<i>meso</i> -DAP; arabinose and galactose	A	Arabinose; galactose
	<i>Tsukamurella</i> spp.	<i>meso</i> -DAP; arabinose and galactose	A	Arabinose; galactose

^a All cell wall preparations contain major amounts of alanine, glutamic acid, glucosamine, and muramic acid.

^b Madurose, 3-*O*-methyl-D-galactose.

II. METHOD

A. Materials

1. Whole-cell preparations of isolates
2. Reagents
 - a. 6 N HCl
 - b. Solvents and reagents
 - methanol400 ml
 - distilled water 89 ml
 - 12 N HCl 11 ml
 - pyridine100 ml
 - c. Control DAP
 - d. Developer—400 mg of ninhydrin (1,2,3-triketohydrinedene hydrate) dissolved in 100 ml of acetone
 - e. Pyrex tank

CALAB 12- by 12- by 24-in Pyrex brand glass tank, using a Pyrex brand glass rack for paper strip chromatography. The trough support unit, which holds the troughs, is placed in position on the two uprights in such a manner that the solvent troughs will be perpendicular to the two sides of the tank, where the two uprights are located. Thus, the two heavier ends of the rack will be directly above the uprights. The apparatus is so designed that placement in this manner eliminates the possibility of the unit dropping into the bottom of the tank.
 - f. Chromatography paper—Whatman no. 1 Chr (46 by 57 mm and 4.25 cm in diameter)

B. Procedure

1. Growth of cultures
 - a. A pure isolate of the organism is grown in 200 ml TSB broth with a few 3-mm-diameter glass beads in a 500-ml flask incubated at 28 to 35°C aerobically on a rotator.
 - b. After maximal growth (24 h to 2 weeks), the cells are harvested.
2. Harvesting and drying the cells
 - a. Autoclave the flask to inactivate the cells (121°C for 15 min).
 - b. Transfer the cell suspension into a 250-ml screw cap centrifuge bottle, trying not to include the beads.
 - c. Centrifuge cell suspension for 20 min at 4,000 × g. Repeat this step if the cells are still in suspension.
 - d. Pour off the supernatant, and add 100 ml of ethanol to the bottle containing the cells. Resuspend the cells in the ethanol by shaking the bottle.
 - e. Incubate the cells at 35°C for 18 to 24 h.
 - f. Centrifuge the cell suspension for 20 min at 4,000 × g. Repeat this step if the cells are still in suspension. Pour off the ethanol supernatant.
 - g. Using a wooden tongue depressor, scrape the cell mass into a disposable petri dish. Place the cover over the dish, and incubate it at 35°C for 18 to 24 h (or until the cell mass is dry enough to grind with a mortar and pestle).
3. Hydrolysis of the cells
 - a. Weigh 10 mg of the cell material into a 2-ml prescored Wheaton vacule or ampoule.
 - b. Using a glass pipette, fill the vacule with 1 ml of 6 N HCl.
 - c. Seal the vacule with oxygen gas flame.
 - d. Incubate the sealed vacule in a 100°C drying oven for 18 h.
4. Preparation of cell hydrolysate
 - a. Remove the Wheaton vacule from the drying oven and open it. Set up a 20-ml beaker with a folded piece of qualitative Whatman no. 1 4.25-cm-

It is imperative that these cultures be handled in a biosafety hood.

II. METHOD (*continued*)

diameter filter paper held in the mouth of the beaker with a metal paper clip. Transfer the Wheaton vacule contents into the filter paper, and filter the cell suspension into the beaker. Rinse the filter paper with sterile distilled water three times.

- b.** Remove and dispose of the filter paper and paper clip.
 - c.** Heat the beaker over a pervaporator or steam bath to evaporate off the HCl solution. The filtrate is dried three consecutive times (add 1 ml of sterile distilled water each time).
 - d.** After last evaporation step, reconstitute the residue with 300 μ l of sterile distilled water.
 - e.** Transfer cellular hydrolysates into a screw cap tube and store at 4°C until ready for use.
- 5.** Preparation of chromatography paper
Using Whatman chromatography paper (no. 1 Chr) in 46- by 57-cm sheets, cut a piece down the middle to make two 23- by 57-cm sheets.
 - a.** Cut straight across the bottom edge with pinking scissors, which will leave a zigzag cut.
 - b.** On the opposite edge, draw lines with a graphite pencil at 1, 2, and 3 in.
 - c.** On the line, 3 in. from the top, make a 1/4-in. tick every 3/4 in. as a guide for the samples and control DAP.
 - d.** Load each position with 20 μ l of sample.
 - e.** Let dry thoroughly before placing in solvent tank.
- 6.** Preparation of chromatography system
Caution: *The tank and solvent preparation should be performed in a chemical fume hood.*
 - a.** Prepare the solvent and mix well. Reserve ~100 ml of the solvent for the trough, and pour the remaining solvent into a 1,000-ml beaker to place in one trough.
 - b.** Place the 1,000-ml beaker of solvent in the center of the tank between the two troughs. When the tank is being set up for the first time, the tank is equilibrated for 24 h with a batch of solvent and is sealed with silicone lubricant. Between uses, the tank is stored sealed with the solvent remaining in it. When the solvent level in the tank reaches about 1 in. below the paper, remove about half of the solvent from the tank.
 - c.** Place paper(s) in the glass trough(s).
 - d.** Pour the 100-ml beaker of solvent into the glass well, and seal the tank. Let the test run for 18 to 20 h. Solvent should be seen dripping from the paper's jagged edges when it has descended the length of the paper.
- 7.** Drying and spraying the paper chromatograph for DAP determination
 - a.** Remove the paper from the tank and air dry completely (10 to 15 min).
 - b.** Prepare the acetonc ninhydrin developer. Store in a dark bottle for reuse (developer is good for 1 month).
 - c.** Pour a layer of developer into a shallow pan (Pyrex or plastic), and wet the paper completely from end to end. Place the paper in a 100°C drying oven for 2 min. Try not to lay the paper flat against anything.
☑ NOTE: DAP is more soluble in H₂O than in pyridine. Better separation of the L-DAP and *meso*-DAP can be achieved if the system goes more slowly. To slow down the flow rate, use more pyridine. If the ninhydrin solution is too old, poor development of the paper may result. Make up fresh developer, and redip the paper.
- 8.** Interpretation of results
DAP spots are olive green and will turn yellow with time. *meso*-DAP runs more slowly than L-DAP, so it is closer to the origin of the spots. Other amino acids present appear as purple spots, which travel faster than the DAP, some migrating off the paper during the migration process.

Mycobacteriology and Antimycobacterial Susceptibility Testing

7.1.1

Safety and Levels of Laboratory Service

I. SAFETY

All specimens and cultures handled in the mycobacteriology laboratory must be processed under an appropriate biological safety cabinet (BSC). Personal protective clothing (gowns, gloves, and respirators) is required for processing, smear prepa-

ration, and culturing for mycobacteria. Centrifuges must be equipped with aerosol-free safety canisters. Refer to CDC publications for detailed safety recommendations (1, 2, 4).

II. LEVELS OF LABORATORY SERVICE

The levels of laboratory service promulgated by the CDC, American Thoracic Society, and CAP (3, 5) are based on workload, expertise, and cost-effectiveness. A laboratory qualifies for levels I through III by performing the procedures listed below. Procedures not performed by level I or II laboratories are referred to a nationally recognized reference facility or a higher-level laboratory.

Procedure	Level		
	I	II	III
Acid-fast smears	Yes	Yes	Yes
Culture	No	Yes	Yes
Identification of <i>Mycobacterium tuberculosis</i> complex	No	Yes	Yes
Identification of all mycobacteria	No	No	Yes
Drug susceptibility	No	Yes	Yes

To maintain proficiency to qualify for level I status, a laboratory must prepare at least 10 to 15 specimens per week and examine them for acid-fast bacilli; to qualify for levels II and III, a laboratory must culture and identify at least 20 specimens per week. Level I laboratories must render the mycobacteria nonviable before acid-fast staining by treating the specimen with an equal volume of 5% sodium hypochlorite solution (undiluted household bleach) and waiting exactly 15 min before pouring this into a 15-ml sterile centrifuge tube. Staining can then be conducted on an open bench after centrifuging and decanting.

Safety precautions for level II laboratories include BSL 2 practices, facilities, and containment equipment (e.g., a class I or class II BSC and centrifuges with safety carriers), and personal protective clothing is required for processing and preparation of smears and culturing for mycobacteria.

7.1.2

Digestion-Decontamination Procedures

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Optimal recovery of mycobacteria from clinical specimens known to be contaminated requires liquefying the organic debris (digestion) and eliminating contaminating organisms (decontamination). Decontaminating procedures are toxic to mycobacteria. Five methods available for digestion and decontamination of specimens for culture of acid-fast bacteria are discussed in this procedure. The most commonly used procedure in the United States is the *N*-acetyl-L-cysteine–sodium hydroxide (NALC-NaOH) method.

A. NACL-NaOH method

NALC is a very effective mucolytic agent that at concentrations of 0.5 to 2.0% can rapidly digest sputa within 2 min. Decontamination is achieved by the addition of sodium hydroxide. One advantage of using the NALC-NaOH method is that a very good mucolytic agent can be used with reduced concentrations of a digestant-decontaminant (the final NaOH concentration in the sputum is 1%). A disadvantage is the short shelf life (24 h) of the final NALC-NaOH working reagent (6, 7, 9).

B. NaOH method

NaOH is a digestant and a decontaminant (6, 9). At a final specimen concentration of 2%, it is toxic for contaminants; however, some mycobacteria are also affected. Timing of the digestion-decontamination step is crucial for effective recovery of mycobacteria. Many laboratories use a combination of NaOH and NALC, which, as stated above, is an effective mucolytic reagent.

C. Zephiran-trisodium phosphate (Z-TSP) method

Zephiran, benzalkonium chloride, is a quaternary ammonium compound. The modification of Wayne et al. utilizes a reduced Zephiran concentration to prevent excessive sediment viscosity while decontaminating the specimen. The Z-TSP method (3, 6, 9) is considered a mild digestion-decontamination procedure. An advantage of Z-TSP is that mycobacteria can withstand prolonged treatment with it, so timing of the digestion-decontamina-

tion process is not critical. A disadvantage is that residual Z-TSP is mycobacteriostatic. Inoculation of agar-based media requires a neutralization step. Egg-based media contain lecithin, which neutralizes the bacteriostatic effect.

D. Oxalic acid method

Oxalic acid (ethanedioic acid [$C_2H_2O_4$]) has a reduced tuberculocidal effect (1). This method is not widely used except as an alternative decontamination method when specimens are known to be consistently contaminated with *Pseudomonas aeruginosa* (1, 6, 9).

E. Cetylpyridinium chloride (CPC)-sodium chloride method

CPC (1-hexadecylpyridinium chloride) is a quaternary ammonium compound. It has been demonstrated that a 1% CPC–2% NaCl solution effectively digested and decontaminated specimens that contained viable tubercle bacteria even after 8 days of exposure (10).

II. SPECIMEN COLLECTION, TRANSPORT, AND STORAGE

A. Specimen collection (5)

1. Use a sterile, leakproof, disposable plastic container, preferably a Sage collection kit (Becton Dickinson Microbiology Systems).
2. Collect specimens before antimicrobial therapy is begun.
3. Specimens that are unacceptable include dry swabs, nonsterile containers, leaky specimens, and unlabeled specimens. Request another specimen.

B. Specimen transport

1. Deliver to the laboratory in as short a time as practical to avoid overgrowth by contaminants.

II. SPECIMEN COLLECTION, TRANSPORT, AND STORAGE (continued)

2. Refrigerate specimens if transport is delayed more than 1 h (8, 10).
3. For blood, collect in BACTEC 13A bottle or Isolator tube. Do not refrigerate. Hold at room temperature.

C. Storage

1. Specimens (except blood) not processed within 1 h of collection should be refrigerated (2 to 8°C).
2. If gastric lavage specimens are delayed more than 4 h, add approximately 100 mg of sodium carbonate to the container to neutralize the acidity.

D. Specimens for decontamination

1. Contaminated specimens requiring decontamination include sputum, bronchial wash, skin, soft tissue, gastric lavage, and urine.
2. Sterile sites not requiring decontamination include CSF, bone marrow, blood, and biopsy sites.

III. MATERIALS

Include QC information on reagent container and in QC records.

Equipment that applies to all procedures listed includes centrifuges with aerosol-free sealed centrifuge canisters, class I or II biological safety cabinets inspected and certified at least annually, and vortex mix-

ers. All reagents must be labeled with the date of preparation or receipt, contents, concentration, storage requirements, and expiration date.

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

Monitor the percentage of contaminated specimens. To determine the contamination rate, decontaminate four to six sputum samples, concentrate them by centrifugation, and inoculate onto general bacteriology media (e.g., blood agar) in addition to the mycobacteriology media normally used. Only minimal or no contaminants should grow after 24 to 48 h of incubation at 37°C. The acceptable range is 3 to 5% with media without antimicrobial agents. A contamination rate significantly less than 3% in the non-antimicrobial-agent-containing media suggests overly harsh contamination. Greater than 5% growth suggests inadequate decontamination or incomplete digestion.

V. PROCEDURES

Observe standard precautions.

With all procedures listed, use only sterile distilled water for all steps to prevent contamination with environmental mycobacteria (see Appendix 7.1.2–1).

A. NaCL-NaOH method

1. Add an equal volume of working NALC-NaOH solution (no more than 24 h old) in a sterile 50-ml conical polypropylene screw-cap centrifuge tube (aerosol free and graduated). If more than 10 ml of specimen is submitted, use a sterile transfer pipette to select 10 ml of the most purulent, bloody, or mucoid portion. Secure the cap tightly.
2. Mix contents of the tube on a vortex mixer for not more than 30 s.
3. Incubate tube for 15 min at room temperature to decontaminate the specimen.
4. Dilute the mixture to the 50-ml mark with either sterile distilled water or sterile 0.067 M phosphate buffer (pH 6.8). This will reduce the continued action of the NaOH and lower the viscosity of the mixture.
5. Recap the tube tightly, and invert several times to mix the contents.
6. Centrifuge the tubes at $\geq 3,000 \times g$ for 15 to 20 min. Use aerosol-free sealed centrifuge cups.
7. Pour off the supernatant into a splash-proof discard container filled with a suitable disinfectant (e.g., Amphyl).

V. PROCEDURES (*continued*)

8. Use a sterile 3-mm-diameter bacteriological loop or the end of a sterile wooden applicator stick to remove a portion of the sediment. Prepare a smear over an area of 1 by 2 cm on a new, clean, unscratched glass slide. If the amount of sediment is very small, delay making the smear after the addition of the 0.2% bovine albumin fraction V. (Bovine albumin fraction V [0.2%] buffers the inoculum and increases the adhesion of the sample.)
9. Suspend the remaining sediment in 1 to 2 ml of sterile 0.85% NaCl or sterile distilled water if media are to be inoculated immediately. Otherwise, suspend the sediment in 1 to 2 ml of sterile 0.2% bovine albumin fraction V. If the amount of sediment is very small, reconstitute the sediment to 1 ml only.
10. Use half of the suspension to make a 1:10 dilution in sterile distilled water (1 part suspension plus 9 parts water) (9).
11. Inoculate each suspension (diluted and undiluted) onto the appropriate media.

B. Sodium hydroxide method

1. Add a volume of 2% NaOH solution equal to the volume of the specimen in a sterile 50-ml conical polypropylene screw-cap centrifuge tube (aerosol free and graduated). If more than 10 ml of specimen is submitted, use a sterile transfer pipette to select 10 ml of the most purulent, bloody, or mucoid portion. Secure the cap tightly.
2. *Note:* Sodium hydroxide should be used at the lowest concentration that will effectively digest and decontaminate the specimen. If excessive contamination occurs with the use of 2% NaOH, increase the concentration to 3 or 4% rather than increasing the time of exposure.
3. Mix the tube on a vortex mixer. Incubate the tube for 15 min at room temperature to decontaminate the specimen, or shake vigorously on a mechanical shaker for 15 min.
4. Dilute the mixture to the 50-ml mark with either sterile distilled water or sterile 0.067 M phosphate buffer (pH 6.8). This will reduce the continued action of the NaOH and lower the viscosity of the mixture.
5. Recap the tube tightly, and invert several times to mix the contents.
6. Centrifuge the tubes at $\geq 3,000 \times g$ for 15 to 20 min. Use aerosol-free sealed centrifuge cups.
7. Pour off the supernatant into a splash-proof discard container filled with a suitable disinfectant (e.g., Amphyl).
8. The sediment may be tested with a drop of phenol red indicator solution. Add 2 N HCl dropwise until the color of the sediment turns from red to *persistent* yellow. The use of lower working concentration of NaOH (e.g., 2%) together with a dilution step should obviate this step.
9. Use a sterile 3-mm-diameter bacteriological loop or the end of a sterile wooden applicator stick to remove a portion of the sediment. Prepare a smear over an area of 1 by 2 cm on a new, clean, unscratched glass slide. If the amount of sediment is very small, delay making the smear after the addition of the 0.2% bovine albumin fraction V.
10. Suspend the remaining sediment in 1 to 2 ml of sterile 0.85% NaCl or sterile distilled water if media are to be inoculated immediately. Otherwise, suspend the sediment in 1 to 2 ml of sterile 0.2% bovine albumin fraction V. If the amount of sediment is very small, reconstitute the sediment to 1 ml only.
11. Inoculate the suspension onto the appropriate media.

C. Z-TSP method

1. Add a volume of Z-TSP reagent equal to the volume of the specimen in a sterile 50-ml conical polypropylene screw-cap centrifuge (aerosol free and graduated). If more than 10 ml of specimen is submitted, use a sterile trans-

V. PROCEDURES (*continued*)

fer pipette to select 10 ml of the most purulent, bloody, or mucoid portion. Secure the cap tightly.

2. Shake vigorously on a mechanical shaker for 30 min.
3. Incubate the tube for 20 to 30 min at room temperature *without* additional shaking.
4. Centrifuge the tubes at $\geq 3,000 \times g$ for 15 to 20 min. Use aerosol-free sealed centrifuge cups.
5. Pour off the supernatant into a splash-proof discard container filled with a suitable disinfectant (e.g., Amphyl).
6. Suspend the sediment in 20 ml of neutralizing buffer, pH 6.6 (2). Agitate thoroughly on a vortex mixer for 30 s.
7. Centrifuge the suspension at $\geq 3,000 \times g$ for 15 to 20 min.
8. Pour off most of the supernatant. Retain a small amount of supernatant for resuspension of the sediment.
NOTE: The buffer will neutralize any remaining Z-TSP. This is especially critical if inoculation of an agar-based medium is intended.
9. Use a sterile 3-mm-diameter bacteriological loop or the end of a sterile wooden applicator stick to remove a portion of the sediment. Prepare a smear over an area of 1 by 2 cm on a new, clean, unscratched glass slide.
10. Inoculate the suspension onto the appropriate media.

D. Oxalic acid method

1. Add an equal volume of 5% oxalic acid to the specimen in a sterile 50-ml conical polypropylene screw-cap centrifuge tube. If more than 10 ml of specimen is submitted, use a sterile transfer pipette to select 10 ml of the most purulent, bloody, or mucoid portion. Secure the cap tightly.
2. Mix the tube on a vortex mixer for 30 s.
3. Incubate the tube for 20 to 30 min at room temperature to decontaminate the specimen. Shake the tube occasionally.
4. Dilute the mixture to the 50-ml mark with sterile 0.85% NaCl.
5. Recap the tube tightly, and invert several times to mix the contents.
6. Centrifuge the tubes at $\geq 3,000 \times g$ for 15 to 20 min. Use aerosol-free sealed centrifuge cups.
7. Pour off the supernatant into a splash-proof discard container filled with a suitable disinfectant (e.g., Amphyl).
8. Add a few drops of phenol red indicator to the sediment.
9. Neutralize the sediment with 4% NaOH until a pale pink color is obtained.
10. Use a sterile 3-mm-diameter bacteriological loop or the end of a sterile wooden applicator stick to remove a portion of the sediment. Prepare a smear over an area of 1 by 2 cm on a new, clean, unscratched glass slide.
11. Resuspend the sediment and inoculate the suspension onto the appropriate media.

E. CPC-sodium chloride method

1. Add an equal volume of CPC-NaCl reagent to the specimen in a sterile 50-ml conical polypropylene screw-cap centrifuge tube (aerosol free and graduated). If more than 10 ml of specimen is submitted, use a sterile transfer pipette to select 10 ml of the most purulent, bloody, or mucoid portion. Secure the cap tightly.
2. Shake by hand until the specimen liquefies.
3. Package the tube as required by postal and International Air Transport Association regulations and send to a processing laboratory or place in a suitable holding area pending local processing. *Be sure to allow at least 24 h for digestion-decontamination to be completed!*
4. Dilute the mixture to the 50-ml mark with either sterile distilled water or neutralizing buffer (4).

V. PROCEDURES (continued)

5. Recap the tube tightly, and invert several times to mix the contents.
6. Centrifuge the tubes at $\geq 3,000 \times g$ for 15 to 20 min. Use aerosol-free sealed centrifuge cups.
7. Pour off the supernatant into a splash-proof discard container filled with a suitable disinfectant (e.g., Amphyl).
8. Use a sterile 3-mm-diameter bacteriological loop or the end of a sterile wooden applicator stick to remove a portion of the sediment. Prepare a smear over an area of 1 by 2 cm on a new, clean, unscratched glass slide. If the amount of sediment is very small, delay making the smear after the addition of the 0.2% bovine albumin fraction V.
9. Suspend the sediment in 1 to 2 ml of sterile 0.85% NaCl or sterile distilled water if media are to be inoculated immediately. Otherwise, suspend the sediment in 1 to 2 ml of sterile 0.2% bovine albumin fraction V. If the amount of the sediment is very small, reconstitute the sediment to 1 ml.
10. Inoculate the suspension onto the appropriate media.
11. *Note:* Residual CPC may inhibit mycobacteria inoculated onto agar-based media. Phospholipids found in egg-based media neutralize this inhibitory action. It has been reported that growth inhibition on agar-based medium may not occur if residual CPC is inactivated with Bacto neutralizing buffer (Difco) (10).

APPENDIX 7.1.2-1

Materials

A. NALC-NaOH method

1. NaOH: sodium citrate stock solution (0.1 M)

Solution 1

sodium citrate dihydrate29 g
 (or sodium citrate, anhydrous)26 g
 distilled waterto 1,000 ml

Solution 2: 4% NaOH solution (1 N)

NaOH pellets40 g
 distilled waterto 1,000 ml

Combine equal volumes of solutions 1 and 2, and autoclave the mixture at 121°C for 15 min in screw-cap flasks. This solution may be stored at room temperature, but refrigeration is preferred.

Caution: *Sodium hydroxide is caustic. Always wear appropriate clothing and eye protection.*

2. Working NALC-NaOH solution

Just before use, combine NALC with the NaOH-sodium citrate solution (Table 7.1.2-A1). The working solution can be used for up to 24 h, after which it must be discarded.

3. 0.067 M (M/15) phosphate buffer (pH 6.8) (6)

Stock alkaline buffer

Na₂HPO₄ (anhydrous) 9.47 g
 distilled waterto 1,000 ml

Stock acid buffer

KH₂PO₄ 9.07 g
 distilled waterto 1,000 ml

Add dry buffer powder to separate 1,000-ml volumetric flasks. Add distilled water to the 1,000-ml mark. Each buffer may be transferred to screw-cap containers and sterilized at 121°C for 15 min to be mixed at a later time, or the buffers may be immediately combined and sterilized. Storage under refrigeration is preferred.

Working phosphate buffer (pH 6.8)

Combine equal volumes of stock alkaline and acid buffers. Check the pH of the working solution with a pH meter. Titrate with appropriate buffer to the correct pH.

4. 0.2% Bovine albumin fraction V solution (6)

Stock 2% bovine albumin solution

NaCl 0.85 g
 bovine albumin fraction V 2.00 g
 distilled water 100 ml

Prepare a solution of 0.85% NaCl by dissolving the NaCl in distilled water. Slowly add the bovine albumin to the NaCl solution, and mix by swirling or gentle agitation on a vortex mixer. Adjust the pH to 6.8 with 4% NaOH. Sterilize by passing the solution through a membrane filter (0.45-µm pore size). Use aseptic technique to dispense 10- to 20-ml aliquots into sterile screw-cap tubes. Store the stock solution in a refrigerator (2 to 8°C) until needed.

Table 7.1.2-A1 Preparation of NALC-NaOH digestant-decontaminant

Total vol needed (ml)	Amt of:	
	NaOH-sodium citrate (ml)	NALC (g)
50	50	0.25
100	100	0.50
250	250	1.25
500	500	2.50
1,000	1,000	5.00

APPENDIX 7.1.2-1 (continued)

Working 0.2% bovine albumin solution

- stock 2% bovine albumin solution 1 part
- sterile 0.85% NaCl
(or sterile distilled H₂O) 9 parts

Dilute the stock solution to the desired volume. Prepare enough for use on 1 day. Discard the remainder at the end of the day.

- 5. Sterile 0.85% NaCl or sterile distilled water

B. Sodium hydroxide method

- 1. 2% NaOH solution (0.5 N) (4, 5)

- NaOH pellets20 g
- distilled waterto 1,000 ml

- 2. 4% NaOH solution (1 N)

- NaOH pellets40 g
- distilled waterto 1,000 ml

Caution: *Sodium hydroxide is caustic.*

Prepare the reagent by rapidly weighing the NaOH in less than 1 liter of distilled water in a beaker. Keep the beaker cool to minimize heat buildup. Transfer to a volumetric flask, and add distilled water to the 1,000-ml mark. Sterilize at 121°C for 15 min. Store at room temperature.

- 3. 0.067 M (M/15) phosphate buffer (pH 6.8) (6)

Stock alkaline buffer

- Na₂HPO₄ (anhydrous) 9.47 g
- distilled waterto 1,000 ml

Stock acid buffer

- KH₂PO₄ 9.07 g
- distilled waterto 1,000 ml

Add dry buffer powder to separate 1,000-ml volumetric flasks. Add distilled water to the 1,000-ml mark. Each buffer may be transferred to screw-cap containers and sterilized at 121°C for 15 min to be mixed at a later time, or the buffers may be immediately combined and sterilized. The solution may be stored at room temperature, but refrigeration is preferred.

Working phosphate buffer (pH 6.8)

Combine equal volumes of stock alkaline and acid buffers. Check the pH of the working solution with a pH meter. Titrate with appropriate buffer to the correct pH.

- 4. 2 N HCl solution (6)

- HCl, concentrated (approximately 12 N or 36%
[wt/vol])33 ml
- distilled waterto 200 ml

Add approximately 100 ml of distilled water to a volumetric flask. *Slowly* add HCl to the water by running the acid down the inside of the flask. *Never add water to acid!* Wear an acid-resistant apron, gloves, and eye protection when working with concentrated HCl. In the event of a spill, immediately flood any area in contact with acid with copious amounts of water. Seek medical attention if required. Sterilize the acid solution at 121°C for 15 min. The solution may be stored at room temperature.

- 5. Phenol red indicator (6)

- Phenol red 8 mg
- 4% NaOH20 ml
- distilled waterto 1,000 ml

Dissolve the phenol red powder in 4% NaOH using a magnetic stirrer. Gentle heat may be required. Transfer the solution to a 1,000-ml volumetric flask. Add distilled water to the 1,000-ml mark. The solution may be stored at room temperature.

C. Z-TSP method

- 1. Z-TSP reagent (3, 7)

- Na₃PO₄ · 12H₂O 1 kg
- hot distilled water 4 liters

APPENDIX 7.1.2-1 (continued)

2. Zephiran (17% benzalkonium chloride)7.5 ml
Dissolve the trisodium phosphate ($\text{Na}_3\text{PO}_4 \cdot 12\text{H}_2\text{O}$) in hot water. Add Zephiran while stirring. Mix well. Store at room temperature.
3. Neutralizing buffer (2)

Bacto neutralizing buffer, dehydrated (Difco)5.2 g
distilled water1,000 ml
4. Rehydrate by dissolving the powder in distilled water on a magnetic stirrer. Gentle heat may be required. Dispense into screw-cap containers, and sterilize at 121°C for 15 min. Refrigerate.

D. Oxalic acid method

1. 5% Oxalic acid reagent (1, 2)

oxalic acid ($\text{C}_2\text{H}_2\text{O}_4$)50 g
distilled waterto 1,000 ml

Dissolve the oxalic acid in a beaker of distilled water. Transfer the solution to a 1,000-ml volumetric flask. Add distilled water to the 1,000-ml mark. Sterilize at 121°C for 15 min. Store at room temperature.

2. Phenol red indicator

phenol red8 mg
4% NaOH20 ml
distilled waterto 1,000 ml

Dissolve the phenol red powder in 4% NaOH on a magnetic stirrer. Gentle heat may be required. Transfer the solution to a 1,000-ml volumetric flask. Add distilled water to the 1,000-ml mark. Store at room temperature.

3. 4% NaOH solution (1 N)

NaOH pellets40 g
distilled waterto 1,000 ml

Caution: Sodium hydroxide is caustic.

Prepare the reagent by rapidly weighing the NaOH in less than 1 liter of distilled water in a beaker. Keep the beaker cool to minimize heat buildup. Transfer to a volumetric flask, and add distilled water to the 1,000-ml mark. Sterilize at 121°C for 15 min. Store at room temperature.

4. Sterile 0.85% NaCl

E. CPC-sodium chloride method

1. CPC-NaCl reagent (6, 8)

CPC10 g
NaCl20 g
distilled water1,000 ml

Dissolve 10 g of CPC and 20 g of NaCl in a beaker of distilled water on a magnetic stirrer. Gentle heat may be required. The solution is self-sterilizing and is stable for long periods. Store at room temperature. Protect from light, excess heat, and evaporation. If crystals form, dissolve them with gentle heat.

2. Neutralizing buffer (2)

Bacto neutralizing buffer, dehydrated (Difco)5.2 g
distilled water1,000 ml

Rehydrate by dissolving the powder in distilled water on a magnetic stirrer. Gentle heat may be required. Dispense into screw-cap containers and sterilize at 121°C for 15 min. Refrigerate.

3. Sterile 0.85% NaCl

APPENDIX 7.1.2-1 (continued)

7.1.3

Reporting

State and local authorities vary in regulations governing reporting of *Mycobacterium tuberculosis* detection. CDC guidelines advocate reporting all positive acid-fast bacterial smears and culture results for *M. tuberculosis* complex rapidly to all appropriate authorities as well as the physician in charge of the patient (1, 2, 3).

- A. Communicate with the state and/or local tuberculosis control officer regarding laws governing the reporting of positive acid-fast smears and cultures.
- B. Telephone diagnostic information as soon as possible to the clinician, the infection control officer, and the public health authorities. Document date, time, and person notified.
- C. Issue a preliminary report each time new information is obtained and whenever isolates are referred to another laboratory for identification and susceptibility testing.
- D. Verbally communicate the existence of the first positive culture (each patient, each episode) and subsequent results that may suggest dissemination, such as a sputum culture isolate followed by a blood culture isolate of suspected *Mycobacterium avium* complex.
- E. Send written reports of preliminary information, final identification, and drug susceptibility results to the clinician, the infection control officer, and the medical records department.
- F. Verbally communicate the first evidence of *M. tuberculosis* in culture. Call in results of additional culture-positive specimens if they were obtained during the time the patient is known or presumed to have been receiving treatment. Positive cultures at this stage will alert the public health officer to possible poor compliance with antituberculosis therapy.
- G. Send a written report of the final identification and drug susceptibility result. This level of reporting will be unnecessary to laboratories that send isolates to their local public health laboratory for identification and/or antimicrobial susceptibility testing.

Turnaround time expectations in typical mycobacteriology laboratory

Time to results from specimen receipt	Positive reports to physician and public health
1 day	Acid-fast smear, direct amplification test
1–2 wks	Culture report
3 wks	<i>M. tuberculosis</i> identification
4 wks	Susceptibility results

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Mycobacteria are difficult to stain due to the presence of large amounts of lipid (mycolic acid) in the cell wall; hence, the use of the traditional Gram stain is of little to no value since the dyes do not usually permeate the mycobacterial cell walls. Instead, the most widely used methods to determine acid-fastness in a clinical specimen are the carbol fuchsin stains (Kin-youn or Ziehl-Neelsen) and the fluorochrome stain (e.g., auramine O or

auramine-rhodamine). The fluorochrome stains are recommended for the examination of clinical specimens because of their increased sensitivity and speed, since they may be examined at a lower magnification than the carbol fuchsin stain (5, 7).

The acid-fast stain remains the most rapid method for the detection of mycobacteria. It can determine the presence of mycobacteria in a clinical specimen,

monitor the progress of patients on anti-mycobacterial therapy, clarify a need for appropriate infection control procedures, dictate the appropriate dilution of sediments for drug susceptibility testing, and confirm the presence of acid-fast bacilli (AFB) in culture. Due to its poor sensitivity and specificity (5), the acid-fast smear is an adjunct and not a substitute for culture.

II. SPECIMENS

It is imperative that these cultures be handled in a biosafety hood.

- A. Clinical specimens suspected of harboring mycobacteria or pure cultures are stained for acid-fastness. The value of staining gastric aspirates and urine is controversial. A smear directly from a clinical specimen (not concentrated) is discouraged because it lacks the sensitivity of a concentrated smear. A negative result from a direct smear must be followed by testing with a concentrated smear.
- B. Specimens for the diagnosis of mycobacterial infection that are routinely acid-fast stained are from the respiratory tract (mostly sputa but also bronchial washings and bronchoalveolar lavage specimens) but may include sterile body fluids or tissue.
- C. AFB smears are made from the sediments of specimens that have been decontaminated, when appropriate, and concentrated by centrifugation.
- D. Preparation of smears for staining
 1. Prepare a smear from the centrifuged specimen with either a bacteriological loop (3 mm in diameter), a sterile wooden applicator stick, or 1 drop from a sterile capillary pipette.
 2. Allow smears to air dry in a biological safety cabinet (1).
 3. Save sediments from each specimen and refrigerate as a backup for stain failure, a doubtful smear result, or contamination of culture. A smear directly from a clinical specimen (not centrifuged) is discouraged because it lacks the sensitivity of a concentrated smear.
 4. Smears must be heat fixed before staining by using an electric staining rack or plate or with a Bunsen burner.

III. MATERIALS

Prepare as indicated in *Clinical Microbiology Procedures Handbook*, vol. 1, pages 3.5.3 to 3.5.5 (4), or purchase from ENG Scientific, Inc., Clifton, N.J.

A. Carbol fuchsin-stained smears (Kinyoun or Ziehl-Neelsen)

1. Carbol fuchsin
2. 3% Acid-alcohol
3. Methylene blue or brilliant green counterstain

4. Filter paper strips, Bunsen burner, or, preferably, an electric staining rack

B. Fluorochrome acid-fast stains

1. Auramine O (with or without rhodamine)
2. 0.5% Acid-alcohol
3. Potassium permanganate or acridine orange counterstain

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

Include QC information on reagent container and in QC records.

A. Positive and negative controls

1. Positive and negative control slides must be included whenever the AFB stain is performed and upon receipt of each new lot of materials, reagents, and media to verify the correct performance of the procedure. *Escherichia coli* is commonly used for the negative control and *Mycobacterium tuberculosis* H37Ra ATCC 25177 is the positive control.
2. Record the results of the control slides before reviewing the smears from clinical specimens. If the control slide is unacceptable, review procedures and reagent preparations.

B. Kinyoun carbol fuchsin stain

1. Positive: *Mycobacterium* species stain red or magenta against a blue or green background depending upon the counterstain used.
2. Negative: *E. coli* stains blue or green depending upon the counterstain used.

C. Fluorochrome stain (auramine O or auramine-rhodamine)

1. Positive: *Mycobacterium* species show a yellow to orange fluorescence (color may vary with the filter system used).
2. Negative: *E. coli* will show no fluorescence.

V. PROCEDURES

Discard slides after examination into a sharps receptacle; wear gloves when handling the slides. To avoid false-negative results, a minimum of 300 microscopic fields should be examined before the slide is reported as negative in industrialized countries and at least 100 fields should be examined in low-income countries (4).

A. Kinyoun carbol fuchsin stain

1. Flood the entire fixed slide with Kinyoun's carbol fuchsin.
2. Allow the smear to stain for 5 min.
3. Rinse the slide with water.
4. Flood the slide with 3% acid-alcohol to decolorize for 2 min and until no more color drains from the slide.
5. Rinse the slide with water; drain excess water from the slide.
6. Flood the slide with counterstain (methylene blue or brilliant green).
7. Counterstain for 2 min.
8. Rinse the slide thoroughly with water; drain excess water from the slide.
9. Air dry. Do not blot.
10. Examine with a 100 \times oil immersion objective (\times 1,000 total magnification) using a light microscope.

B. Ziehl-Neelsen (a hot carbol fuchsin stain)

1. Cover the heat-fixed slide with filter paper at 2 by 3 cm to minimize precipitation of crystals due to the heating and to keep the stain on the slide.

V. PROCEDURES (*continued*)

2. Flood the filter paper strip with the carbol fuchsin stain.
3. Heat the slide to steaming on an electric staining rack or with a Bunsen burner.
4. Let stand for 5 min. Add more stain if the smear dries, but do not reheat.
5. Remove filter paper strips with a forceps and discard into a container to be autoclaved later.
6. Wash slides with water.
7. Flood smear with acid-alcohol and allow destaining for 2 min.
8. Wash smear with water and drain.
9. Flood smear with the counterstain (methylene blue or brilliant green) for 1 to 2 min.
10. Rinse with water, drain, and then air dry.
11. Examine with a 100 \times oil immersion objective (\times 1,000 total magnification) using a light microscope.

C. Fluorochrome

1. Flood the slide with the fluorochrome stain.
2. Stain for 15 min.
3. Rinse the slide with water; drain the excess water from the slide.
4. Flood with 0.5% acid-alcohol.
5. Decolorize for 2 min.
6. Rinse the slide with water; drain the excess water from the slide.
7. Flood the slide with the counterstain (potassium permanganate or acridine orange).
8. Counterstain for precisely 2 min (a longer period may quench the fluorescence of the AFB when using the permanganate as counterstain).
9. Rinse with water; drain the excess water from the slide.
10. Air dry; do not blot.
11. Examine the smear with a fluorescent microscope with a 25 \times or 40 \times objective (\times 250 or \times 450 total magnification).
12. The morphology is confirmed under oil immersion at a \times 1,000 or \times 450 magnification.
13. Fluorochrome-stained slides may be directly restained with the carbol fuchsin stain after immersion oil is removed with xylene.

VI. RESULTS

- A. Fluorochrome stain
 1. Positive: yellow to orange fluorescence (depending upon the filter system used) against a black background. Artifacts may fluoresce, so morphology must be carefully scrutinized.
 2. Negative: no fluorescence
- B. Carbol fuchsin (Kinyoun, Ziehl-Neelsen) stain
 1. Positive: red-stained rods against blue or green background, depending on the counterstain used
 2. Negative: no red-stained rods observed.
- C. Mycobacteria typically appear as slender rods, curved, bent or filamentous, 1 to 10 μ m long. Morphology of mycobacteria from liquid medium may assist in presumptive differentiation of *M. tuberculosis* complex from other mycobacteria as follows: *M. tuberculosis* and *Mycobacterium bovis* form typical serpentine cords and clumps, while other mycobacteria (except *Mycobacterium kansasii*) do not form cords.
- D. Data are number of AFB per indicated number of microscopic fields. This takes into account the larger number of fields covered with the lower magnification examined under the fluorescent microscope.

VI. RESULTS (continued)

Fluorochrome		Carbolfuchsin, × 1,000	Report
× 250	× 450		
0	0	0	No AFB seen
1–9/10 fields	2–18/50 fields	1–9/100 fields	1 +
1–9/field	4–36/10 fields	1–9/10 fields	2 +
10–90/field	4–36/field	1–9/field	3 +
>90/field	>36/field	>9/field	4 +

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Negative: when no AFB are observed, report as “Negative for acid-fast bacilli.”
- B. Positive: report as “Positive for acid-fast bacilli” and provide the count.
- C. Recommended reporting is listed on the chart above (3).

VIII. LIMITATIONS

- A. The acid-fast stain is not specific for mycobacteria. Also, nonmycobacterial microorganisms such as *Nocardia*, *Rhodococcus*, *Legionella micdadei*, cysts of *Cryptosporidium* species, and *Isospora* species and other microsporidia may exhibit various degrees of acid-fastness (6).
- B. The acid-fast stains cannot differentiate *M. tuberculosis* from nontuberculous mycobacteria.
- C. The acid-fast smear lacks sensitivity. Compared with culture, sensitivities ranging from 22 to 78% have been reported (2). Although slow-growing mycobacteria like *M. tuberculosis* are consistently acid-fast, the rapidly growing mycobacteria may be variably acid-fast or even negative for acid-fastness especially with the fluorochrome stain. Also, a negative acid-fast smear does not rule out mycobacterial infection, because estimated detection levels for AFB in sputum are only 5,000 to 10,000 bacilli per ml of sputum (5). Culture detects 10 to 100 viable mycobacteria (2).

7.3

Solid Media for Isolation

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Both liquid and solid media are recommended for optimal recovery of mycobacteria. The advantage of solid media (tubed or in plates) is that they enable detection of mixed cultures and contaminants. Egg-based and agar-based media may be used. The main advantage of an egg-based me-

dium is that it supports the growth of most mycobacteria and permits niacin testing. However, contamination occurs more easily involving the total surface of the medium. The main advantages of agar-based media are less contamination and earlier and easier visibility of colonial morphol-

ogy. Colonial morphology aids in the identification of mycobacteria. Use of both nonselective and selective media is needed for isolation, the latter containing one or more antimicrobial agents to prevent overgrowth by contaminating bacteria or fungi (2).

II. SPECIMEN

It is imperative that these cultures be handled in a biosafety hood.

- A. Only pure cultures that are acid-fast bacillus (AFB) positive are identified.
- B. Discard contaminated cultures. If the patient's specimen is still available, decontaminate by another method or request another specimen. Specimens repeatedly contaminated with *Pseudomonas* species or other organisms could be decontaminated by the oxalic acid, *N*-acetyl-L-cysteine–NaOH–oxalic acid, or other methods (1, 6).

III. MATERIALS

A. Media

Table 7.3–1 lists the selective and nonselective media commonly available. Nonselective media are recommended for use with specimens from normally sterile sites. Selective media are recommended for use with contaminated specimens.

B. Supplies

1. Bactericidal-mycobactericidal disinfectant
2. Gloves, masks, and gowns
3. Cotton or gauze pads
4. Sterile Pasteur pipettes

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

Include QC information on reagent container and in QC records.

A. Prepared media

1. Laboratories purchasing commercially prepared media that are quality controlled by the manufacturers in accordance with NCCLS-proposed standards need not perform QC checks for sterility, growth, selectivity, or biochemical response on Lowenstein-Jensen and Middlebrook media (3).
2. Documentation of the manufacturer's QC procedures should be obtained, by placing the lot number of each medium in a log book.
3. All other media, including user-prepared media, must be quality controlled with the appropriate positive and negative control organisms to ensure sat-

Table 7.3–1 Media commonly available for recovery of mycobacteria (2)^a

Medium	Components	Inhibitory agent
Nonselective		
Lowenstein-Jensen	Coagulated whole eggs, defined salts, glycerol, potato flour	Malachite green, 0.025 g/100 ml
Petragnani	Coagulated whole eggs, egg yolks, whole milk, potato flour, glycerol	Malachite green, 0.052 g/100 ml
American Thoracic Society	Coagulated fresh egg yolks, potato flour, glycerol	Malachite green, 0.02 g/100 ml
Middlebrook 7H10	Defined salts, vitamins, cofactors, oleic acid, albumin, catalase, glycerol, glucose	Malachite green, 0.0025 g/100 ml
Middlebrook 7H11	Defined salts, vitamins, cofactors, albumin, catalase, glycerol, 0.1% casein hydrolysate	Malachite green, 0.025 g/100 ml
CHOC	Hemolyzed blood agar with IsoVitaleX and bovine hemoglobin enrichment	
Selective		
Gruft modification of Lowenstein-Jensen	Coagulated whole eggs, defined salts, glycerol, potato flour, RNA (5 mg/100 ml)	Malachite green, 0.025 g/100 ml Penicillin, 50 U/ml Nalidixic acid, 35 µg/ml
Mycobactosel Lowenstein-Jensen	Coagulated whole eggs, defined salts, glycerol, potato flour	Malachite green, 0.025 g/100 ml Cycloheximide, 400 µg/ml Lincomycin, 2 µg/ml Nalidixic acid, 35 µg/ml
Mycobactosel Middlebrook 7H10	Defined salts, vitamins, cofactors, oleic acid, albumin, catalase, glycerol, glucose	Malachite green, 0.025 g/100 ml Cycloheximide, 360 µg/ml Lincomycin, 2 µg/ml Nalidixic acid, 20 µg/ml
Selective 7H11 (Mitchison's medium)	Defined salts, vitamins, cofactors, oleic acid, albumin, catalase, glycerol, glucose, casein hydrolysate	Carbenicillin, 50 µg/ml Amphotericin B, 200 U/ml Polymyxin B, 200 U/ml Trimethoprim lactate, 20 µg/ml

^a Reproduced and modified from **H. M. Sommers**, 1984. Mycobacterial diseases. In J. B. Henry (ed.), *Clinical Diagnosis and Management by Laboratory Methods*, 17th ed. The W. B. Saunders Co., Philadelphia, Pa., with permission of Elsevier.

IV. QUALITY CONTROL (continued)

isfactory performance and examined for signs of deterioration (color, dehydration, presence of contamination, bubbles, etc.).

4. Do not use media beyond the expiration date.
5. User-prepared media may be checked for sterility by incubating 1 to 3% of each batch and must be quality controlled and documented for performance. The microorganisms chosen for QC depend on the media. Generally, ATCC stock cultures of *Mycobacterium tuberculosis*, *Mycobacterium kansasii*, *Mycobacterium scrofulaceum*, *Mycobacterium intracellulare*, and *Mycobacterium fortuitum* are used. *Escherichia coli* can be the test organism to determine the inhibitory effectiveness of selective antimicrobial media.

IV. QUALITY CONTROL*(continued)*

6. All QC results must be documented and reviewed by a designated supervisor. Documentation of corrective action, resolution, and follow-up of the situation is required.

B. Inoculation

1. Make a suspension of the organism in 7H9 broth equal to a 0.5 McFarland standard.
2. For tubed media, use a calibrated loop or pipette to inoculate each tube to be tested with 10 μ l of suspension. Incubate at 35 to 37°C in 5 to 10% CO₂ for up to 21 days.

C. Interpretation of results

Expected results of QC testing of mycobacterial media are shown below.

<u>Control type and recommended ATCC strains</u>	<u>Result</u>
Positive controls	
<i>M. tuberculosis</i> ATCC 25177	Growth on all media
<i>M. kansasii</i> ATCC 12478	Growth on all media
<i>M. scrofulaceum</i> ATCC 19981	Growth on all media
<i>M. intracellulare</i> ATCC 13950	Growth on all media
<i>M. fortuitum</i> ATCC 2841	Growth on all media
Negative control	
<i>E. coli</i> ATCC 25922	Partial or total inhibition

V. PROCEDURE

- A. Add 3 drops of sediment to Lowenstein-Jensen agar with a sterile transfer pipette, allowing the sediment to spread over the surface of the slant. Store slants with caps loosened and place in a slanted rack.
- B. Add 1 drop of sediment to plated agar (Middlebrook 7H10 and/or 7H11) and streak sediment over the surface of the agar. Place each plate uninverted into a CO₂-permeable plastic bag. Invert plates after 24 h to allow sediment to be absorbed into the agar.
- C. Incubate all cultures in the dark at 35 to 37°C, with the exception of skin or soft tissue suspected to be infected with *Mycobacterium marinum*, *Mycobacterium ulcerans*, or any specimen suspected to be infected with *Mycobacterium haemophilum* for which an additional separate set of media is incubated at 30°C.
- D. Examine solid media within 3 to 5 days after incubation, twice a week up to week 4, and weekly thereafter until week 8 (4).
- E. Before examining agar plates, seal with Parafilm and examine these plates microscopically to facilitate the early observation of microcolonies.

VI. RESULTS AND INTERPRETATION**Morphological features**

- A. AFB smear-positive colonies growing in pure culture are considered positive.
- B. These pure cultures should be identified (5).
- C. Colonies on clear agar media in petri dishes should be inverted and examined under a microscope for cording and presence of filaments. Slow-growing, dry, corded colonies are suggestive of *M. tuberculosis* or *M. kansasii* (1).

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report as culture positive only when confirmed by acid-fast smear.
- B. Report as "Culture positive for mycobacteria, identification pending."
- C. Immediate reporting of AFB-positive results to the physician in charge and the local or state department of health is required.

7.4.1

BACTEC 460TB Radiometric System

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

In the BACTEC 460TB radiometric system (Becton Dickinson Diagnostic Systems, Sparks, Md.), growth medium for culturing mycobacteria is supplemented with a substrate labeled with radioactive carbon (^{14}C). This substrate is utilized by mycobacteria, and during metabolism,

carbon dioxide ($^{14}\text{CO}_2$) is produced from the substrate. The $^{14}\text{CO}_2$ is detected quantitatively by counting the radioactivity with a BACTEC 460 instrument. The rate and amount of $^{14}\text{CO}_2$ produced are directly proportional to the rate and amount of

growth occurring in the medium. This principle is applied for isolation of mycobacteria from clinical specimens, differentiation of the *Mycobacterium tuberculosis* complex from other mycobacteria, and antimicrobial susceptibility testing.

II. SPECIMENS

Observe standard precautions.

- A. Pulmonary and extrapulmonary specimens can be inoculated in BACTEC 12B medium for mycobacterial isolation. Blood, bone marrow, and sometimes CSF are inoculated into BACTEC 13A medium.
- B. Blood specimens are collected as follows.
 1. If the BACTEC 13A medium is to be inoculated at the patient's bedside, collect 5 ml of blood aseptically with a syringe without any anticoagulants.
 2. If the specimen is to be transported, collect blood in a tube with an anticoagulant that is acceptable for bacterial cultures, such as sodium polyanethol sulfonate (e.g., WAMPOLE ISOLATOR tube, Wampole Laboratories, Cranbury, N.J.).

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Media

1. Non-blood specimens
 - a. BACTEC 12B (Middlebrook 7H12) medium
This is a broth medium with 7H9 broth base, bovine serum albumin, casein hydrolysate, catalase, and ^{14}C -labeled substrate (1 $\mu\text{Ci/ml}$). A 20-ml vial containing 4 ml of broth is sealed with a rubber septum. BACTEC 12B medium may be used as a stand-alone medium, but for a maximum recovery of mycobacteria, an additional solid medium is recommended.
 - b. Antimicrobial mixture PANTA
PANTA is a mixture of five an-

timicrobial agents (polymyxin B, amphotericin B, nalidixic acid, trimethoprim, and azlocillin) provided in lyophilized form and should be added to 12B medium for suppression of contaminating bacteria and fungi. PANTA is used for primary isolation only.

- c. Reconstituting fluid
This fluid is used to reconstitute lyophilized PANTA. It is an aqueous solution of polyoxyethylene stearate (POES) that is known to enhance growth of mycobacteria, especially the *M. tuberculosis* complex.

III. MATERIALS (continued)

- d. Diluting fluid
This fluid (0.2% Tween 80 and 0.2% fatty acid-free bovine serum albumin in water) is used for diluting cultures for susceptibility testing.
 2. Blood specimens
 - a. BACTEC 13A, Middlebrook 7H13 medium: hypotonic medium, 30 ml in a 50-ml vial sealed with a rubber septum
 - b. BACTEC 13A enrichment: to be added to 13A medium for support of mycobacterial growth
 - c. Antimicrobial mixture PANTA: to suppress the growth of contaminating bacteria
 - d. Reconstituting fluid: to reconstitute lyophilized PANTA
- B. Supplies**
1. Disposable allergist's or tuberculin syringes with permanently attached needles
 2. Bactericidal-mycobactericidal disinfectant (examples: Amphyl, Cidex)
 3. Gloves, respirators, and gowns
 4. Cotton or gauze pads
 5. Alcohol swabs

C. Equipment

1. BACTEC 460 instrument
This semiautomated instrument can test 60 vials at a time at a rate of 82 ± 2 s per vial. The headspace gas from the vial is aspirated by two needles, and the quantity of $^{14}\text{CO}_2$ is determined on a scale of 0 to 999 called the growth index (GI). These numbers are displayed on the front panel and printed on a tape along with information about the position of the vial on the instrument.
2. A carbon dioxide tank containing 5 to 10% CO_2 and 90 to 95% air is attached to the instrument. During testing, the instrument introduces fresh 5 to 10% CO_2 , which is required for the growth of many mycobacteria.
3. BACTEC TB hood
The BACTEC 460 instrument should be used with a BACTEC TB hood, which is placed on top of the instrument. The hood is equipped with a UV light, a HEPA filter, and a laminar-flow system.
4. Biological safety cabinet
5. Incubator, $37 \pm 1^\circ\text{C}$
6. Vortex mixer

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

A. BACTEC 12B medium

1. Prepare a uniform suspension of *M. tuberculosis* H37Rv ATCC 27294 with turbidity equivalent to a McFarland no. 1 standard. A standardized suspension frozen at -70°C may also be used.
2. Dilute the suspension 1:500 by using the diluting fluid. Mix well.
3. Inoculate 0.1 ml per vial into four vials of 12B medium.
4. Incubate at $37 \pm 1^\circ\text{C}$, and test daily on a BACTEC 460 instrument for 12 to 14 days.
5. The average peak growth index should be 400 or above and should be achieved in 12 ± 2 days.
6. If results do not meet the specification, check the incubation temperature and adjust to $37 \pm 1^\circ\text{C}$. Check the culture suspension. It should be made from a fresh viable culture that is not more than 3 weeks old. If the suspension is frozen at -70°C , it should be used within 6 months of storage and should contain at least 2×10^6 CFU/ml.

B. Instrument QC

1. Performance test
 - a. Performance test should be done each day of testing by following the procedure given in the *BACTEC 460 Operation and Maintenance Manual* (supplied by the manufacturer).
 - b. A growth index of 50 to 60 should be obtained.

IV. QUALITY CONTROL*(continued)*

- c. If the growth index is outside this range, repeat the test with the same acid vial.
 - d. If the repeat test fails, do not test patient vials. Refer to the *BACTEC 460 Operation and Maintenance Manual*.
2. Instrument maintenance
 - a. The maintenance schedule for the BACTEC 460 instrument should be strictly followed. Good maintenance of the needle heater, filter, medium trap, and UV light will help prevent cross-contamination.
 - b. Change needles daily. Proper maintenance of the instrument needles is especially critical.

V. PROCEDURE*Observe standard precautions.***A. Non-blood specimen processing**

1. The *N*-acetyl-L-cysteine–sodium hydroxide procedure for specimen decontamination is the method of choice.
2. The sodium hydroxide and oxalic acid methods can also be used.
3. Do not use the Zephiran-trisodium phosphate, benzalkonium chloride, lauryl sulfate, or cetylpyridinium chloride method with the BACTEC procedure, as residual quantities of these substances in the inoculum inhibit mycobacterial growth.

B. Inoculation of non-blood specimens

1. Prior to inoculation, flush 12B vials with 5 to 10% CO₂ by testing them on a BACTEC 460 instrument. Do not use vials with a growth index of ≥ 20 , as this may indicate contaminated medium.
2. Addition of PANTA

Prior to the inoculation of concentrated, decontaminated specimens, add PANTA to the vial to suppress contamination.

 - a. Add 5 ml of reconstituting fluid to the lyophilized PANTA vial.
 - b. Mix thoroughly. When PANTA is completely dissolved, add 0.1 ml of the solution to each 12B vial. The same syringe may be used to add PANTA into several vials.
 - c. The remaining PANTA solution may be stored at 2 to 8°C for 3 days, –5 to –20°C for 3 months, or –70°C for 6 months.
 - d. It is not necessary to add PANTA to specimens (such as certain extrapulmonary specimens) that are expected to be free of contaminating organisms. In such a case, add only 0.1 ml of diluting fluid to introduce POES in the medium. If in doubt, use two 12B medium vials, one with and one without PANTA, especially with extrapulmonary specimens.
3. Inoculation of specimen

Use a tuberculin syringe with a permanently attached needle to inoculate 0.1 to 0.5 ml of processed specimen into a 12B vial supplemented with PANTA. For tissue or other particulate specimens, use a larger-gauge needle (20 to 22 gauge) with a Luer-Lock. Use a separate syringe for each specimen.
4. Clean the top of the rubber septum with an appropriate mycobactericidal disinfectant and then wipe the septum with a 70% isopropyl alcohol swab.

C. Blood specimen processing

Blood is collected aseptically, and thus, a digestion-decontamination step is not required. Because of the large volume of the medium, up to 5 ml of specimen can be inoculated into the medium, which is hypotonic, thus resulting in lysis of the blood cells (8).

D. Inoculation of blood specimens

1. Inoculate up to 5 ml of blood directly into 13A medium after disinfecting the top of the vial with an alcohol swab.

V. PROCEDURE (*continued*)

2. Disinfect the top of the vial with an alcohol swab, and add 0.5 ml of 13A enrichment to a 13A vial before or after specimen inoculation.
3. Use a separate syringe for each vial if the enrichment is added after the specimen is inoculated.
4. Do not test the vial on a BACTEC 460 instrument before or just after inoculation. The vials contain a CO₂ atmosphere and a vacuum sufficient to accommodate 5 to 7 ml of blood.
5. Add BACTEC antimicrobial supplement PANTA if the specimen is expected to be contaminated with other bacteria. Reconstitute PANTA with 2.5 ml of reconstituting fluid, and add 0.4 ml to a 13A vial.
6. Clean the top of the vial septum with an alcohol swab before inoculation and with an appropriate mycobactericidal disinfectant. Then use an alcohol swab to wipe after inoculation.

E. Incubation

1. Incubate vials at $37 \pm 1^\circ\text{C}$.
2. The temperature of incubation is critical. Check temperature with an accurate thermometer right where the vials are placed.
3. Specimens taken from wounds or ulcers should be incubated in duplicate, one at 37°C and the other at 30°C , because certain mycobacteria such as *Mycobacterium marinum* grow at the lower temperature.
4. It is not necessary to incubate vials in the dark, in a CO₂ incubator, or with shaking.

F. Testing schedule

The testing schedule should be decided according to the workload.

1. Maximum testing (low-volume laboratories): three times per week, with a 2- to 3-day interval for the first 3 weeks, and weekly thereafter for a total of 6 weeks.
2. Minimum testing (high-volume laboratories): twice weekly, with a 3- to 4-day interval for the first 2 weeks, and weekly thereafter for a total of 6 weeks.
3. With more frequent testing, earlier detection of positive cultures is expected.
4. Once the growth index reaches 10 or more, test the vial daily.

VI. RESULTS**A. Non-blood specimens: detection of growth**

1. Negative: growth index less than 10.
2. Positive: growth index of 10 or more. Separate these vials and test daily.
3. Examine all positive vials for the presence of contamination, which is indicated by the presence of turbidity or a very rapid increase in growth index.
4. If contaminated, the culture can be salvaged by reprocessing the medium.
 - a. Remove the medium from the vial.
 - b. Add an equal quantity of 4% sodium hydroxide solution.
 - c. Mix well, and let stand for 15 to 20 min.
 - d. Add phosphate buffer (pH 6.8) to the 40-ml line indicated on the tube.
 - e. Concentrate by centrifugation ($3,000 \times g$) for 20 min.
 - f. Suspend the sediment in 0.5 ml of pH 6.8 phosphate buffer, and inoculate 0.5 to 1.0 ml into a fresh 12B vial with PANTA.
 - g. Incubate, and continue testing on the BACTEC 460 instrument.

B. Non-blood specimens: expected values

1. Growth index of ≥ 10

Culture is presumptive positive. Test the vial daily, and rule out contamination.
2. Growth index of 50 to 100
Perform BACTEC NAP test.

VI. RESULTS (*continued*)

3. Growth index of ~ 100

Make a smear, stain for acid-fast bacilli, and confirm if it is positive for mycobacteria. BACTEC 12B medium does not stick to the slide well unless additional proteins are added to the smear. Therefore, a 20% solution of rabbit serum (in sterile water with 0.02% thimerosal and 0.5% phenol) as a smear-fixing solution yields the best results.
4. Growth index of ≥ 500

Perform antimicrobial susceptibility test if desired. The rate of growth in 12B medium depends on the species of mycobacteria isolated, *M. tuberculosis* and *Mycobacterium bovis* being the slowest. Among mycobacteria other than the *M. tuberculosis* complex commonly isolated from specimens, *Mycobacterium kansasii* is the slowest grower. Most other mycobacteria, including those that grow slowly on solid media, grow rapidly in 12B medium.
5. BACTEC 12B medium has been reported to yield more positive cultures from clinical specimens than other media (5, 7, 10). This is particularly significant with smear-negative specimens and specimens from chronic, treated patients (6, 7). Improved detection of *Mycobacterium avium* complex in 12B medium has also been reported (2).
6. Time to detection for positive growth is significantly shorter than with any other medium (1, 2, 6, 7). The detection time could vary because of the following factors.
 - a. Type of specimen
The average detection time is longer for certain specimens, such as extrapulmonary specimens, that harbor smaller numbers of bacteria.
 - b. Degree of smear positivity
Organisms in a smear showing numerous acid-fast bacilli may be detected as early as 24 h, while organisms in smear-negative, culture-positive specimens may take 5 to 6 weeks to be detected.
 - c. Therapy status of the patient
Generally, organisms in specimens from patients receiving antituberculosis treatment take a longer time to grow.
 - d. Decontamination procedure
Higher sodium hydroxide concentrations or harsh treatment damages mycobacterial cells, and they take a longer time to grow. Generally, laboratories using lower concentrations of sodium hydroxide or milder decontamination procedures report results within an average of 7 to 9 days.
 - e. Incubation temperature
Temperature is critical for the BACTEC system, since the system is based on metabolism of mycobacteria, which is optimum at 37.0 to 37.5°C. Lower temperatures slow down the detection time. Generally, it has been reported that positive cultures are detected between 9 and 12 days (6, 7, 10).
7. If contamination in 12B medium is higher than 5%, check all procedures and reagents thoroughly. If a higher contamination rate exists, take the following steps.
 - a. Increase the sodium hydroxide concentration to 5%. (Do not increase time of exposure to sodium hydroxide.)
 - b. Increase the concentration of PANTA by reconstituting PANTA with 3 or 4 ml (instead of 5 ml) of reconstituting fluid. Add 0.1 ml of the reconstituted PANTA. This will result in a higher concentration of PANTA in the 12B medium.
 - c. Increase the concentration of *N*-acetyl-L-cysteine if specimens are more mucoid and hard to liquefy.

VI. RESULTS (*continued*)**C. Blood vials: detection of growth**

1. Background/negative growth index: 10 to 15
2. Positive growth index: 20 or more
3. Prepare a smear at this point, and stain for acid-fast bacteria.
4. If the smear is positive, pull out the vial and incubate separately for further investigation. If the smear is negative, continue incubation and testing.
5. If the growth indices are high and the acid-fast smear is negative, check for contamination by Gram stain, and subculture on a blood agar plate.
6. Mycobacterial growth and other bacterial growth may be present.
7. Add the recommended concentration of BACTEC antimicrobial supplement PANTA if bacterial growth is observed. Continue incubation and testing.

D. Blood specimens: expected values

1. BACTEC 13A is a sensitive medium and can detect blood specimens having a very low concentration of viable acid-fast bacilli (11).
2. The detection of growth is slightly slower in 13A medium than in 12B medium because of the presence of blood. The smear made at a growth index of 20 is usually positive.
3. A positive culture can usually be detected in 12 to 16 days (3, 4, 9).

POSTANALYTICAL CONSIDERATIONS**VII. REPORTING RESULTS****A. Blood and non-blood specimens**

1. Report as culture positive only when the growth index is positive and is confirmed by acid-fast smear made from the positive broth.
2. Report as "Culture positive for mycobacteria, identification pending."

B. Blood only

Subculture in 12B medium and/or Lowenstein-Jensen medium for further identification and antimicrobial susceptibility testing.

VIII. LIMITATIONS

- A. Colony morphology cannot be observed.
- B. Infection with more than one *Mycobacterium* species or the presence of both mycobacteria and bacteria cannot be detected separately.
- C. If even a single contaminating bacterium is present, the entire medium will be contaminated.
- D. A subculture on a Middlebrook agar plate is needed to isolate a mixed culture.

7.4.2

BACTEC MGIT 960 Automated System

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The mycobacteria growth indicator tube (MGIT tube) is designed for the rapid detection of mycobacteria in all types of clinical specimens except blood and urine. The BACTEC MGIT 960 automated system, by Becton Dickinson Diagnostic Systems (Sparks, Md.) includes a liquid culture medium (modified Middlebrook 7H9

broth), a growth supplement, and an antimicrobial agent mixture. The antimicrobial agent mixture suppresses the growth of contaminating bacteria.

A fluorescent compound is embedded in silicone on the bottom of each MGIT tube, which is sensitive to the presence of oxygen dissolved in the broth. Initially,

the large amount of dissolved oxygen quenches the emissions of fluorescence from the compound and little fluorescence can be detected. Later, actively respiring microorganisms consume the oxygen and the depletion of oxygen allows the compound to fluoresce.

II. SPECIMENS

The MGIT tubes are used for the isolation of mycobacteria from pulmonary and extrapulmonary specimens. Use of urine and blood specimens is not validated. Specimens that are expected to contain other bacteria, such as sputum, must be digested and decontaminated. Aseptically collected specimens, which are not expected to contain contaminating bacteria, can be inoculated without decontamination.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Media and instrumentation

1. BBL MGIT

This medium contains 7 ml of modified Middlebrook 7H9 broth base with casein peptone.

2. MGIT 960 supplement kit

The kit contains the following items.

a. Growth supplement containing bovine albumin with glucose, catalase, oleic acid, and polyoxyethylene stearate

b. BBL MGIT PANTA

A lyophilized mixture of antimicrobials (polymyxin B, amphotericin B, nalidixic acid, trimethoprim, and azlocillin)

3. BACTEC MGIT 960 system instrument

B. Supplies

1. Automated pipettor for addition of growth supplement into MGIT tube
2. Bactericidal-mycobactericidal disinfectant (examples: Amphyl, Cidex)
3. Safety equipment

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Each new shipment or lot number of MGIT tubes may be tested using the following strains and dilutions. The test culture should not be more than 15 days old. Prepare a suspension from growth on solid medium, which is well dispersed, free of large clumps, and with a turbidity comparable with a Mc-Farland 0.5 standard. When 0.5 ml of diluted suspension is inoculated into an MGIT tube supplemented with enrichment, it should be detected as instrument positive within the time frames shown below.

Species	Dilution of 0.5 Mc-Farland in saline	Days to instrument positivity
<i>Mycobacterium tuberculosis</i> ATCC 27294	1:500	6–10
<i>Mycobacterium kansasii</i> ATCC 12478	1:50,000	6–11
<i>Mycobacterium fortuitum</i> ATCC 6841	1:5,000	1–3

All the inoculations should be done under a biological safety cabinet with all the standard safety precautions.

- B. The following is performed daily on the BACTEC MGIT 960 instrument.
1. Check temperature readout of each drawer ($37 \pm 2^\circ\text{C}$).
 2. Check all three external indicator lamps on all three drawers by pressing “test drawer indicators” soft key.
 3. For each drawer, test red and green light-emitting diode (LED) lights by pressing appropriate soft keys.
 4. Check printer paper supply and print out “Quality Control Report.”
 5. Clean and replace filters monthly.

V. PROCEDURE

Observe standard precautions.

It is imperative that these cultures be handled in a biosafety hood.

A. Specimen preparation

1. For those specimens requiring digestion and decontamination, use established conventional procedures for digestion and decontamination that are compatible with non-egg-based media. The *N*-acetyl-L-cysteine–sodium hydroxide method is the method of choice. Concentrate by established centrifugation procedure. If using the Petroff’s NaOH method, a very high pH for the inoculum may result in a temporary fluorescence.
2. Do not use the Zephiran-trisodium phosphate, lauryl sulfate, benzylkonium chloride, or cetylpyridinium chloride method with the MGIT medium.
3. For specimens that do not require decontamination, inoculate 0.5 ml after the process of concentration by centrifugation.

B. Specimen inoculation

1. Reconstitute a lyophilized vial of BBL MGIT PANTA antimicrobial agent mixture with 15 ml of BACTEC MGIT growth supplement.
2. Label the MGIT tube with the specimen number.
3. Aseptically add 0.8 ml of growth supplement-antimicrobial agent mixture into the 7-ml MGIT tube just prior to specimen inoculation.
4. Add 0.5 ml of specimen suspension (digested, decontaminated, and concentrated if required); tightly recap and mix well.
5. Enter tubes into the instrument by scanning the bar codes.
6. Insert tubes into the instrument in the slots assigned by the BACTEC MGIT instrument, indicated by a green light.

V. PROCEDURE *(continued)***C. Instrument-positive cultures**

1. The positive indicator lamp on the front of the drawer illuminates and the audible alert sounds until acknowledged.
2. Press the silence alarm key and open appropriate drawer.
3. Remove positive tubes whose stations illuminate with flashing green and red indicators.
4. Scan the positive tube's bar code to extinguish LED light for that tube's station.
5. Prepare an acid-fast stain.
6. An acid-fast bacillus (AFB) smear-positive BBL MGIT tube can be subcultured to both selective and nonselective mycobacterial media for isolation, identification, and susceptibility testing.
7. Contamination may also cause instrument-positive results. Contaminated cultures may be reprocessed by decontamination/concentration and inoculated into a fresh MGIT tube.
8. Smear-negative "instrument-positive" tubes with no contamination may be returned to the instrument within 5 h of their removal.

D. Out-of-protocol negatives

1. Press the "remove negative tubes" soft key.
2. Remove tubes from flashing green stations.
3. The flashing red light on the front panel indicates station error.

VI. RESULTS AND INTERPRETATION

- A. Positive culture: positive tubes are detected by the instrument and confirmed by an acid-fast smear.
- B. Negative culture: negative tubes are not detected by the instrument and are removed as "out-of-protocol" negatives after 42 or 56 days.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. If AFB smear from MGIT tube is positive, report as "AFB present; identification to follow."
- B. If AFB negative and contaminated, report as contaminated.
- C. All out-of-protocol negative tubes should be observed visually before being reported as negative.

VIII. LIMITATIONS

- A. Recovery and time to detection of positive culture for mycobacteria are dependent on the number of organisms present in the specimen, specimen quality, specimen collection method, method of specimen processing, and patient factors such as history of antituberculosis treatment.
- B. Colony morphology and pigmentation can be determined only on solid media. Mycobacteria may vary in acid-fastness depending on species, age of culture, and other variables.
- C. BBL MGIT tubes which are instrument positive may contain other nonmycobacterial species. Nonmycobacterial species may overgrow mycobacteria present in the medium.
- D. BBL MGIT tubes which are instrument positive may contain one or more species of mycobacteria. Faster-growing mycobacteria may be detected prior to slower-growing mycobacteria; therefore, it is important to subculture positive MGIT tubes onto solid media to ensure proper identification of all mycobacteria present in the sample.

VIII. LIMITATIONS (*continued*)

- E.** Due to the richness of the BBL MGIT broth and to the nonselective nature of the MGIT indicator, it is important to strictly follow the recommended digestion-decontamination procedure to reduce the possibility of contamination. Adherence to procedural instruction, which includes use of the recommended inoculum volume (0.5 ml), is critical for optimal recovery of mycobacteria.
- F.** The use of BBL MGIT PANTA antimicrobial agent mixture, although necessary for all nonsterile specimens, may have inhibitory effects on some mycobacteria.

7.4.3

VersaTREK (ESP Culture System II)

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The VersaTREK (ESP Culture System II) (Trek Diagnostic Systems, Inc., Westlake, Ohio) for the isolation of mycobacteria from clinical specimens consists of a modular arrangement of incubator and detection instruments and medium-containing culture bottles. The VersaTREK instrument consists of a series of drawers, each containing locations for the placement of culture bottles. The Myco bottles contain 7H9 broth and cellulose sponges utilized as a growth platform. The Myco bottles

are supplemented with Myco growth supplement (GS) (Middlebrook oleic acid-albumin-dextrose-catalase [OADC] enrichment) and an antimicrobial agent solution prior to inoculation with the specimen. Each location contains a sensor to which the inoculated culture bottle is attached via a plastic connector. The VersaTREK (ESP) instrument detects mycobacterial growth by automatically monitoring (every 24 min) the rate of consumption of oxygen within the headspace of the culture

bottle. This information is used to generate a curve (graph) for each bottle. Internal algorithms analyze these changes and signal a positive culture when appropriate. Positive culture bottles are smeared and stained to confirm the presence of acid-fast bacilli (AFB) (2). Aliquots from the bottles containing AFB may be tested directly with nucleic acid probes to rapidly identify the majority of mycobacteria growing in the culture system.

II. SPECIMENS

All specimen types, including blood and bone marrow specimens, can be utilized in the VersaTREK (ESP) system. Blood specimens must be collected in either an ISOLATOR tube or a tube containing EDTA or sodium polyanethol sulfate and inoculated into the Myco bottle after processing.

Decontaminate specimens obtained from body sites normally contaminated with bacterial microbiota prior to inoculation into the Myco culture bottles. Viscous specimens like sputa must also be digested prior to inoculation. Utilize standard laboratory protocol for the digestion and decontamination of clinical specimens for mycobacterial culture.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Reagents (see Appendix 7.4.3–1)

B. Equipment

1. VersaTREK (ESP) instrument
2. VersaTREK (ESP) Myco bottles
3. VersaTREK (ESP) Myco GS
4. VersaTREK (ESP) Myco AS or PVNA
5. VersaTREK (ESP) bottle connectors
6. 1-ml tuberculin syringe with fixed needles
7. Alcohol pads (70% isopropyl alcohol)

8. 12- by 75-mm sterile capped tubes

9. Lowenstein-Jensen (LJ) slants

10. LJ-Gruft slants

11. Middlebrook 7H11 agar plates

12. Middlebrook 7H10 (0.4%) hemoglobin plates

C. Storage

The Myco bottles should be stored at 15 to 30°C protected from light. VersaTREK Myco GS, AS, and PVNA must be stored at 2 to 8°C in the dark.

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

A. Temperature QC

1. Verify that the temperature in each unit is as displayed on the controller. Each readout should be verified by the use of an NBS-certified thermometer.
2. Print out the temperature report on a daily basis for review. Each module must be at $35 \pm 1^\circ\text{C}$.
 - ☑ The temperature printout will contain daily temperature readings for 31 days. Each daily sheet may be discarded the following day. The printout should be saved on the last day of each month and placed in a QC book.

B. Sensor QC

1. QC of each sensor is performed whenever a new bottle is placed in that location.
2. If an error message should be obtained for any location, remove the bottle, let it come to room temperature, fit the bottle with a new connector (perform under a biological safety hood), and place it back into the instrument.
3. If the sensor fails a second time, disable the location (refer to VersaTREK [ESP] manual), place the bottle in a new location, and notify a supervisor.
4. Additional sensor QC need not be performed if each location is used at least once every 90 days.
5. QC must be performed on any sensor that has been replaced (*see* system manual).

C. ESP Myco Bottle QC

1. Add 1 ml of ESP Myco GS and 0.5 ml of rehydrated ESP Myco AS or ESP Myco PVNA to an ESP Myco culture bottle.
2. QC organisms may be used from frozen aliquots or solid medium (Table 7.4.3–1).
3. Prepare a suspension in sterile 0.85% saline equivalent to a McFarland standard no. 1.
4. Allow clumps to settle for 30 min.
5. Dilute the organism to 10^4 CFU/ml in sterile saline.
6. Inoculate the bottle with 1 ml of diluted organism.

V. PROCEDURE

Observe standard precautions.

It is imperative that these cultures be handled in a biosafety hood.

A. Preparation of Myco bottles

1. Disinfect the septum of each VersaTREK (ESP) Myco bottle with 70% isopropyl alcohol.
2. Aseptically reconstitute Myco AS or PVNA by injecting 25 ml of sterile distilled or deionized water through the disinfected septum using a needle and syringe.
3. Disinfect the bottle stopper with 70% isopropyl alcohol.
4. Aseptically add 1 ml of VersaTREK (ESP) Myco GS by injecting through the septum with a needle and syringe.
5. Aseptically add 0.5 ml of VersaTREK (ESP) Myco AS or PVNA solution by injecting through septum with needle and syringe.
 - ☑ **NOTE:** If the bottles are not to be inoculated within 2 h after the addition of supplements, they may be stored refrigerated for up to 8 h.

Table 7.4.3–1 Expected QC results

Organism	ATCC no.	CFU/ml	Days to positivity
<i>Mycobacterium tuberculosis</i>	27294	10^4	6–10
<i>Mycobacterium avium</i>	25291	10^4	4–8
<i>Mycobacterium intracellulare</i>	13950	10^4	4–8

V. PROCEDURE *(continued)***B. Specimen processing and inoculation**

1. All specimens should be processed as per standard protocol.
2. Place approximately 1.2 ml of each specimen into a labeled sterile 12- by 75-mm capped tube.
3. Disinfect the septum of a Myco bottle which has been previously labeled with the specimen number.
4. Inoculate each Myco bottle with up to 1.0 ml of processed sample.
5. Inoculate solid media according to the following schedule.
 - a. Respiratory, urine, gastric, and stool specimens are inoculated into an LJ-Gruft slant or other mycobacterial solid agar or egg-based medium.
 - b. Blood, bone marrow, CSF, and other normally sterile body fluids are inoculated onto an LJ plain slant or other mycobacterial solid agar or egg-based medium.
 - c. Tissues, biopsy specimens, and specimens from skin lesions are inoculated onto an LJ plain slant and a 7H10 hemoglobin plate. As an alternative, the specimen can be inoculated onto a 7H10 or 7H11 agar plate to which an (hemin-containing) X factor strip (BBL) is added.
 - d. Incubate all solid media at 35°C except the 7H10 hemoglobin or X factor-containing plate, which is incubated at 30°C.

C. Placement of the ESP-Myco bottles into the ESP Culture System II

1. Disinfect the top of each inoculated Myco bottle with standard disinfectant solution (70% isopropyl alcohol). Allow to air dry and place a connector onto each bottle.
2. Transport the bottle with connector to the instrument area in the carrier.
3. Place the bottles into the next available slots in the instrument, taking care to fill all locations on a rotating basis.
4. Accession the bottles in the ESP computer as follows.
 - a. From the Main Menu select Specimen Entry; press Enter. The instrument will search for unidentified bottles. The statement “Unidentified Bottles Exist” will appear on the screen.
 - b. Hit any key; the specimens’ entry screen will appear.
 - c. Press Enter. The first unidentified location will appear.
 - d. Enter the accession number; press Enter to move the cursor to the next box. Enter the patient name (last name, comma, space, first name) and chart number, hitting the enter key each time to advance the cursor. Press page down after entering the chart number to go to the next patient. The length of incubation will default to 42 days.
 - e. After the last specimen is accessioned, press the end key to accept all entered patient information.

D. Workup of positive specimens

1. When the ESP signals a positive culture, check the graph to look for a declining slope indicating the consumption of oxygen. A rising graph indicates the production of carbon dioxide, which implies a contaminated culture.
2. Remove the bottle from the ESP instrument and transport to the AFB laboratory with the connector in place.
 - **NOTE:** Connectors may not be removed from the bottle unless under a biological safety hood.
3. Disinfect the septum with disinfectant (70% isopropyl alcohol).
4. Vortex the bottle. Using a sterile 1-ml syringe with a fixed needle, remove a small aliquot and place 1 or 2 drops on a clean glass slide. Perform an acid-fast stain.
5. If AFB smear negative and without signs of contamination, place the bottle into the instrument in its original location after fitting the bottle with a new connector.

V. PROCEDURE *(continued)*

6. If AFB smear positive, using a sterile 1-ml syringe with a fixed needle, remove approximately 0.15 ml of medium and inoculate onto a 7H11 agar plate.
7. Add 1 ml of medium to a sterile centrifuge tube. Centrifuge at $3,500 \times g$ for 15 min to obtain a pellet for AccuProbe mycobacterial identification.
8. Resuspend pellet with 7H9 broth to a McFarland no. 1 equivalent and assay using the AccuProbe kit, following manufacturer's instructions for the broth culture method. It is recommended that if the relative light unit (RLU) value falls within the equivocal range (10,000 to 29,999 RLU_s) the specimen be retested. Specimens containing blood may also be tested directly from a positive bottle following three washings with phosphate-buffered saline (1).
9. For susceptibility testing, remove 0.1 to 0.5 ml from the Myco bottle and inoculate it directly onto the appropriate susceptibility testing medium.
10. Examine all corresponding medium slants for growth of AFB. If negative, place the tubes in a separate rack and examine weekly for growth.

E. Reprocessing of contaminated specimens

In the case of smear-positive specimens (with the exception of stool specimens) that become contaminated with bacteria, the Myco bottle must be reprocessed. Cultures should be reprocessed as follows.

1. Vortex the ESP bottle and withdraw all of the liquid using a sterile 5-ml syringe.
2. Place the aspirated culture medium into a 50-ml sterile centrifuged tube.
3. Add an equal volume of sterile 4% NaOH; vortex.
4. Allow to stand for 15 min.
5. Neutralize with an equal volume of 0.067 M phosphate buffer, pH 6.8 (e.g., M/15 phosphate buffer).
6. Centrifuge at $3,500 \times g$.
7. Pour off all but 1 ml of the supernatant.
8. Vortex and inoculate into a freshly supplemented Myco bottle.
9. Place the Myco bottle in a new location, allowing for a full 42-day incubation period. If the bottle should become contaminated a second time, discard the bottle. If the corresponding medium slant is also contaminated, finalize the culture as "contaminated." If the slant is not contaminated, continue to incubate the slant as per standard protocol.

F. Removal of culture bottles from the ESP Culture System II**1. Positive cultures**

Bottles that have been physically removed from the instrument must be removed from the computer system as well. This may be accomplished as follows.

- a. From the Main Menu, select Remove Specimen, and press Enter.
- b. Select Bottles Removed, and hit Enter.
- c. Any location from which a bottle has been removed will appear on a worksheet.
- d. Either select all by pressing the function key F4 or press F3 to mark one and arrow down for each record you wish to remove.
- e. Press End. Records will be removed from the system one at a time.

2. Contaminated specimens

Those specimens determined to be terminally contaminated are removed from the system as described above.

V. PROCEDURE *(continued)***3. Negative cultures**

All cultures are incubated for 42 days before it is determined that they are negative. Bottles that have completed their incubation time may be removed from the system as follows.

- a. From the Main Menu select Remove Specimen; press Enter.
- b. Select Completed Removal; press Enter. All bottles that have completed their designated incubation time will appear on the worksheet.
- c. Press the function key F4 to mark all of the bottles for removal.
- d. Press End. The Light-emitting diode light on each drawer from which bottles are to be removed will light a steady red light. Each individual location will flutter to easily identify those bottles that must be removed. Remove the bottle by pushing down on the bottle below the connector. Once removed, the indicator light will cease fluttering. Dispose of the bottle-connector combination as per laboratory protocol. The confirmation screen will be blank if all of the bottles have been removed.
- e. Return to Main Menu.

VI. RESULTS AND INTERPRETATION**A. Negative cultures**

Cultures negative after 6 weeks in the VersaTREK (ESP) with a negative-to-date solid medium culture are to be assigned a preliminary report: "Broth culture negative 6 weeks, solid media pending." If the solid medium remains negative after 8 weeks, the culture result is finalized: "No growth in 8 weeks."

B. Positive VersaTREK (ESP), positive solid medium

If identification was made by probing the Myco bottle directly, examine the solid medium. If the growth on the solid medium agrees with the identification made from the Myco bottle, the report may be finalized. Always examine for mixed cultures.

C. Positive VersaTREK (ESP), negative solid medium

If probe positive, report the results but leave in preliminary report status. The report is kept preliminary until the subculture plate grows and the morphology is consistent with the probe identification. All subculture plates must be carefully examined for mixed mycobacterial cultures.

D. Negative VersaTREK (ESP), positive solid medium

Report the culture as per standard protocol.

POSTANALYTICAL CONSIDERATIONS**VII. REPORTING RESULTS****A. Preliminary report**

1. Positive: when the contents of the bottle are confirmed as acid-fast smear positive, report as "AFB present, identification to follow."
2. **Negative:** when a bottle is negative after 6 weeks, report as "Broth culture AFB negative after 6 weeks, solid medium pending."

B. Final report

1. Positive: when the mycobacteria are identified to species level, report as "Positive for *Mycobacterium*."
2. Negative: when a bottle is negative after 8 weeks, report as "No growth in 8 weeks."

VIII. LIMITATIONS

- A. One specimen may not be sufficient to diagnose a mycobacterial infection. In general three first-morning sputum specimens should be obtained.
- B. Patients on antitubercular therapy may have smear-positive but culture-negative specimens.
- C. Patients suspected of having infections due to *Mycobacterium haemophilum* will require their specimens to be plated onto a hemoglobin- or heme-containing medium (e.g., CHOC).
- D. Patients with infections due to *Mycobacterium marinum* or *Mycobacterium ulcerans* may require that solid media be incubated at 30°C for isolation.
- E. Due to different growth rates, mixed mycobacterial infections may not be obvious in liquid cultures. Both the primary slant and agar plate subculture must be examined to detect mixed cultures.

APPENDIX 7.4.3-1

Reagents

A. VersaTREK (ESP) Myco (12.5 ml of broth culture medium and compressed sponge)

Formula per liter:

Middlebrook 7H9 broth	5.66 g
Casitone	1.2 g
glycerol	2.4 g

B. VersaTREK (ESP) Myco GS (50 ml of Middlebrook OADC enrichment)

Formula per liter:

bovine serum albumin	75 g
glucose	30 g
oleic acid	0.9 ml
catalase	72,000 U
sodium chloride	12.75 g

C. VersaTREK (ESP) Myco AS and PVNA contain lyophilized mixtures of antimicrobial agents that are rehydrated to 25 ml.

Formula per milliliter:

VersaTREK (ESP) Myco AS

polymyxin B	1,500 U
azlocillin	75 µg
fosfomycin	540 µg
nalidixic acid	420 µg
amphotericin B	150 µg
stabilizer	1 %
filler	7.7 %

VersaTREK (ESP) Myco PVNA

polymyxin B	1,500 U
nalidixic acid	600 µg
amphotericin B	150 µg
vancomycin	90 µg
solubilizing agent	5 %

7.4.4

MB/BacT Mycobacterial Detection

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The MB/BacT mycobacterial detection system (bioMérieux, Hazelwood, Mo.), in conjunction with BacT/ALERT MP process bottles and BacT/ALERT MB blood culture bottles, is designed to recover mycobacterial species commonly isolated from patient specimens. The BacT/ALERT MP process bottles are designed for use with MB/BacT antimicrobial agent supplement and MB/BacT reconstitution fluid. The MB/BacT antimicrobial agent supplement is intended to reduce break-

through contamination due to bacteria that may survive the decontamination process. The MB/BacT reconstitution fluid contains components that are necessary to ensure optimal growth of mycobacteria. The MB/BacT microbial detection system utilizes a colorimetric sensor, which detects the production of CO₂ dissolved in the culture medium as microorganisms grow. If microorganisms are present in the sample, CO₂ is produced as the organisms metabolize the substrate in the culture medium.

As growth of the microorganisms produces CO₂, the gas-permeable, liquid emulsion sensor on the bottom of each culture bottle changes from a blue-green to yellow color. Positive bottles are determined by software algorithms and are indicated as yellow sensors and high reflectance units. Negative bottles result from darker sensors and low reflectance units. Bottles are read every 10 min and processed through the software algorithms to measure changes in reflected light.

II. SPECIMENS

Observe standard precautions.

A. Pulmonary and extrapulmonary specimens

Follow recommended specimen collection, transport, and processing procedures. Standard safety precautions must be followed (1).

B. Blood specimens

1. Proper skin disinfection is essential to reduce the incidence of contamination.
2. BacT/ALERT MB blood culture bottle septa must be disinfected with 70% isopropanol or iodine before being inoculated.
3. Inoculate 3 to 5 ml of whole blood into the blood culture bottles. Blood specimens may be drawn using the bioMérieux blood collection adapter system or collected into a sterile Vacutainer tube containing sodium polyanethol sulfonate (SPS) or heparin.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. BacT/ALERT MP process bottle (3)

1. Middlebrook 7H9 broth, pancreatic digest of casein, bovine serum albumin, catalase
2. Atmosphere of CO₂, nitrogen, and oxygen under vacuum
3. 10 ml of medium in bottle
4. Color coded with red labels and seals

B. MB/BacT antimicrobial agent supplement kit

MB/BacT antimicrobial agent supplement (to reduce contamination)
Lyophilized antimicrobial agent supplement containing amphotericin B, azlocillin, nalidixic acid, polymyxin B,

III. MATERIALS (continued)

trimethoprim, vancomycin, and bulking agent

1. MB/BacT reconstitution fluid
oleic acid, glycerol, amaranth, and bovine serum albumin in purified water
2. Preparation
 - a. Prior to use, aseptically add 10 ml of MB/BacT reconstitution fluid to each vial of MB/BacT antimicrobial agent supplement required for testing. Swirl to mix the contents.
 - b. Once reconstituted, the antimicrobial agent supplement has a shelf life of 7 days when stored at 2 to 8°C.

C. BacT/ALERT MB (blood) culture bottle

1. Middlebrook 7H9 broth, pancreatic digest of casein, SPS in purified water
2. Atmosphere of CO₂ in oxygen under vacuum
3. 29 ml of medium in bottle
4. Color coded with black printing and seals

D. MB/BacT enrichment fluid

1. Bovine serum albumin, sodium chloride, oleic acid, and saponin (lytic agent) in purified water
2. 5.5 ml of colorless fluid in each bottle

ANALYTICAL CONSIDERATIONS**IV. QUALITY CONTROL**

- A. A certificate of conformance is provided with each case of BacT/ALERT MP (process) media indicating satisfactory growth performance of *Mycobacterium tuberculosis* ATCC 25177 and *Mycobacterium intracellulare* ATCC 13950. A certificate of conformance is provided with each case of BacT/ALERT MB (blood) culture media indicating satisfactory growth performance of *Mycobacterium avium* ATCC 25291 and *M. intracellulare* ATCC 13950 (2). Upon receipt, new lots or shipments of BacT/ALERT MP and MB bottles may be tested for QC as follows.
 1. Add 0.5 ml of rehydrated MB/BacT antimicrobial agent supplement to each BacT/ALERT MP (process) bottle required or 1.0 ml of MB/BacT enrichment fluid to each BacT/ALERT MB (blood) culture bottle for testing.
 2. Inoculate representative BacT/ALERT MP (process) bottles with 0.5 ml of selected control organisms listed below, diluted to 10⁴ CFU/ml in sterile physiological saline or sterile unsupplemented Middlebrook 7H9 broth. Subculture onto Middlebrook 7H11 plates to determine viability and count. Load bottles into BacT/ALERT 3D.
 3. Inoculate representative BacT/ALERT MB (blood) culture bottles with 5.0 ml of selected control organisms listed below, diluted to 10³ CFU/ml in sterile sheep blood, defibrinated. Subculture onto Middlebrook 7H11 plates to determine viability and count. Load bottles into BacT/ALERT 3D.

Organism	ATCC no.	Days to positivity
<i>M. tuberculosis</i> (MP)	27294	11–13
<i>M. tuberculosis</i> (MP)	25177	11–13
<i>M. intracellulare</i> (MP and MB)	13950	7–14
<i>Mycobacterium kansasii</i> (MP)	12478	11–15
<i>Mycobacterium fortuitum</i> (MP)	6841	2–5
<i>M. avium</i> (MB)	25291	7–14

B. Instrument calibration and preventive maintenance

1. Record temperature.
2. Cell calibration is performed with a set of four calibration standards. The system will alert the user when cells are due to be calibrated. Refer to the operator's manual for calibration instructions as needed.

V. PROCEDURE

Observe standard precautions.

A. BacT/ALERT MP inoculation: specimens other than blood

1. BacT/ALERT MP (process) bottles must be at room temperature before inoculation.
2. Disinfect the top of each bottle septum with an alcohol pad.
3. Using a syringe and needle, aseptically add 0.5 ml of reconstituted antimicrobial agent supplement to each process bottle. For sterile fluids, inoculate the bottles with 0.5 ml of reconstitution fluid only. A pink tinge will indicate that the supplement or reconstitution fluid was added.
4. Using a 3-ml syringe and needle, transfer 0.5 ml of each processed or sterile patient sample into the appropriately labeled MP bottle.
5. Swab bottle septa with an appropriate mycobactericidal agent.
6. Load inoculated BacT/ALERT MP (process) bottles into an MB cabinet.

B. BacT/ALERT MB inoculation: blood specimens

1. Remove the plastic flip-top from the culture bottle and disinfect the septum with 70% isopropyl alcohol. Allow to dry.
2. Enrichment fluid is provided separately and must be added to the blood culture bottle for growth of mycobacteria. This can be done within 24 h before or after inoculation. Using a syringe and needle, aseptically add 1.0 ml of enrichment fluid to each blood bottle.
3. Collect the blood (refer to item II.B above) specimen according to specimen collection procedures.
4. After inoculation of the bottle with 3 to 5 ml of blood, clean the septum with 70% isopropyl alcohol. Allow to air dry.
5. DO NOT VENT THE BOTTLE.
6. Immediately transport the inoculated bottle to the laboratory.
7. Invert and load inoculated BacT/ALERT MB (blood) culture bottles into an MB/BacT MB cabinet.

C. Loading bottles

1. Press the ⟨Load Bottles⟩ button on the monitor screen.
2. Scan the bottle bar code. The cell address appears on the screen. A flashing green light will direct you to the correct cell. Load bottle into the assigned cell. The light will go out and the screen will clear if the bottle is in the correct cell.
3. Touch ⟨CANCEL⟩ to exit the function.
4. Remember to press ⟨Log off⟩ when finished.

D. Unloading negative bottles

1. Touch the ⟨Unload MB Negatives⟩ button on the monitor screen.
2. An automatic unload report will print (optional).
3. Cell lights will illuminate, directing you to the negative bottle.
4. Unload and scan the bottles' bar code labels one at a time. Scanning is optional.
5. Touch the ⟨Test Day Status Report⟩ button on the monitor screen to obtain a status report on final, negative cultures (optional).

E. Unload and work up positive bottles

1. Touch the ⟨Unload MB Positives⟩ button on the monitor screen.
2. An automatic unload positives report will print (optional).
3. Cell lights will illuminate, directing you to the positive bottle(s).
4. Unload and scan the bottle's bar code label. Scanning is optional.
5. Work up all positive cultures as per laboratory procedures.
6. All culture workup should take place under the biological safety hood.

It is imperative that these cultures be handled in a biosafety hood.

V. PROCEDURE (*continued*)

7. When bacterial contamination is detected, reprocess by removing entire contents of bottle and decontaminate contents by the *N*-acetyl-L-cysteine–sodium hydroxide or other procedure. Rely on solid medium results, or obtain a new specimen and process. When bacteria are detected in a BacT/ALERT MB blood bottle, consider bacterial septicemia. If the physician still requests a blood culture for mycobacteria, a new blood specimen must be obtained.

VI. RESULTS AND INTERPRETATION

- A. Positive: positive bottles are detected by the instrument determined by software algorithms and are indicated as yellow sensors and high reflectance units.
- B. Negative: negative bottles are detected by the instrument from darker sensors and low reflectance units.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Positive: when the contents of the bottle are confirmed as acid-fast smear positive, report as “Acid-fast bacilli present; identification to follow.”
- B. Negative: when a bottle is negative after 42 or 56 days, report as “No acid-fast bacilli isolated after 42/56 days.”

7.4.5

Wampole ISOLATOR Tube

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

To detect mycobacteremia in patients, blood is aseptically collected in a 10-ml Wampole ISOLATOR tube (Wampole Laboratories, Cranbury, N.J.). The tube contains saponin, which lyses all blood cells and releases intracellular mycobacteria. Tubes are centrifuged, thus concen-

trating organisms in the sediment; the supernatant is discarded, and the sediment (approximately 1.5 ml) is inoculated onto the appropriate media (1).

Blood cultures for mycobacteria are most often performed for patients with hu-

man immunodeficiency virus infection or for those who are immunosuppressed and have a fever of unknown origin. The use of blood cultures for the diagnosis of tuberculosis has increased (2).

II. SPECIMEN

Observe standard precautions.

Blood (10 ml) is collected in ISOLATOR 10 microbial tubes under aseptic conditions from adults. Blood (1.5 ml) is collected in ISOLATOR 1.5 microbial tubes under aseptic conditions from pediatric patients.

III. MATERIALS

A. Collection tool and media

1. Wampole ISOLATOR tube (store at room temperature)
 - a. Saponin—host cell lysis
 - b. Polypropylene glycol—foam retardant for saponin
 - c. Sodium polyanethol sulfate—anticoagulant
 - d. EDTA—anticoagulant
 - e. Fluorinert—liquid plastic immiscible with water concentrates bacteria
2. Media for recovery of mycobacteria, e.g., Lowenstein-Jensen; Middlebrook 7H10, 7H11 or 7H11 selective; or BACTEC 13A

B. Supplies

1. ISOLATOR tube
2. ISOSTAT pipettes and caps (two types of pipettes are used: one to remove supernatant and one to aspirate sediment)
3. 70% Isopropanol preparations
4. Providone-iodine
5. 20-gauge needle with 3-ml syringe

C. Equipment

1. Fixed-angle rotor centrifuge (3,000 × g), ambient temperature
2. Centrifuge adapters for 10-ml tubes
3. 5 to 10% CO₂ incubator, 35 to 37°C
4. Vortex mixer
5. ISOSTAT press and rack

ANALYTICAL CONSIDERATIONS**IV. PROCEDURE**

Observe standard precautions.

A. ISOLATOR 10

1. Invert the tube several times to mix and lyse cells.
2. Centrifuge the ISOLATOR tube for 30 min at $3,000 \times g$ in fixed-angle centrifuge.
3. Remove each ISOLATOR tube carefully from its centrifuge adapter, and place the tubes in the ISOSTAT rack.
4. Disinfect the top stopper with providone-iodine followed by 70% isopropanol. Do not allow the disinfectant to pool in the topper cavity. Allow to dry for 1 min.
5. Place the rack on the base of the ISOSTAT press.
6. Remove an ISOSTAT cap from the sterile package. Place cap over the top stopper of each ISOLATOR tube.
7. Position a tube with its cap under the press head. Gently pull the handle of the press down as far as possible. The spike will penetrate the stopper, and the cap will be firmly seated on the top of the tube.
8. Remove a supernatant pipette from the package. Squeeze the bulb of the ISOSTAT pipette to collapse it and provide a vacuum for withdrawal of the supernatant. Do this before inserting the stem into the tube.
9. Insert the pipette as far as possible into the tube; the base of the bulb should rest on the cap. Remove the pipette and discard.
10. Vortex ISOLATOR for 10 s.
11. Remove a concentrate pipette from its package. Squeeze the bulb to collapse it and create a vacuum for withdrawal of the concentrate. Do this before inserting the stem into the tube.
12. Gradually release pressure on the bulb, and allow the concentrate to be drawn into the pipette.
13. Inoculate onto appropriate media.

B. ISOLATOR 1.5

1. Vortex tube for at least 10 s.
2. Insert 20-gauge needle with 3-ml syringe.
3. Withdraw blood and inoculate onto appropriate media.
4. Discard needle and syringes appropriately.

V. RESULTS AND INTERPRETATION

- A. Positive: due to the high sensitivity of the ISOSTAT System, only one or two colonies on streak area is enough to indicate a positive culture (3).
- B. Negative: no colonies on streak area.
- C. Colonies appearing only outside the inoculated area should be considered contaminants.

POSTANALYTICAL CONSIDERATIONS**VI. REPORTING RESULTS**

- A. If acid-fast bacillus (AFB) colonies are present, identify and report as "Positive for *Mycobacterium* (indicate the species)."
- B. If AFB colonies are absent, report as "No acid-fast bacilli isolated after 56 days."

VII. LIMITATIONS

- A. The ISOSTAT system permits recovery and detection of microorganisms at concentrations of less than 1 CFU/ml of blood.
- B. Do not refrigerate or incubate the specimen.
- C. ISOLATOR tubes may be held for up to 8 h if necessary.
- D. Pneumatic transport systems are not recommended.

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The BD BBL Septi-Chek AFB mycobacterial culture system (Becton Dickinson Microbiology Systems, Cockeysville, Md.) is a biphasic medium with a self-contained CO₂ environment. It consists of

Middlebrook 7H9 broth and a slide of Middlebrook 7H11, modified egg, and chocolate media. The system offers sensitivity comparable to those of conventional agar and broth methods (1, 4). The

inclusion of CHOC in this system is advantageous because it detects contaminants and when incubated at 30°C, *Mycobacterium haemophilum* can be detected.

II. SPECIMENS

The Septi-Chek system is used for the detection and isolation of mycobacteria from sputum, bronchial washings or aspirates, body fluids (CSF and pleural, ascites, or synovial fluid), urine, stool, biopsy tissues, or wounds and skin (3) when mycobacteriosis is suspected. For blood specimens, Septi-Chek has been successfully used with ISOLATOR-procured blood concentrated by centrifugation and the addition of 0.75-ml volumes to two sets of Septi-Chek AFB broth (2).

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Media

1. Septi-Chek AFB mycobacterial culture bottle
 - a. Store at 15 to 30°C. Protect from light.
 - b. Do not use if turbid. Broth should appear pale green to colorless.
 - c. Broth to which 1 ml of supplement has been added is stable at 2 to 8°C for 14 days.
 - d. Do not freeze.
 - e. Do not inoculate after expiration date shown on bottle label.
2. Septi-Chek AFB mycobacterial culture supplement
 - a. Store at 2 to 8°C. Protect from light.
 - b. Supplement reconstituted with sterile distilled water can be stored at 2 to 8°C or at -20°C for up to 14 days prior to use.
 - c. Do not use to supplement culture bottle after the expiration date shown on the bottle label.

3. Septi-Chek AFB slide

- a. Slide 1: nonselective Middlebrook 7H11 agar, modified, suitable for growth of most mycobacteria
- b. Slide 2: egg-based medium, suitable for growth of most mycobacteria
- c. Slide 3: CHOC
Store at 2 to 8°C. Do not freeze. Do not use dehydrated or contaminated Septi-Chek AFB slides. Do not attach to bottle after expiration date shown on package.

B. Supplies

1. Bactericidal-mycobactericidal disinfectant (e.g., Amphyl, Cidex)
2. Gloves, masks, and gowns
3. Cotton or gauze pads
4. Sterile Pasteur pipettes

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Upon receipt of a new shipment or lot number, one of the following organisms is recommended for incubation of Septi-Chek AFB mycobacterial culture bottle or Septi-Chek AFB slide at 10^4 CFU/bottle: *Mycobacterium tuberculosis* ATCC 25177, *Mycobacterium kansasii* ATCC 12478, *Mycobacterium scrofulaceum* ATCC 19981, *Mycobacterium intracellulare* ATCC 13950, and *Mycobacterium fortuitum* ATCC 6841. One of the following organisms is recommended for inoculation at 10^5 CFU/bottle: *Escherichia coli* ATCC 25922, *Streptococcus pneumoniae* ATCC 6305, and *Staphylococcus aureus* ATCC 25923.
- B. Add 1 ml of reconstituted supplement to each bottle.
- C. Add 0.5 ml of the 10^{-4} dilution of each control organism to its culture bottle.
- D. Remove the cap from the culture medium bottle and immediately attach the slide. Inspect for tightness of fit. Slowly rotate the system 360° around the vertical axis twice.
- E. Incubate in a vertical position at 37°C .
- F. Observe the contents daily for the first week. Continue incubation and check for growth at 21 and 28 days.

V. PROCEDURE

Observe standard precautions.

- A. All manipulations should be carried out aseptically under a vertical laminar-flow hood using standard safety precautions for handling mycobacteria.
- B. Reconstitute the supplement with 9 ml of sterile distilled water. Add 1 ml of supplement to each bottle of culture broth. (Remove screw cap or inject through stopper.)
- C. Add 0.5 to 1.0 ml of treated specimen to culture bottle. Invert to mix.
- D. Hold the slide upright while unscrewing the white bottom cap of the slide container. Do not touch the inner thread.
- E. Remove the cap from the culture medium bottle and immediately attach the slide. Inspect for tightness of fit. Label slide so as not to obscure any bacterial growth.
- F. Slowly rotate the system 360° around the vertical axis twice.
- G. Incubate in a vertical position at 37°C (except for skin specimens, which require one system at 37°C and another at 30°C). A CO_2 incubator is not required but may be used.
- H. Observe the contents of the bottle daily during the first week to detect rapidly growing mycobacteria or potential contaminants. After 1 week, examine negative cultures weekly for up to 8 weeks. Observed changes may include turbidity, flakes or granules in broth, and colonies of various forms on the slide.
- I. Invert and rotate daily during the first week and then weekly for 8 weeks or until growth is observed. Inversion may wash off colonies and is not recommended once any colonies are seen.
- J. Autoclave Septi-Chek bottles and slides prior to discarding.

It is imperative that these cultures be handled in a biosafety hood.

VI. RESULTS AND INTERPRETATION

- A. Observe weekly for visible growth on slides and turbidity (or grains or flakes) in broth.
- B. Perform acid-fast stain on suspicious colonies and/or broth.
- C. If contaminated, culture can be salvaged by processing the broth medium as per standard operating procedure and reincubating another Septi-Chek system.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report as culture positive only when confirmed by acid-fast smear.
B. Report as “Culture positive for mycobacteria; identification pending.”
-

VIII. LIMITATIONS

Mycobacteria are often fastidious, and a single negative culture should not be used to rule out their presence.

The Roche Septi-Chek AFB system is intended for use in the detection, isolation, and subculture of mycobacteria. Conventional identification methods or probe technologies are required for species identification.

7.6.1

Conventional Biochemicals

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Whenever possible, mycobacteria should be identified to the species level. A level II laboratory must routinely process and culture at least 20 colonial specimens per week in order to ensure proficiency in identifying *Mycobacterium tuberculosis*. However, this low workload necessitates referring nontuberculosis mycobacteria to a level III laboratory for identification (3). In addition to colonial morphology (5) and acid-fastness, the identification of mycobacteria is largely based on rapid DNA probes (AccuProbe) and conventional methods. The conventional biochemicals used to identify mycobacteria are discussed in this procedure.

A. Arylsulfatase test

Arylsulfatase is an enzyme that hydrolyzes the bond between the sulfate and the aromatic rings of tripotassium phenolphthalein. Free phenolphthalein can be recognized by the red color formed when an alkali is added. The 3-day test is used to identify and distinguish among rapid growers. The 14-day test aids in the identification of slower-growing species and some rapid growers.

B. Catalase tests

The enzyme catalase splits hydrogen peroxide into water and oxygen. The oxygen appears as bubbles. Two measurements of catalase activity are (i) the heat stability of catalase at 68°C and (ii) the amount of catalase produced (semiquantitative test). All mycobacteria except some isoniazid-resistant strains of *M. tuberculosis* and *Mycobacterium bovis* display catalase activity. However, mycobacteria vary

in the amount of catalase produced and in the heat stability of the enzyme.

C. Growth rate and pigment production

Mycobacteria may be separated into two main groups based on growth rate, preferred growth temperature, and pigment production with or without light exposure (1, 2). The growth rates, preferred growth temperatures, and pigment production of mycobacteria can be determined by observing growth on freshly made subcultures on Lowenstein-Jensen agar slants. This medium is preferred because the color contrast makes it easy to observe the presence and pigment of mycobacterial colonies growing on it. Middlebrook 7H10 can be used for mycobacteria that will not grow on Lowenstein-Jensen agar.

D. Growth on MAC without crystal violet

Growth on MAC without crystal violet (2) is used to separate isolates of the rapidly growing mycobacteria. This test is often used in combination with the 3-day arylsulfatase test.

E. Iron uptake

Mycobacterium fortuitum and a few other rapid and slow growers can convert ferric ammonium citrate to iron oxide. The iron oxide is viewed as a rust color in the colonies when they are grown in the presence of ferric ammonium citrate.

F. Sodium chloride (NaCl) tolerance

Few mycobacteria are able to grow in culture media containing 5% sodium chloride, the exceptions including *Mycobacterium triviale* and most of

the rapid growers except *Mycobacterium chelonae* and *Mycobacterium mucogenicum*.

G. Niacin accumulation

All mycobacteria produce nicotinic acid during growth. *M. tuberculosis* and some isolates of *Mycobacterium simiae* and *M. chelonae* do not metabolize the nicotinic acid further and therefore accumulate more. The niacin test should not be used alone to distinguish *M. tuberculosis* from *M. bovis* because approximately 4% of *M. bovis* strains are niacin positive (6). The niacin is excreted into the agar, from which it can be extracted and detected (2).

H. Nitrate reduction

Mycobacteria differ in their ability to reduce nitrate. This is denoted by the development of a color when nitrite reacts with the appropriate reagents.

I. Pyrazinamidase

Certain mycobacteria possess the enzyme pyrazinamidase, which deaminates pyrazinamide (PZA) to pyrazinoic acid and ammonia, which can be detected by the addition of ferrous ammonium sulfate. In addition, the mechanism of PZA resistance of *M. tuberculosis* appears to be the inability of the organism to produce pyrazinoic acid, which is assumed to be the active component of PZA. Therefore, this test has been used to determine PZA resistance of *M. tuberculosis*. Once the organism has become pyrazinamidase negative, it is assumed to be PZA resistant as well.

J. Inhibition of thiophene-2-carboxylic acid hydrazide (TCH; T2H)

M. tuberculosis and most of the other slowly growing mycobacteria are resistant to TCH at levels of 1 to 5 µg/ml. This test differentiates niacin-positive *M. bovis* from *M. tuberculosis* since *M. bovis* is susceptible to the low concentrations. The exception exists with strains of *M. bovis* resistant to isoniazid (INH) which may also be resistant to TCH.

K. Tellurite reduction

Most mycobacteria have the ability to reduce tellurite to metallic tellurium (2, 5), visible in liquid cultures of mycobacteria as a fine black precipitate.

However, the speed with which most organisms are able to accomplish this reduction varies. *Mycobacterium avium* complex, *Mycobacterium celatum*, and most rapid growers are able to reduce tellurite within 3 days in an actively growing broth culture. This test is most useful, in conjunction with other tests, for identifying *M. avium* complex.

L. Tween 80 hydrolysis

The ability to hydrolyze Tween 80 is a valuable test for the separation of potentially pathogenic slow-growing scotochromogens and nonphoto-

chromogens. In this test, Tween 80 acts as a lipid, binding the neutral red indicator and causing the solution to be yellow. If the mycobacterial lipase hydrolyzes the Tween 80, the neutral red indicator is no longer bound, and it reverts back to its normal red color at pH 7.

M. Urease

The urease test is used to differentiate mycobacteria on the basis of their abilities to hydrolyze urea (1, 2). Use only urea broth made specifically for use with mycobacteria.

II. SPECIMEN

A pure culture of acid-fast bacilli growing on solid medium

III. MATERIALS

Include QC information on reagent container and in QC records.

To perform biochemical tests, biological safety cabinets, incubators, water baths, vortex mixers, and sterile pipettes and screw-cap tubes are required as per individual protocols.

A. Arylsulfatase test

1. Media
 - a. Arylsulfatase stock substrate
 - b. Arylsulfatase broth: 3-day test
 - c. Arylsulfatase broth: 2-week test
2. Reagents
 - a. 2 N sodium carbonate (Na₂CO₃)
 - b. Arylsulfatase color standards
 - c. Prepare the standards per Table 7.6.1-1.

B. Catalase tests

1. Media
 - a. Dubos Tween broth or Middlebrook 7H9 broth
 - b. Lowenstein-Jensen deeps prepared in screw-cap test tubes (25 by 150 mm)
2. Reagents
 - a. 30% H₂O₂
 - b. 10% Tween 80
 - c. 10% Tween 80-30% H₂O₂ reagent

- d. 10% Tween 80-30% H₂O₂
- e. M/15 phosphate buffer (0.067 M)

C. Growth rate and pigment production

1. Media
 - a. Dubos Tween broth or Middlebrook 7H9 broth
 - b. Lowenstein-Jensen slants
2. Supplies
 - a. Sterile applicator sticks
 - b. Sterile Pasteur pipettes
 - c. Pieces of heavy brown wrapping paper or aluminum foil approximately 4 by 5 in.
 - d. The paper must be large enough to cover the entire slant of medium.
3. Equipment
 - a. Slant racks
 - b. Lamp with a 60-W light bulb

D. Growth on MAC without crystal violet

Medium: MAC plates without crystal violet

Table 7.6.1-1 Preparation of arylsulfatase standards (5)

Tube no.	Amt of:		Interpretation
	Na ₂ HPO ₄	Phenol red	
1	4 ml	10 drops of stock solution	5 +
2	4 ml	1 ml from tube 1	4 +
3	3 ml	2 ml from tube 2	3 +
4	3 ml	2 ml from tube 3	2 +
5	3 ml	2 ml from tube 4	1 +
6	3 ml	2 ml from tube 5	±

III. MATERIALS (continued)**E. Iron uptake**

1. Medium: Lowenstein-Jensen slants
2. Reagent: 20% ferric ammonium citrate

F. Sodium chloride tolerance

1. Media
 - a. Lowenstein-Jensen slants without NaCl
 - b. Lowenstein-Jensen slants with 5% NaCl
 - c. Dubos Tween or Middlebrook 7H9 broth
2. Supplies
 - a. Sterile applicator sticks
 - b. Sterile 1-ml pipettes
 - c. McFarland no. 1 standard

G. Niacin accumulation

1. Reagents
 - a. 4% Aniline
 - b. 10% Aqueous cyanogen bromide
 - c. 10% Sodium hydroxide (NaOH)
 - d. Niacin filter strips (impregnated with cyanogen chloride) (Becton Dickinson, Sparks, Md.)
2. Supplies
 - a. Sterile screw-cap test tubes (20 by 125 mm)
 - b. Sterile Pasteur pipettes
 - c. Sterile 5-ml pipettes

H. Nitrate reduction

1. Reagents
 - a. Nitrate substrate broth
 - b. 1:1 Solution of concentrated HCl and sterile H₂O (nitrate reagent 1)
Wear goggles/face shields.
 - c. 0.2% Sulfanilamide (nitrate reagent 2)
 - d. 0.1% β -N-(1-naphthyl)ethylenediamine dihydrochloride (nitrate reagent 3)

- e. Crystalline reagents (Lampe's method) (4)
- f. Nitrate reduction color standard

2. Supplies

- a. Sterile applicator sticks
- b. Sterile Pasteur pipettes
- c. Sterile 5-ml pipettes

I. Pyrazinamidase

1. Medium: pyrazinamidase substrate medium
2. Reagent: 1% ferrous ammonium sulfate

J. Inhibition by TCH

1. Media
 - a. Conventional method
 - (1) Dubos Tween or Middlebrook 7H9 broth
 - (2) TCH susceptibility medium
 - b. BACTEC method
 - (1) BACTEC 12B medium
 - (2) TCH stock medium
2. Supplies
 - a. Conventional method
 - (1) 35 to 37°C, 8 to 10% CO₂ incubator
 - (2) Pasteur pipettes
 - b. BACTEC method
 - (1) BACTEC 460 instrument
 - (2) 1-ml tuberculin syringes with attached needles

K. Tellurite reduction

1. Medium: Middlebrook 7H9 broth with glycerol
2. Reagent: 0.2% potassium tellurite

L. Tween 80 hydrolysis

1. Media
 - a. Tween hydrolysis reagent (Difco)
 - b. Sterile water
2. Supplies
 - a. Sterile screw-cap tubes
 - b. Sterile pipettes

M. Urease: Wayne method

Medium: urea broth

ANALYTICAL CONSIDERATIONS**IV. PROCEDURE, RESULTS, AND QUALITY CONTROL**

(See Tables 7.6.1-2 and 7.6.1-3 and Fig. 7.6.1-1.)

It is imperative that these cultures be handled in a biosafety hood.

A. Arylsulfatase test (2, 5, 6)**1. Procedure**

- a. Inoculate labeled tubes of 3- and 14-day test media with 0.1 ml of a 7-day broth culture, 0.1 ml of a slightly turbid suspension, or a loopful of growth from an actively growing culture.
- b. Incubate at 35 to 37°C in a non-CO₂ incubator.
- c. After 3 days of incubation, add 6 drops of 2 N sodium carbonate to the 3-day test tube.
- d. After 14 days, add 6 drops of 2 N sodium carbonate to the 14-day test tube.

^a Modified from reference 6. Plus and minus signs indicate the presence and absence, respectively, of the feature; blank spaces indicate either that the information is not currently available or that the property is unimportant. V, variable; ±, usually present; -/+ , usually absent. The percentage of CDC-tested strains positive in each test is given in parentheses, and the test result is based on these percentages.

^b R, rough; S, smooth; SR, intermediate in roughness; t, thin or transparent; f, filamentous extensions.

^c P, photochromogenic; S, scotochromogenic; N, nonchromogenic (*M. szulgai* is scotochromogenic at 37°C and photochromogenic at 24°C).

^d Urease test performed by the method of Steadham (*J. Clin. Microbiol.* 10:134-137, 1979).

^e Probe identifies *M. tuberculosis* complex.

^f Requires hemin as growth factor.

^g Arylsulfatase reaction at 14 days is positive.

^h Young cultures may be nonchromogenic or possess only pale pigment that may intensify with age.

ⁱ Includes *M. fortuitum*, *M. peregrinum*, *M. fortuitum* third biovariant complex.

Table 7.6.1-3 Features useful for making a presumptive identification of mycobacteria (2)

Organism	Growth rate (days)	Pigment production in:		Colonial morphology on:	
		Light	Dark	Middlebrook 7H10 agar	Egg-based media (e.g., Lowenstein-Jensen)
<i>M. avium</i> complex	10–21	Buff to yellow	Buff to yellow	Thin, transparent, glistening or matte, smooth, entire, rounded; some rough and wrinkled	Thin, transparent, smooth; sometimes domed; some rough and wrinkled; raised edges
<i>M. bovis</i>	25–90	Colorless to buff	Colorless to buff	Small, thin, often nonpigmented, raised, rough, later wrinkled and dry; some inhibited on this medium	Rough, dry, friable; heaped-up center with thin, trailing transparent edge; sometimes flat and spreading
<i>M. chelonae</i>	3–7	Buff	Buff	Rounded, smooth, matte, periphery entire or scalloped, no branching filaments; some rough and wrinkled	Rounded, smooth, matte, periphery entire or scalloped, no branching filaments; some rough and wrinkled
<i>M. fortuitum</i>	3–7	Buff	Buff	Smooth, domed; sometimes rough branching filaments on periphery are obvious	Smooth and domed; sometimes rough branching filaments on periphery are obvious
<i>M. gastri</i>	10–21	Colorless to buff	Colorless to buff	Round, smooth, convex, glistening; often resemble <i>M. avium</i> complex	Round, smooth, convex, glistening; often resemble <i>M. avium</i> complex
<i>M. gordonae</i>	10–25	Yellow to orange	Yellow to orange	Round, smooth, convex, yellow to orange, glistening	Round, smooth, convex, yellow to orange, glistening
<i>M. haemophilum</i>	14–28	Buff to gray	Buff to gray	Grayish white, smooth to rough; require hemin for growth	Grayish white, smooth to rough; require hemin for growth
<i>M. kansasii</i>	10–21	Yellow	Buff	Raised, smooth; some rough and wrinkled; carotene crystals numerous after exposure to light	Raised and smooth; some rough and wrinkled; carotene crystals numerous after exposure to light
<i>M. marinum</i>	5–14	Yellow	Buff	Round, smooth; some may be wrinkled	Round, smooth; some may be wrinkled
<i>M. scrofulaceum</i>	10–14	Yellow	Yellow	Smooth, moist, yellow, round	Smooth, moist, yellow, round
<i>M. simiae</i>	7–14	Yellow	Buff	Smooth, domed, slightly pigmented	Smooth, domed, slightly pigmented
<i>M. smegmatis</i>	3–7	Buff to coral	Buff to coral	Raised, rough, wrinkled, edges scalloped	Raised, rough, wrinkled, edges scalloped
<i>M. szulgai</i>	14–28	Yellow to orange	Buff at 25°C; yellow at 37°C	Smooth to rough; periphery somewhat irregular	Smooth to rough, periphery somewhat irregular
<i>M. terrae</i>	10–21	Buff	Buff	Round, smooth to rough, glistening, sometimes colorless	Round, smooth to rough, glistening, sometimes colorless
<i>M. tuberculosis</i>	12–28	Buff	Buff	Flat, rough, spreading; irregular periphery	Rough, dry, friable; heaped-up center with thin, trailing transparent edge; sometimes flat and spreading
<i>M. xenopi</i>	28–42	Yellow	Yellow	Small, domed, yellow, smooth or rough; at 45°C, resemble miniature bird's nest	Small, domed, yellow, smooth or rough; at 45°C, resemble miniature bird's nest

IV. PROCEDURE, RESULTS, AND QUALITY CONTROL (continued)

2. Results

- a. Positive: immediate color change to pink or red after addition of the carbonate solution
- b. Negative: no color change

3. QC

a. 3-day test

- (1) Positive control: *M. fortuitum* ATCC 6841 (3 to 5+) or *Mycobacterium xenopi* if available (3 to 5+)
- (2) Negative control: *M. intracellulare* ATCC 13950
- (3) Uninoculated medium and reagent only: no color

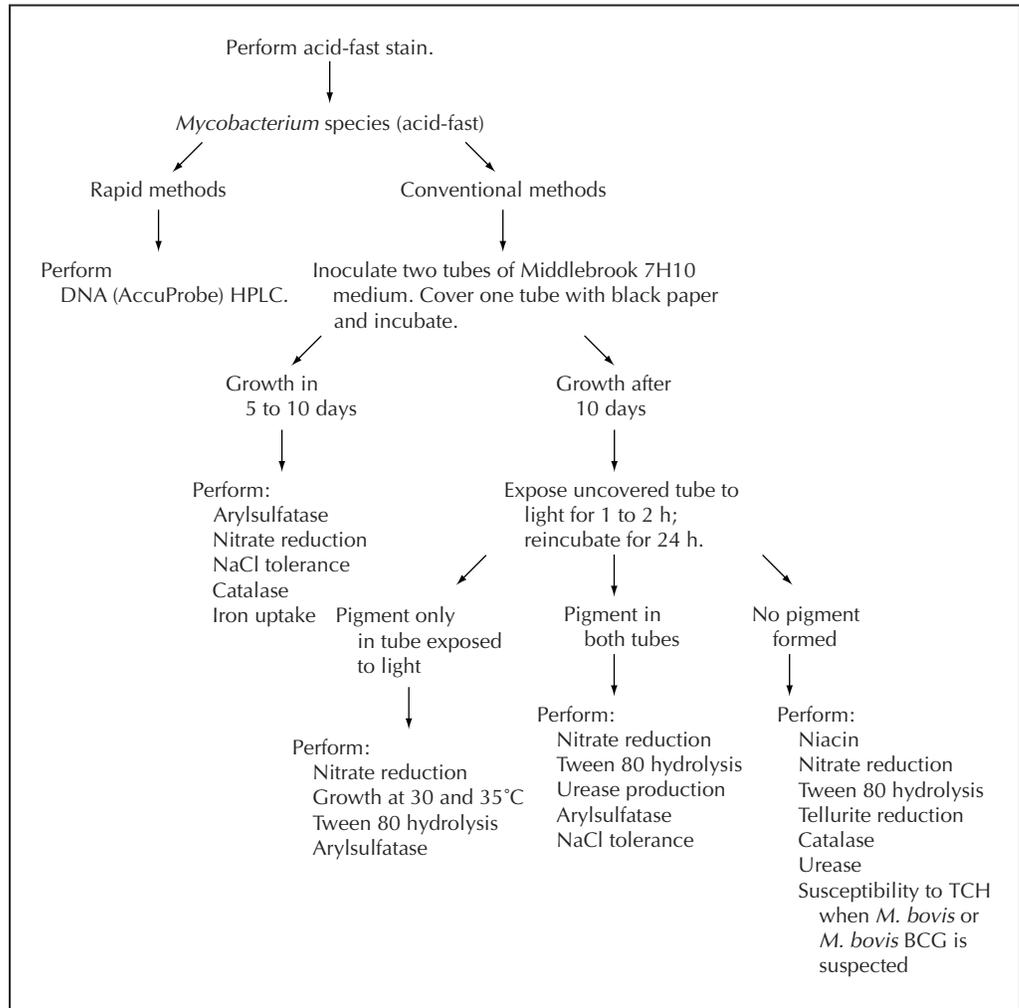

Figure 7.6.1–1 Procedure for identification of acid-fast bacilli from culture (2). HPLC, high-performance liquid chromatography.

IV. PROCEDURE, RESULTS, AND QUALITY CONTROL
(continued)

b. 2-week test

- (1) Positive control: *M. triviale* ATCC 23292 (4 to 5+)
- (2) Negative control: *Mycobacterium terrae* ATCC 15755 (0 to 2+)
- (3) Uninoculated medium and reagent only: no color

B. Catalase (2, 5, 6)

1. Semiquantitative test

a. Procedure

- (1) Inoculate surfaces of Lowenstein-Jensen deep (butt) tubes with 0.1 ml of 7-day-old liquid culture or a loopful of growth from an actively growing slant.
- (2) Incubate at 37°C in a 8 to 10% CO₂ incubator for 2 weeks (caps loose).
- (3) Add 1 ml of catalase reagent. (Prepare same as with 68°C test, described below.) Observe for 5 min.
- (4) Measure the height of the column of bubbles (millimeters) above the surface of the medium.

IV. PROCEDURE, RESULTS, AND QUALITY CONTROL (continued)

- b. Results
 - (1) Weak positive: <45 mm
 - (2) Strong positive: \geq 45 mm
 - (3) Negative: no bubbles
 - c. QC
 - (1) Controls
 - (a) High catalase: *M. fortuitum* ATCC 6841
 - (b) Low catalase: *M. tuberculosis* ATCC 25177
 - (c) 0 mm of foam: uninoculated medium and reagent only
 - (2) Failure of the control cultures to give expected results is usually due to the age or purity of the control cultures. Use only actively growing cultures, and check the purity of control cultures frequently. Old cultures cause false low-catalase results. Cultures contaminated with bacteria other than mycobacteria can cause false high-catalase results.
 - (3) Use only freshly prepared reagent. Old reagents can cause false-negative results.
 - (4) False-negative results can also be caused by inadequate growth in the Lowenstein-Jensen deeps due to insufficient inoculation and/or insufficient incubation of the broth or deeps. Inadequate growth can also be due to incubation of the deep in tubes with tightened caps.
 - (5) For best results, use Lowenstein-Jensen deeps prepared in tubes that are 25 by 150 mm. These tubes allow adequate surface area for growth and adequate height for the column of foam.
 - (6) If the results of the control cultures are not as expected, repeat the tests.
2. 68°C test
 - a. Procedure
 - (1) Make a heavy suspension of the organism in 0.5 ml of 0.067 M phosphate buffer (pH 7) in a screw-cap tube.
 - (2) Incubate in a 68°C water bath or heating block for 20 min.
 - (3) Cool to room temperature.
 - (4) Add 0.5 ml of the catalase reagent (50–50 solution of 10% Tween 80 and 30% H₂O₂). Recap tubes loosely.
 - (5) Read after 5 min. Hold negative tubes for 20 min before discarding.
 - b. Results
 - (1) Positive: formation of bubbles. Rarely, bubbles may be seen rising from bottom in such a small quantity that foam does not form at the surface. Record this as a positive reaction.
 NOTE: Do not shake tubes, or they may read as false positive.
 - (2) Negative: no bubbles.
 - c. QC
 - (1) Positive control: *Mycobacterium gordonae* ATCC 14470
 - (2) Negative control: *M. tuberculosis* ATCC 25177
 - (3) Reagents only will not bubble at all.
- ### C. Growth rate and pigment production (2, 5, 6)
1. Procedure
 - a. Inoculate one tube of Dubos Tween or Middlebrook 7H9 broth for each culture to be tested with a spadeful of growth.
 - b. Mix the inoculated broth cultures on a vortex mixer for 10 s.
 - c. Using a Pasteur pipette, transfer 6 drops from the broth to each of three Lowenstein-Jensen slants.
 - d. Immediately wrap two of the slants in brown paper or aluminum foil.
 - e. Loosen the caps of the tubes.
 - f. Incubate one wrapped slant at room temperature (20 to 25°C).

IV. PROCEDURE, RESULTS, AND QUALITY CONTROL (continued)

- g. Incubate the other wrapped slant and the unwrapped slant at 37°C (8 to 10% CO₂).
 - h. Examine the unwrapped slants weekly for 3 weeks for growth and pigment production. Do not remove the covers until the third week.
 - i. Record the color of the growth on the slant. Mycobacteria are usually described as buff to cream (nonpigmented) or as yellow to orange (pigmented).
 - j. When the subculture is 3 weeks old, remove the paper or foil.
 - k. Record the growth on and colors of the covered slants.
 - l. Light test
For any cultures having orange or yellow pigment on the uncovered slant and no pigment on the covered slant(s), expose the unpigmented slant to light.
 - (1) Expose the slant to a 60-W bulb at a distance of 10 to 12 in. for 1 h. Incubate the slant at its original incubation temperature.
 - (2) Examine the exposed slant for pigment production after 24 h of incubation.
2. Results
 - a. Nonpigmented (buff or cream) covered and uncovered: nonphotochromogenic
 - b. Pigmented (yellow to orange) covered and uncovered: scotochromogenic
 - c. Pigmented (yellow to orange) uncovered and nonpigmented covered: photochromogenic
 3. QC
 - a. *M. terrae* ATCC 15755: slow grower, ± growth at room temperature (22 to 25°C), no pigment in light or dark
 - b. *M. fortuitum* ATCC 6841: rapid grower, good growth at room temperature, no pigment in light or dark
 - c. *M. goodnae* ATCC 14470: slow grower, slight growth at room temperature, orange pigment in light and dark
 - d. *Mycobacterium kansasii* ATCC 12478: slow grower; very slight growth at room temperature; orange pigment in light, no pigment in dark, pigment after light test.
- D. Growth on MAC without crystal violet (2, 5, 6)**
1. Procedure
 - a. Inoculate rapid growers to be tested onto MAC by placing a 3-mm loopful of 7-day liquid culture, and streak for isolation.
 - b. Incubate without CO₂ (28°C).
 2. Results
M. fortuitum and *M. chelonae* complexes show growth in <7 days.
 3. QC
 - a. Positive control: *M. fortuitum* ATCC 12478
 - b. Negative controls: *Mycobacterium phlei* ATCC 11758; uninoculated medium
- E. Iron uptake (2, 5, 6)**
1. Procedure
 - a. Inoculate Lowenstein-Jensen slant with barely turbid liquid suspension of the organism.
 - b. Incubate until there is visible growth.
 - c. Add 1 drop of ferric ammonium citrate solution for each milliliter of Lowenstein-Jensen medium (usually about 8 drops).
 - d. Reincubate for up to 21 days and read weekly.

**IV. PROCEDURE, RESULTS,
AND QUALITY CONTROL**
(continued)

2. Results
 - a. Positive: rusty brown color in the colonies and tan discoloration of the media
 - b. Negative: no change in color
 3. QC
 - a. Positive control: *M. fortuitum* ATCC 6841
 - b. Negative controls: *M. chelonae* ATCC 35751; uninoculated medium and reagent only
- F. Sodium chloride tolerance (2, 5, 6)**
1. Procedure
 - a. Prepare a barely turbid suspension of growth from Lowenstein-Jensen slant.
 - b. Inoculate a Lowenstein-Jensen slant with 5% NaCl and a control slant without NaCl with 0.1 ml of inoculum (4 drops).
 - c. Incubate at 35 to 37°C and 8 to 10% CO₂.
 - d. Read once a week for growth.
 - e. Culture may be discarded after 4 weeks of incubation.
 2. Results
 - a. Positive: growth on NaCl
 - b. Negative: no growth on NaCl and growth on control slant
 - c. Invalid test: no growth on NaCl control slant
 3. QC
 - a. Positive control: *M. fortuitum* ATCC 6841
 - b. Negative control: *M. gordonae* ATCC 14470
- G. Niacin (2, 5, 6)**
1. Procedure
 - a. Add 1 to 1.5 ml of sterile distilled water or saline to a 4-week-old Lowenstein-Jensen culture slant.
 - b. Cut and/or stab medium surface several times with a sterile needle or loop.
 - c. Slant the tube so that the liquid covers the surface of the medium.
 - d. Allow 30 min to 2 h for niacin extraction.
 - e. Remove 0.6 ml of extract to a sterile test tube.
 - f. With forceps, insert a niacin strip into the extract at the bottom of the tube, with the arrows on the strip pointing downward.
 - g. Stopper the tube tightly.
 - h. Leave at room temperature for 15 to 20 min, with occasional gentle agitation.
 - i. Observe the color of the liquid at the bottom of the tube against a white background.
 2. Results
 - a. Positive: yellow color in extract fluid
 - b. Negative: colorless fluid
 3. QC
 - a. Positive control: *M. tuberculosis* ATCC 25177
 - b. Negative controls: *M. intracellulare* ATCC 13950; uninoculated medium and reagents only
 - c. If the controls do not give the expected results, repeat the tests and controls with freshly prepared aniline and cyanogen bromide. Make sure that the aniline is colorless.
 - ☑ If the aniline has turned brown, the color will interfere with the interpretation of the test.

IV. PROCEDURE, RESULTS, AND QUALITY CONTROL (continued)

H. Nitrate (2, 5, 6)

1. Procedure

- a. Inoculate nitrate broth with a loopful of growth from an actively growing culture.
- b. Shake to mix, and incubate at 35 to 37°C for 2 h.
- c. Add 1 drop of reagent 1.
- d. Add 2 drops of reagent 2.
- e. Add 2 drops of reagent 3.

2. Results

- a. Positive: pink to deep red color
- b. Negative: no color change; confirm by adding small amount of zinc dust. If pink to red color develops, then result is a true negative.

3. QC

- a. Positive control (more than 3+): *M. tuberculosis* ATCC 25177
- b. Negative control (0 or ±): *M. intracellulare* ATCC 13950
- c. Negative control (no color): uninoculated medium and reagents only

I. Pyrazinamidase (2, 5, 6)

1. Procedure

- a. Include an uninoculated control tube. Place a heavy inoculum from a fresh culture slant on the surface of each of two tubes of medium. Use enough inoculum so that it may be readily seen with the naked eye.
- b. Incubate at 35 to 37°C in a non-CO₂ atmosphere.
- c. After 4 days, remove one tube from the incubator, and add 1.0 ml of freshly prepared 1% ferrous ammonium sulfate to the tube.
- d. Place the tubes at room temperature for 30 min, and then refrigerate at 2 to 8°C to prevent growth of contaminants.
- e. After 4 h, examine tubes for a pink band in the agar. To read, hold the tubes against a white background by using incident room light.
- f. After 7 days of incubation, remove the second tube from the incubator and proceed as described above.
 NOTE: If the 4-day test is positive, it is not necessary to hold the second tube for the 7-day test.

2. Results

- a. Positive: pink band formed.
- b. Negative: no band formed.

3. QC

- a. Positive control: *M. intracellulare* ATCC 13950
- b. Negative controls: *M. kansasii* ATCC 12478; uninoculated medium and reagent only

J. Inhibition of TCH (T2H) (2, 5, 6)

1. Procedure

- a. Prepare a 7- to 10-day-old liquid culture (or prepare a barely turbid suspension of organisms from a drug-free medium).
- b. Dilute with sterile saline or distilled water to 1:1,000.
- c. With a sterile capillary pipette, inoculate a control and TCH medium with 3 drops of the dilution.
- d. Incubate for 3 weeks in a 35 to 37°C, 5 to 10% CO₂ atmosphere.
- e. Read in the same manner as drug susceptibility test plates, comparing growth on TCH with that on control medium.

2. Results

Record the organism as susceptible if growth on TCH medium is <1% of the growth on the control.

**IV. PROCEDURE, RESULTS,
AND QUALITY CONTROL**
(continued)**3. QC****a. Conventional method**

- (1) Susceptible to 10 µg of TCH per ml: *M. bovis* ATCC 35734
- (2) Resistant to 10 µg of TCH per ml: *M. tuberculosis* ATCC 25177

b. BACTEC method

- (1) Susceptible to TCH: *M. bovis* ATCC 35734
- (2) Resistant to TCH: *M. tuberculosis* ATCC 25177

K. Tellurite reduction (2, 5, 6)**1. Procedure**

- a.** Heavily inoculate Middlebrook 7H9 liquid medium.
- b.** Incubate at 37°C in 5 to 10% CO₂ for 7 days. The broth should contain sediment on the bottom of the tube.
- c.** Add 2 drops of sterile potassium tellurite solution to each test culture and controls. Shake tubes to mix.
- d.** Reincubate at 37°C in 5 to 10% CO₂ for 3 days, but do not shake.
- e.** On the third day, examine sedimented cells in each culture tube, taking care not to shake.

2. Results

- a.** Positive: black precipitate of metallic tellurium
- b.** Negative: no black precipitate. A light brown or gray precipitate should be considered negative.

3. QC

- a.** Positive control: *M. intracellulare* ATCC 13950
- b.** Negative controls: *M. tuberculosis* ATCC 25177; uninoculated medium and reagent only

L. Tween 80 hydrolysis (2, 5, 6)**1. Procedure**

- a.** Add 2 drops of the Tween 80 hydrolysis substrate concentrate to 1.0 ml of sterile deionized water.
- b.** Take a loopful of an actively growing culture from a slant and inoculate the above Tween 80 mixture.
- c.** Incubate aerobically at 35 to 37°C in a non-CO₂ incubator and examine at 1, 5, and 10 days.
- d.** Observe for the appearance of a pink to red color (positive test) and record. Do not shake tubes while reading.
- e.** Discard when positive or on the 11th day.

2. Results

- a.** Positive: a pink or red color in 10 days or less
- b.** Negative: an amber color remaining after 10 days of incubation

3. QC

- a.** Positive control: *M. intracellulare* ATCC 13950
- b.** Negative controls: *M. tuberculosis* ATCC 25177; uninoculated medium and reagent only

M. Urease (2, 5, 6)**1. Procedure**

- a.** Transfer a young, actively growing culture of the mycobacteria to be tested to the urea broth.
- b.** Inoculate to a visible turbidity.
- c.** Incubate at 35 to 37°C without CO₂ for up to 7 days.

2. Results

- a.** Positive: dark pink to red color
- b.** Negative: no color change

IV. PROCEDURE, RESULTS, AND QUALITY CONTROL (continued)

3. QC
 - a. Positive control: *M. kansasii* ATCC 12478
 - b. Negative controls: *M. intracellulare* ATCC 13950; uninoculated medium only

POSTANALYTICAL CONSIDERATIONS

V. REPORTING RESULTS

- A. While biochemical tests are in progress, send a preliminary report as “acid-fast bacilli present; identification to follow.”
- B. When identification is known, then report as “Positive for *Mycobacterium* _____.”

7.6.2

Gen-Probe AccuProbe Mycobacterial Culture Identification Test

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Nucleic acid hybridization assays are based on the ability of complementary nucleic acid strands to come together to form stable double-stranded complexes under appropriate conditions (1, 2, 3). The AccuProbe system uses a chemilumines-

cently labeled, single-stranded DNA probe which is complementary to the rRNAs of the target organisms. The rRNA is released from the organism through action of a lysing reagent and sonication.

The DNA probe then combines with the target organism's rRNA to form a stable DNA:RNA hybrid. The labeled DNA:RNA hybrids are measured in the Gen-Probe Leader luminometer (2).

II. SPECIMENS

The Gen-Probe assays are designed to identify members of the *Mycobacterium tuberculosis* complex, *Mycobacterium avium* complex, *Mycobacterium gordonae*, and *Mycobacterium kansasii* growing on standard Lowenstein-Jensen or Middlebrook media or broth (3). Morphology on solid or liquid media can be used to determine which probe will be tested first (4).

III. MATERIALS

A. Materials available from Gen-Probe

1. Each of the following kits contain Probe reagent tubes and lysing reagent tubes:
Gen-Probe *M. tuberculosis* complex culture identification test kit, Gen-Probe *M. avium* complex culture identification test kit, Gen-Probe *M. gordonae* culture identification test kit, and Gen-Probe *M. kansasii* culture identification test kit.
2. Reagent kit
 - a. Reagent 1 (specimen diluent)
 - b. Reagent 2 (probe diluent)
 - c. Reagent 3 (selection reagent)
3. Detection reagents
 - a. Reagent 1 (0.1% hydrogen peroxide in 0.001 N nitric acid)
 - b. Reagent 2 (1 N NaOH)

4. Gen-Probe equipment
Gen-Probe Leader luminometer

B. Materials not provided

1. 1- μ l plastic, sterile inoculating loops, plastic needles or applicator sticks for selecting colonies, control culture strains
2. Water bath ($60 \pm 1^\circ\text{C}$)
3. Heating block ($95 \pm 5^\circ\text{C}$)
4. Micropipettes (100 and 300 μ l) and Eppendorf pipettes (100 and 300 μ l)
5. Vortex mixer
6. Sonicator
7. Positive and negative control cultures

ANALYTICAL CONSIDERATIONS**IV. QUALITY CONTROL**

Include QC information on reagent container and in QC records.

- A. Positive and negative controls are tested on each day of use. The following organisms are used as controls and are tested in the same manner as patient culture samples.
1. *M. tuberculosis* complex culture identification test
 - a. Positive control: *M. tuberculosis* ATCC 25177
 - b. Negative control: *M. avium* ATCC 25291
 2. *M. avium* complex culture identification test
 - a. Positive control: *M. avium* ATCC 25291
 - b. Negative control: *M. tuberculosis* ATCC 25177
 3. *M. gordonae* culture identification test
 - a. Positive control: *M. gordonae* ATCC 14470
 - b. Negative control: *M. scrofulaceum* ATCC 19981
 4. *M. kansasii* culture identification test
 - a. Positive control: *M. kansasii* ATCC 12478
 - b. Negative control: *M. tuberculosis* ATCC 25177
- B. A tritium standard is used to test the performance of the optics in the Leader instrument. The ratio of the observed mean to the expected value should be between 0.95 and 1.05.
- C. QC results: positive values should be >30,000 relative light units (RLU) and negative values should be <10,000 RLU.

V. PROCEDURE

It is imperative that these cultures be handled in a biosafety hood.

- A. **Sample preparation**
1. Pipette 100 µl of reagent 1 and 100 µl of reagent 2 (probe diluent) into all lysing reagent tubes. If broth cultures are to be tested, do not add reagent 1 to the lysing tube.
 2. Inoculum
 - a. Solid medium method: growth can be removed with a 1-µl disposable plastic loop or an applicator stick. Avoid taking any of the solid medium with the cells.
 - b. Broth culture method: pipette a 100-µl sample from the broth suspension into the lysing reagent tube.
 3. Recap the lysing tubes and vortex.
- B. **Sample lysis**
1. Sonicate for 15 min as recommended by the manufacturer.
 2. Place the lysing reagent tubes on the heating block for 10 min at $95 \pm 5^\circ\text{C}$.
- C. **Hybridization**
1. Pipette 100 µl of the lysed specimens from the lysing reagent tubes into the corresponding probe reagent tubes.
 2. Recap the probe reagent tubes and incubate for 15 min in 59.5 to 60°C water bath or a heating block. The temperature should be observed throughout the process of hybridization to ensure that 59.5 to 60°C is maintained.
- D. **Selection and detection**
1. Remove the probe reagent tubes from the water bath. Pipette 300 µl of reagent 3 (selection reagent) into each tube. Recap the tubes and vortex.
 2. Incubate the probe reagent tubes in a 60°C water bath for 10 min for the *M. tuberculosis* complex probe, 8 min for the *M. kansasii* probe, and 5 min for the *M. gordonae* and *M. avium* complex probes.
 3. Remove the probe reagent tubes from the water bath and leave them at room temperature for at least 5 min. Read the results in the luminometer within 1 h.

VI. RESULTS AND INTERPRETATION

- A. Positive: signals greater than or equal to 30,000 RLU are considered positive.
- B. Negative: signals less than 30,000 RLU are considered negative.
- C. If the results are between 20,000 and 29,000 RLU, the test should be repeated.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. If the result is positive, then report the following: “Positive for *M. tuberculosis* complex identified by DNA probe technology,” “Positive for *M. avium* complex identified by DNA probe technology,” “Positive for *M. kansasii* identified by DNA probe technology,” or “Positive for *M. gordonae* identified by DNA probe technology.”
- B. If the result is negative for all probes, then report the following: “Acid-fast bacilli present; identification to follow.”

VIII. LIMITATIONS

- A. This method has been tested using fresh growth from solid media and from broth cultures. The efficacy of this test has not been demonstrated on direct clinical specimens (e.g., urine, stool, or respiratory specimens).
- B. Results from all AccuProbe culture identification tests should be interpreted in conjunction with other laboratory and clinical data available to the clinician.
- C. The AccuProbe *M. tuberculosis* complex identification test does not distinguish species within the *M. tuberculosis* complex.

7.6.3

BACTEC NAP Test

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The BACTEC NAP (Becton Dickinson Diagnostic Systems, Sparks, Md.) test utilizes *p*-nitro- α -acetylamino- β -hydroxypropiophenone (NAP), which selectively inhibits growth of mycobacteria belonging to the *Mycobacterium tuberculosis* com-

plex, while it does not inhibit or partially inhibit growth of mycobacteria other than the *M. tuberculosis* complex. The inhibition in 12B medium results in the reduction of $^{14}\text{CO}_2$ production compared to the growth control index readings.

II. SPECIMEN

- A. Only actively growing cultures at an early phase of growth in BACTEC 12B medium are recommended for the NAP test.
- B. If the culture is old, overgrown, or on solid medium, subculture onto 12B medium, incubate at $37 \pm 1^\circ\text{C}$, and test on a BACTEC 460 instrument daily.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Media and reagents obtained from Becton Dickinson Diagnostic Systems

1. BACTEC 12B medium. The NAP test cannot be carried out with 13A medium because of the presence of blood.
2. BACTEC NAP vial containing a 5- μg NAP disk

B. Supplies

1. Tuberculin syringe with permanently attached needle
2. Control organisms (*M. tuberculosis* ATCC 27294 and *Mycobacterium kansasii* ATCC 35775)

3. Bactericidal-mycobactericidal disinfectant (e.g., Amphyl, bleach)

4. Gloves, respirators, and gowns
5. Cotton or gauze pads
6. Alcohol swabs

C. Equipment

1. BACTEC 460 instrument
2. Instrument attached to 5 to 10% CO_2 and 90 to 95% air
3. BACTEC TB hood
4. Biological safety cabinet
5. Incubator, well calibrated at $37 \pm 1^\circ\text{C}$
6. Vortex mixer

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Include *M. tuberculosis* ATCC 27294 and *M. kansasii* ATCC 35775 as controls. Grow the organisms on solid medium, and store a homogeneous suspension frozen at -70°C in aliquots.
- B. Test these cultures along with the test cultures at least once a month and every time a new lot of NAP is used. *M. tuberculosis* should be inhibited by NAP, while *M. kansasii* should have increasing growth indices in the presence of NAP.
- C. Do not report test results if the control results are unsatisfactory. Repeat the test.

V. PROCEDURE

Observe standard precautions.

A. Inoculation

1. If the growth index in 12B medium from the primary isolation or subculture vial is ≥ 10 , test daily until it is 50 to 100.
2. Homogenize the culture by pulling the medium up into a syringe (with permanently attached needle) and pushing it back into the vial several times. Then aseptically transfer 1 ml of the medium into the NAP vial. The remaining 3 ml of medium serves as a control.
3. If the daily growth indices are >100 , dilute the culture with fresh 12B medium according to the following table. Transfer 1 ml of inoculum into the NAP vial after diluting the culture. The remaining medium acts as a growth control.

Growth index	Vol (ml) transferred into 12B vial
50–100	None
101–200	0.8
201–400	0.6
401–600	0.4
601–800	0.3
801–999	0.2
999 for >1 day	0.1

4. Mix the contents of the vial thoroughly.
5. Clean the tops of inoculated vials with an appropriate disinfectant.
6. Wipe them with an alcohol swab.

B. Incubation and testing

1. Incubate the NAP and the control vial at $37 \pm 1^\circ\text{C}$, unless another optimal incubation temperature is indicated.
2. Test daily on the BACTEC 460 instrument for about 2 to 7 days.

VI. RESULTS AND INTERPRETATION

- A. Growth indices in the control vial should increase steadily, 2 to 2.5 times daily for the *M. tuberculosis* complex and higher with other mycobacteria. If there is no satisfactory steady increase in the growth indices, do not interpret the results.
- B. The following criteria are applicable to all mycobacteria.
 1. *M. tuberculosis* complex (*M. tuberculosis*, *Mycobacterium bovis*, *Mycobacterium africanum*): two consecutive significant ($\geq 20\%$) decreases in growth indices after inoculation.
 2. Mycobacteria other than the *M. tuberculosis* complex: increase in growth indices to ≥ 400 within 4 days or slight decrease or no increase in the first 1 to 3 days, followed by two consecutive daily significant ($\geq 20\%$) increases.
- C. A growth index of ≤ 10 is a background reading and is not considered in the interpretation.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Reporting is done within 2 to 7 days, with an average of 4 days (2, 3).
- B. The *M. tuberculosis* complex should not be reported in fewer than 4 days.
- C. Among mycobacteria other than the *M. tuberculosis* complex, certain strains of *M. kansasii*, *Mycobacterium gastri*, *Mycobacterium szulgai*, *Mycobacterium terrae*, and *Mycobacterium triviale* are partially inhibited by NAP (1). In such instances, there is a longer lag phase in the presence of NAP, and results interpreted in the first 2 to 4 days may be misleading. Incubate further, and test for an additional 2 to 3 days before reporting.
- D. Mycobacteria with an optimum temperature other than 37°C should not be incubated at 37°C for the test. The NAP test for specimens originating from wounds or skin should be done in duplicate, with incubation at 37 and 30°C. The growth control vial should show satisfactory growth and increase in growth index.

VIII. LIMITATIONS

- A. Confirmation of the NAP test and further identification require additional testing by conventional or other methods.
- B. Mixed cultures of two mycobacteria or contaminated cultures give erroneous results.

Susceptibility Tests by Modified Agar Proportion

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Drug susceptibility testing should be performed on all initial *Mycobacterium tuberculosis* complex isolates and in relapse or retreatment cases and when primary drug resistance is suspected. The modified agar proportion method is used to determine the susceptibility of slow-growing mycobacteria (e.g., *M. tuberculosis* complex, *Mycobacterium kansasii*), either directly from decontaminated acid-fast smear-positive sputum or indirectly from

a pure culture. The agar medium is contained in quadrant plates; one is the control without antimicrobial agents and the other quadrants contain antimicrobial agents. The primary drugs, i.e., isoniazid (INH), ethambutol, and rifampin, are commonly selected for testing; however, pyrazinamide cannot be tested by this method (3, 4).

Direct susceptibility testing is based on inoculation of drug-containing media with only those processed sputum specimens

that are acid-fast smear positive to determine the proportion or percentage of resistant *M. tuberculosis* complex strains. The advantages include the ability to obtain results within 3 weeks from the time of specimen receipt in the laboratory, cost-effectiveness, and the belief that the proportion of resistant bacteria recovered is a better representation of the patient's bacterial population (3).

II. SPECIMENS

Susceptibility testing should be performed on the first isolate of *M. tuberculosis* complex obtained from each patient, when patient cultures fail to convert to negative after 3 months of therapy, or in cases of therapeutic failure (1, 3).

A. Direct testing

Digested, decontaminated specimens that are acid-fast smear positive

B. Indirect testing

Pure culture of *M. tuberculosis* complex from solid medium

III. MATERIALS

Include QC information on reagent container and in QC records.

A panel of four primary drugs used for susceptibility testing of *M. tuberculosis* complex includes INH at two concentrations (critical and higher), rifampin, ethambutol, and pyrazinamide. Often streptomycin is tested based on the patient population served, prevalence of drug resistance, and standard drugs used for treatment in the community (3).

A. Drug-containing disks

1. INH with 1 µg/ml for final concentration of 0.2 µg/ml
2. INH with 5 µg/ml for final concentration of 1 µg/ml
3. Ethambutol with 25 µg/ml for final concentration of 5 µg/ml

4. Streptomycin with 10 µg/ml for final concentration of 2 µg/ml
5. Streptomycin with 50 µg/ml for final concentration of 10 µg/ml
6. Rifampin with 5 µg/ml for final concentration of 1 µg/ml
7. Pyrazinamide—see procedure 7.8.2.

B. Media and reagents

Store reagents at room temperature unless otherwise indicated.

1. Middlebrook 7H10 agar base
2. Middlebrook oleic acid-albumin-dextrose catalase (OADC)
3. Glycerol
4. Antimicrobial stock solutions prepared at 1,000 µg/ml (–70°C)

III. MATERIALS (*continued*)

5. Solvents are shown in parentheses for the drugs listed below.
 - a. Ethambutol (sterile distilled water)
 - b. INH (sterile distilled water)
 - c. Rifampin (methanol or dimethyl sulfoxide)
 - d. Streptomycin (sterile distilled water)
6. Blood agar plate (2 to 8°C)

C. Supplies

1. Sterile plastic petri plates (15 by 100 mm) with four compartments (quadrant plates)
2. 1.0 McFarland turbidity standard
3. Glass beads (3-mm diameter)
4. 1-, 5-, and 10-ml sterile serological pipettes
5. Sterile cotton-plugged glass Pasteur pipettes
6. CO₂-permeable plastic polyethylene bags (6 by 8 in.) for plate incubation (15 by 100 mm)
7. 0.22- μ m-pore-size filters
8. Sterile polypropylene tubes (17 by 100 mm)

D. Equipment

1. Pipettors
2. Hot plate with magnetic stirring mechanism to create vortex that optimizes mixing
3. 50 to 56°C water bath
4. Vortex mixer
5. Stereoscopic (dissecting) microscope ($\times 30$ to $\times 60$)
6. $36 \pm 1^\circ\text{C}$ incubator with 5 to 10% CO₂
7. Biological safety cabinet

E. Plate preparation**1. Drug-impregnated disk method**

The disk elution method is a simplified procedure in which paper disks containing specified amounts of antituberculous drugs are placed in individual quadrants of 100-mm plastic petri plates (5). The submerged-disk method obviates problems of imprecision in weighing and dilution drugs and mislabeling media and is less labor-intensive.

- a. Paper disks containing appropriate concentrations of drugs are available commercially (BBL Sensi-Disc; Becton Dickinson Cockeysville, Md).
- b. Place disks aseptically into individual quadrants of sterile petri dishes. Omit disk from one quadrant per plate to be used as the growth control.
- c. Dispense 5 ml of OADC-enriched 7H10 medium into each

quadrant, overlaying the disks to keep them centered.

- d. Allow to solidify at room temperature with lids partially removed to allow excess moisture to evaporate.
- e. Close lids and incubate at room temperature overnight to permit drug to diffuse uniformly.
- f. Store for up to 28 days in sealed plastic bags at 4 to 8°C.

Drug	Concn in disk ($\mu\text{g/ml}$)	Final concn in medium ($\mu\text{g/ml}$)
INH	1	0.2
	5	1.0
Streptomycin	10	2.0
	50	10.0
Rifampin	5	1.0
	25	5.0
Ethambutol	25	5.0
	50	10.0
Ethionamide	25	5.0
Kanamycin	30	6.0

2. Preparation of drug-containing media

- a. Heat water bath to 50 to 56°C.
- b. Prepare 7H10 agar base.
 - (1) Weigh out the amount of Middlebrook 7H10 agar powder specified by the manufacturer, and slowly add it to the water.
 - (2) Heat on hot plate (with constant stirring, with magnetic stirrers) until the medium clears (approximately 20 min).
 - (3) Add 10 ml of glycerol to the flask, and continue to mix for another 3 to 5 min.
 - (4) Remove flask from hot plate.
 - (5) Cover flask with either plastic screw caps or sponge plugs and then cover with aluminum foil, and autoclave for 15 min at 121°C on slow exhaust.
 - (6) After autoclaving, place flask in 50 to 56°C water bath to cool.
 - (7) If desired, agar can be allowed to solidify at room temperature and stored in tightly capped containers protected from light at 2 to 8°C for up to 2 weeks. Prior to plate preparation, melt the agar by placing container in a boiling water bath.

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Strains**
1. *M. tuberculosis* H37Rv (ATCC 27294) (4)
 2. A strain of *M. tuberculosis* resistant to each of the test drugs may also be selected from clinical isolates as a secondary QC strain.
 3. Test a QC strain by following the routine procedure each time a new batch of medium or antimicrobial agent is used or at least once a week. Test the QC organism at 10^{-2} and 10^{-4} dilutions.
- B. *M. tuberculosis* H37Rv must be susceptible (at <1% growth) to all the primary and secondary antituberculosis drugs (4).**
- C. Growth controls**
Quadrant I (control; no drug) usually yields 200 to 400 colonies on the 10^{-2} dilution and 20 to 40 colonies on the 10^{-4} dilution.
- D. Sterility check of medium**
1. Incubate 10% of each batch of plates prepared at 36°C (CO₂) for 48 h.
 2. Following incubation, examine for bacterial and fungal contamination. Discard batch of plates if more than one plate is contaminated (one contaminated plate is probably due to sporadic contamination).
- E. Acceptable results**
1. QC strains performance within acceptable limits.
 2. Growth and inoculum controls show adequate growth.

V. PROCEDURE

Observe standard precautions.

A. Direct susceptibility testing

1. Perform on acid-fast bacillus (AFB) smear-positive specimens.
2. Stain and examine smears of concentrated clinical specimens.
3. Make dilutions of the sediment in 7H9 broth according to the following table based on the number of AFB per oil immersion field.

No. of AFB	Dilution inocula
Less than 1/field	Undiluted and 10^{-2}
1–10/field	10^{-1} and 10^{-3}
More than 10/field	10^{-2} and 10^{-4}

4. Inoculate 3 drops of each dilution onto each control and drug quadrant.
5. Keep lids of plates slightly open until drops have dried. Thereafter, plates may be inverted. Place in CO₂-permeable plastic bags.
6. Incubate at 35 to 37°C under 5 to 10% CO₂.
7. Read initially after 2 weeks. Report at 3 weeks.

B. Indirect susceptibility tests from culture

1. Prepare a no. 1 McFarland suspension from culture.
2. Dilute suspension to 10^{-2} and 10^{-4} .
3. Continue as with direct susceptibility procedure.

It is imperative that these cultures be handled in a biosafety hood.

VI. RESULTS AND INTERPRETATION

- A. The results are obtained by counting the number of colonies growing within the plate quadrant, as follows.

No. of colonies	Report
0–50	Actual count
50–100	1 +
100–200	2 +
200–500	3 +
>500 (confluent growth)	4 +

- B. Susceptibility is defined as growth on the control quadrant of 3+ to 4+ and no growth in the drug-containing quadrant.
- C. Resistance is defined as growth on drug-containing quadrants that is greater than 1% of the number of colonies that grow on the drug-free quadrant (2). The formula to calculate the percentage for resistant colonies is as follows: (no. of colonies on the drug quadrant/no. of colonies on the control quadrant) × 100.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. If there is no growth of AFB on the drug-containing media and growth on the control quadrant, then report as “Susceptible.”
- B. If there is >1% growth of AFB on the drug-containing media and growth on the control quadrant, then report as “Resistant.”
- C. When an organism is tested against two concentrations of INH, to the lower concentration of which the organism is resistant and to the higher of which it is susceptible, add the following comment to the report: “These test results indicate low-level resistance to INH. Some evidence indicates that patients infected with strains exhibiting this level of INH resistance may benefit from continuing therapy with INH. Consultation with a specialist is advised concerning appropriate dosages and therapeutic regimen” (3).

7.8.1

BACTEC 460TB (Radiometric) System—Indirect Susceptibility Testing for *Mycobacterium tuberculosis*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The BACTEC 460TB radiometric antimicrobial susceptibility test (Becton Dickinson Diagnostic Systems, Sparks, Md.) is a rapid method based on the principle used for primary isolation of mycobacteria. A ^{14}C -labeled substrate is incorporated in BACTEC 12B medium. When mycobacteria grow in the medium, $^{14}\text{CO}_2$ is produced during metabolism, which is measured as the growth index (GI). If a test drug to which mycobacteria are susceptible is added to this medium, the growth is inhibited, resulting in diminishing GIs as measured by the BACTEC 460 instrument. Radiometric antimicrobial susceptibility testing of *Mycobacterium tuberculosis* has been well documented and widely used (2, 3, 6, 7). Results show good agreement with the agar proportion method and are available within 4 to 6 days, compared with 3 weeks with the conventional method.

Primary and secondary agents that should be considered for testing against

M. tuberculosis include the following (4).

- A. Primary: ethambutol, isoniazid (INH), rifampin, and pyrazinamide (PZA)
- B. Secondary: capreomycin, ethionamide, kanamycin, and streptomycin
- C. Newer antimicrobials: amikacin, ofloxacin, rifabutin, and clarithromycin

Generally, only the primary agents are recommended for testing. Consider testing the secondary agents, which is usually done in reference laboratories (5), when an isolate is resistant to one or more primary agents or if the patient has failed therapy. Additionally, testing of secondary agents would be warranted with isolates from patients who may have become infected in an area in which resistant isolates are endemic.

The BACTEC method for susceptibility testing of isolated *M. tuberculosis* cul-

tures is based on the modified proportion method (1). Mycobacteria are inoculated into vials of BACTEC 12B (Middlebrook 7H12) medium with and without antimycobacterial agents and incubated in a 37°C ambient-air incubator.

The number of organisms added to the control medium (without antimicrobial agent) is 100-fold less than that added to medium containing antimicrobial agent. The inoculated vials are incubated and subsequently read daily on the BACTEC 460 instrument, and the results are interpreted by evaluating the rate of increase in the GI of the control compared with the rate of increase in the GI in the antimicrobial agent-containing medium. If the GI increase in the antimicrobial medium vial is less than that in the control, the isolate is considered susceptible; if it is greater than the increase in the control, the isolate is considered resistant.

II. SPECIMEN

Use pure culture grown on solid medium with growth not more than 4 weeks old. If liquid medium is used, note the following: BACTEC 12B medium (GI of >500 or within 1 week after the peak GI is achieved; peak is the highest GI after which the GI starts declining).

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Media and reagents (storage conditions)

1. BACTEC 12B with Middlebrook 7H12 medium (22 to 25°C): 4 ml of liquid medium in a 20-ml glass vial sealed with a rubber septum
2. BACTEC diluting fluid (22 to 25°C)

3. BACTEC SIRE kit, which includes separate vials of lyophilized streptomycin, INH, rifampin, and ethambutol (2 to 8°C)

B. Equipment

1. BACTEC 460 instrument with a BACTEC TB hood

III. MATERIALS (*continued*)

2. Biological safety cabinet
 3. CO₂ tank (5 to 10% CO₂ in air)
 4. 37 ± 1°C ambient-air incubator
 5. Vortex mixer
- C. Other supplies (storage conditions)**
1. Disposable tuberculin syringes with permanently attached 25- to 26-gauge needles
 2. Disposable 5.0-ml syringes with 18-gauge needles
 3. 0.5 and 1.0 McFarland turbidity standards
 4. Sterile disposable 1- and 10-ml pipettes and pipette bulb
 5. Blood agar plate (2 to 8°C)
 6. Middlebrook 7H10 or 7H11 agar plates (2 to 8°C)
 7. Other antimicrobial powders: capreomycin, ethionamide, kanamycin, etc. (desiccator, 2 to 8°C).

ANALYTICAL CONSIDERATIONS**IV. QUALITY CONTROL****A. Strains**

1. *M. tuberculosis* H37Rv (ATCC 27294) and any monoresistant strain may also be selected from clinical isolates as a secondary QC strain (store at –70°C).
2. Test one or more QC strains by following the routine procedure used with patient isolates.

B. Expected results

1. *M. tuberculosis* H37Rv must be completely susceptible to all antituberculosis drugs tested, and monoresistant strains must be resistant to a selected drug. (A well-homogenized suspension devoid of large clumps and equal to a McFarland no. 1 standard may be frozen at –70 ± 10°C.)
2. Growth control vial (including that for *M. tuberculosis* H37Rv) must yield a GI of >30 in 3 to 5 days. Purity plates must be free of contamination.
3. Growth and inoculum controls must show adequate growth.

V. PROCEDURE

Observe standard precautions.

A. Preparation of antimicrobial stock solutions

1. Primary antimicrobial agents
 - a. Disinfect septum top of each vial with an alcohol swab.
 - b. Using a 5-ml syringe, reconstitute lyophilized antimicrobials by adding 5 ml of sterile deionized water to each vial. Mix until completely dissolved.
 - c. Generally, only one critical concentration of each antimicrobial agent is tested; however, higher concentrations may also be tested if resistance to the critical concentration is observed.
2. Secondary antimicrobial agents

These antimicrobials are not available in lyophilized form and must be obtained in pure powder form from the manufacturer or a supplier. Different antimicrobials are dissolved in different solvents. Prepare a stock solution of a test antimicrobial as recommended by the manufacturer or described in literature (5). In a multicenter study, the concentrations listed in Appendixes 7.8.1–2 to 7.8.1–4 have been recommended (5).

B. Preparation of antimicrobial agent-containing medium

1. Using a disposable tuberculin syringe, add 0.1 ml of each well-mixed antimicrobial solution to a BACTEC 12B vial (one vial per concentration).
2. Once the antimicrobial agent has been added, use the BACTEC 12B medium the same day. If storage is necessary, refrigerate (2 to 8°C), and use within 3 days.
3. Include one BACTEC 12B vial without any antimicrobial agent as a growth control.

V. PROCEDURE *(continued)***C. Inoculum preparation**

1. Preparation of inoculum from a positive BACTEC 12B vial
Use the growth in the vial as the inoculum source for the susceptibility tests once the specified GI is attained.
 - a. If a primary isolation vial is used, once the GI is >10 , test the vial daily until the GI reaches >500 , or test until the GI reaches 300 and then incubate for one more day.
 - b. If a subculture is made onto BACTEC 12B medium, test the vial daily until the GI is >500 .
 - c. If the GI is >800 , dilute the suspension 1:1 by adding 1 ml of the culture to 1 ml of BACTEC diluting fluid in a sterile tube.
2. Preparation of inoculum from growth in 7H9 broth
Adjust the turbidity of the culture with BACTEC diluting fluid to match that of a McFarland no. 1.0 standard for the daily schedule.
3. Preparation of inoculum from growth on solid medium
 - a. Use a spatula or hard loop to scrape off numerous representative colonies, being careful not to transfer medium with the colonies.
 - b. Transfer colonies to a sterile screw-cap round-bottom glass test tube containing glass beads and 3 ml of BACTEC diluting fluid.
 - c. Emulsify and vortex until the suspension is well dispersed and moderately turbid (more than McFarland no. 1 standard). Allow the suspension to stand for about 30 min.
 - d. Using a sterile pipette, transfer the supernatant into a sterile tube. Discard the sediment.
 - e. Adjust the turbidity of the suspension with BACTEC diluting fluid to match that of a McFarland no. 1.0 standard for a daily schedule.
4. For the control vial, dilute the standardized inoculum suspension 1:100 by adding 0.1 ml of the standardized suspension to 9.9 ml of BACTEC diluting fluid. Mix well by inverting the bottle several times.

D. Inoculation and incubation

1. Establish a 5% CO₂ atmosphere in each vial by initially testing all BACTEC 12B vials to be used on the BACTEC 460 instrument. The 5% CO₂, which is connected to the instrument via tubing, is infused into each bottle when they are probed for ¹⁴C production. Do not use any vial with a GI of ≥ 20 on initial testing.
2. Disinfect the rubber septum on each of the BACTEC 12B vials with an alcohol swab.
3. Mix the inoculum suspension well, and use a tuberculin syringe to add 0.1 ml of the undiluted standardized suspension to each of the 12B vials containing antimicrobial agent.
4. Subculture a few drops of the inoculum suspension to a blood agar plate and a 7H10 or 7H11 agar plate to check for purity.
5. Inoculate 0.1 ml of the well-mixed 1:100-diluted suspension into the control vial.
6. Disinfect the rubber septum of each vial with an appropriate disinfectant, followed by an alcohol swab.
7. Incubate all vials in the dark in a $37 \pm 1^\circ\text{C}$ incubator.

E. BACTEC testing schedule

1. Daily schedule
 - a. Test at approximately the same time (± 2 h) each day.
 - b. Test for a minimum of 4 days (5 days of incubation).
 - c. Once the GI in the control vial is ≥ 30 , interpret results.
 - d. If the GI is ≥ 30 before day 4, the inoculum is probably too heavy. Repeat the test. Never report results earlier than 4 days of incubation.

It is imperative that these cultures be handled in a biosafety hood.

V. PROCEDURE (*continued*)

- e. If the GI does not reach 30 within 14 days of incubation, consider the test uninterpretable.
 - f. Generally, with a completely susceptible culture, there is a sharp decline in the daily GIs within a few days in the presence of streptomycin, INH, and rifampin. Ethambutol is not as active, and thus there is a slight initial increase in the GI before the decline.
2. Non-weekend schedule
- For those laboratories where the weekend coverage is not available, a non-weekend schedule can be followed. For the non-weekend schedule the basic test procedure is similar to that used for the daily schedule, with the following changes.
- a. All the tests are batched and are performed on Friday only.
 - b. For a positive BACTEC 12B vial, the inoculum is the same as in daily testing, such as a GI of >500 or a GI of 300 plus one additional day of incubation. For growth on solid medium, prepare inoculum equivalent to a McFarland no. 0.5 standard. Emulsify and vortex until the suspension is well dispersed and matches that of a McFarland 0.5 standard.
 - c. Testing on the BACTEC 460 instrument starts on Monday, skipping the weekend.
 - d. The vials should be tested on Monday, Tuesday, and Wednesday (minimum of 5 days). If the GI is not 30 or more on Wednesday, continue testing until it reaches 30 but not for more than a total of 14 days.
 - e. Disregard GIs of the first Monday for interpretation of results; this means that if the GI is 30 or more on Tuesday, the vials still have to be tested on Wednesday to interpret results.

VI. RESULTS AND INTERPRETATION

- A. Providing QC is acceptable, interpret results as follows. At the time when the growth control shows a GI of 30 or more, calculate the difference in the GIs (Δ GIs) from the previous day for the control and the drug-containing vials. Negative Δ GIs indicate a decrease in growth and Δ GI output, while positive Δ GIs indicate an increase in growth and GI output.
1. Interpret results as follows.
 - a. Susceptible: Δ GI of control > Δ GI of drug vial
 - b. Resistant: Δ GI of control < Δ GI of drug vial
 - c. Borderline or partially resistant: Δ GI of control \sim Δ GI of drug vial
 2. If the GI in the drug-containing vial exceeds 500 and remains >500 on the next day, interpret the test result as resistant regardless of the Δ GIs. (First make certain that the test was not overinoculated, as indicated by a GI of >30 in control vial in less than 3 days, or that it is not contaminated.)
 3. If borderline results are obtained, test the vial for two to three additional days. This additional testing will often establish a trend, and the Δ GI either increases or decreases compared with that of the control. If no trend is observed, the isolate may truly be borderline or partially resistant.
 4. Because there is a 100-fold-higher inoculum in the drug vials than in the control vial, the GI readings are usually higher in the drug vials than in the control vial for the first day or two.
 5. The Δ GIs of the control and drug vials depend on the degree of susceptibility of the test organism and the potency and inhibitory effect of the antimicrobial agent.
 6. If the strain is susceptible, the GI levels off or decreases on subsequent days. If the strain is resistant, the GI continues to increase until it is equal to or greater than the Δ GI of the control. Therefore, resistant strains can be detected and reported earlier than susceptible strains.

VI. RESULTS AND INTERPRETATION (continued)

- B. Susceptibility: growth is inhibited in media with antituberculosis drugs with susceptible mycobacteria. This results in a decrease in the daily $^{14}\text{CO}_2$ production or no increase that can be noted by GI readings compared to those of the growth control.
- C. Resistance: if there is no or very little inhibition of growth in the drug-containing medium, a culture is resistant to the test drug, and the GI output will thus increase daily.
- D. If 1% of the bacterial population in a test culture is resistant to an antimicrobial agent, 99% of the bacteria will be inhibited and only 1% will grow in the presence of the antimicrobial agent. Since the inoculum in the control is 1/100 of that in the antimicrobial medium, the rates of growth (GI increases) in the control and the drug-containing medium will be equal, resulting in approximately equal GI outputs.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

Report drug concentration tested and interpretation according to laboratory policy and format. The following is an example.

<i>M. tuberculosis</i>		
Drug	Amt ($\mu\text{g/ml}$)	Interpretation
Ethambutol	2.5	S
INH	0.1	R
Rifampin	2.0	S
Streptomycin	2.0	S

VIII. LIMITATIONS

- A. Quantitative results that describe percentage of resistance cannot be reported.
- B. Susceptibility results are valid only if the culture is pure.
- C. Results cannot be reported if there is poor growth in the control vial.

7.8.2

BACTEC 460TB System—Indirect Susceptibility Tests with Pyrazinamide for *Mycobacterium tuberculosis*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Pyrazinamide (PZA) is an antimicrobial agent active only against *Mycobacterium tuberculosis* and only at a low pH. Therefore, susceptibility testing of *M. tuberculosis* by the conventional method is performed at a pH of 5.5, at which many cultures fail to grow. Based on the information that the MIC of PZA increases

with an increase in the pH of the medium (3), a special modification of the BACTEC susceptibility test procedure has been developed for susceptibility testing of PZA. With the BACTEC PZA method, the test is performed at a pH of 6.0, at which mycobacteria grow better than at pH 5.5. More reportable results can thus be

achieved. The BACTEC method correlated well with PZA test results obtained by using alternative methods (3, 4). PZA testing is considered problematic, and there is no uniform standardized method for testing this agent on solid media.

II. SPECIMEN

Same as in procedure 7.8.1

III. MATERIALS

Include QC information on reagent container and in QC records.

Same as in procedure 7.8.1. In addition, the following media and reagents are required (storage conditions).

- A. BACTEC PZA susceptibility test medium, which is modified BACTEC 12B at pH 6.0 (22 to 25°C)
- B. BACTEC lyophilized PZA obtained from the manufacturer (2 to 8°C)

C. BACTEC reconstituting fluid (2 to 8°C)

BACTEC reconstituting fluid is an aqueous solution of polyoxyethylene stearate (POES) that enhances the growth of mycobacteria (5).

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

Use a well-dispersed and standardized suspension of the QC strain *M. tuberculosis* H37Rv with each PZA susceptibility test setup. The growth control of the QC culture must yield a growth index (GI) of ≥ 30 in 3 to 8 days and must be completely susceptible to PZA.

V. PROCEDURE

A. Preparation of PZA solution

It is recommended that 100 $\mu\text{g/ml}$ of PZA medium should be tested in the BACTEC system. This amount is equivalent to 25 to 50 $\mu\text{g/ml}$ in the conventional method.

1. Reconstitute lyophilized PZA by adding 5 ml of BACTEC reconstituting fluid to the vial. Mix well until dissolved. Once reconstituted, aliquots may be stored at 2 to 8°C for 3 days, -5 to -20°C for up to 3 months, and -70°C for up to 6 months.

V. PROCEDURE (continued)

Observe standard precautions.

2. If PZA powder is used, prepare stock solution in BACTEC reconstituting fluid by dissolving 40 mg of PZA powder in 10 ml of BACTEC reconstituting fluid (final concentration, 4,000 µg/ml). Dissolve completely, filter sterilize, and store as described above for other stock solutions.

B. Preparation of PZA-containing medium

1. Using a disposable tuberculin syringe, add 0.1 ml of the PZA solution to a BACTEC PZA test medium vial (final concentration, 100 µg/ml).
2. Add 0.1 ml of BACTEC reconstituting fluid to the control BACTEC PZA test medium vial.

C. Inoculum preparation

1. Use an actively growing culture in BACTEC 12B medium supplemented with 0.1 ml of BACTEC reconstituting fluid. Prepare by subculturing growth from the following.
 - a. BACTEC 12B medium with a GI of 300 to 999
Add 0.1 ml to a vial of fresh 12B medium supplemented with 0.1 ml of reconstituting fluid.
 - b. 7H9 broth when turbidity is less than or equal to that of a McFarland no. 1 standard
Add 0.1 ml to a vial of fresh 12B medium supplemented with 0.1 ml of reconstituting fluid.
 - c. Solid medium
Prepare a suspension with turbidity comparable to that of a McFarland no. 1 standard, and add 0.1 ml of this suspension to a vial of fresh 12B medium supplemented with 0.1 ml of reconstituting fluid.
2. Incubate in a $37 \pm 1^\circ\text{C}$ incubator in the dark.
3. Test the subculture daily on the BACTEC 460 instrument.
 - a. Once the GI is 300 to 500, use this culture as the inoculum source.
 - b. If the GI is >500 , dilute as follows by adding the specified volume of regular BACTEC 12B medium to the vial containing the actively growing organisms.
 - (1) GI of 300 to 499, no dilution
 - (2) GI of 500 to 599, add 1.0 ml of 12B medium
 - (3) GI of 600 to 699, add 1.5 ml of 12B medium
 - (4) GI of 700 to 799, add 2.0 ml of 12B medium
 - (5) GI of 800 to 899, add 2.5 ml of 12B medium
 - (6) GI of 900 to 999, add 3.5 ml of 12B medium
 - c. Do not use cultures more than 1 day after peak GI or a GI of >999 has been reached in BACTEC 12B vials supplemented with BACTEC reconstituting fluid.

D. Inoculation and incubation

1. Prepare BACTEC bottles as described in procedure 7.8.1.
2. Mix the inoculum suspension well, and use a tuberculin syringe to add 0.1 ml of the standardized suspension to the PZA-containing BACTEC 12B vial and the control vial (do not dilute inoculum for the control vial).
3. Subculture a few drops of the inoculum suspension onto a blood agar plate and a 7H10 or 7H11 agar plate to check for purity.
4. Incubate in the dark in a $37 \pm 1^\circ\text{C}$ incubator.

E. Daily BACTEC testing schedule

1. Examine plates for purity.
2. Test daily on the BACTEC 460.
3. Test at approximately the same time (± 2 h) each day.
4. Test for a minimum of 4 days (5 days minimum of incubation).
5. Once the GI in the control vial is ≥ 200 , interpret results.
6. If the GI does not reach 200 within 14 days of incubation, consider the test uninterpretable.

It is imperative that these cultures be handled in a biosafety hood.

V. PROCEDURE (*continued*)**F. Non-weekend schedule** (1)

For those laboratories where weekend coverage is not available, a non-weekend testing schedule has been reported to work well (2). The non-weekend schedule is similar to the one used for SIRE antimicrobials. In this multicenter study, there was an overall 94% agreement between results of daily and non-weekend results, with no significant difference in time to complete the test.

VI. RESULTS AND INTERPRETATION

- A. Calculate the percentage of growth in the PZA vial compared with that in the control vial [(GI in PZA vial/GI in control vial) × 100].
- B. Interpret results as follows
 1. Susceptible: GI in PZA vial <10% of GI in control vial
 2. Resistant: GI in PZA vial >10% of GI in control vial
 3. Borderline or partially resistant: GI in PZA vial within 5 to 15% of GI in control vial

POSTANALYTICAL CONSIDERATIONS**VII. REPORTING RESULTS**

- A. Susceptible: report the concentration of PZA tested and report according to laboratory policy and format, such as “*Mycobacterium tuberculosis*, BACTEC PZA susceptibility test, 100 µg/ml, susceptible.”
- B. Resistance: based on correlation with other methods, resistance is calculated at the 10% level.
- C. Generally, results are available in 4 to 7 days, with good correlation with conventional test results (2, 4). Results indicating resistance may be interpreted in less than 4 days, but results indicating susceptibility must never be reported in less than 4 days.

VIII. LIMITATIONS

- A. Quantitative results that describe percentage of resistance cannot be reported.
- B. Susceptibility results are valid only if the culture is pure. Mixed or contaminated cultures may give erroneous results.
- C. Results cannot be reported if there is poor growth in the control vial. Some *M. tuberculosis* strains grow poorly at pH 6.0.
- D. Strains of *M. tuberculosis* susceptible to POES at pH 6.0, though rare, have been encountered. In this situation, perform the PZA susceptibility test without POES (reconstitute PZA with sterile deionized water) (2).

7.8.3

BACTEC 460TB System—Indirect Susceptibility Tests for Slow-Growing Mycobacteria other than *Mycobacterium tuberculosis*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The drugs currently recommended for therapy of *Mycobacterium avium* complex still include those recommended for *Mycobacterium tuberculosis*. However, these are nearly always inactive in vitro when tested by the conventional method. While isoniazid (INH) is usually inactive, susceptibility to streptomycin, rifampin, and ethambutol (especially at higher concentrations) is variable when tested by BACTEC 460TB, with most organisms being susceptible to these drugs (2). The antimicrobial agents and the concentrations tested (particularly for *M. avium* complex)

should be determined following consultation with a clinician with expertise in treating infections caused by these organisms.

With some modifications, the BACTEC procedure can be used for testing nontuberculous mycobacteria (NTM). Results for most antimicrobial agents are reproducible but do not correlate well with those obtained by the conventional method. Good correlation between BACTEC and conventional methods has been reported only for *Mycobacterium kansasii* and *Mycobacterium marinum* when testing with INH, rifampin, and ethambutol

(1). In general, NTM show greater susceptibility in BACTEC 12B medium than on solid medium (2, 4, 5). Among NTM, only *M. avium* susceptibility testing with the BACTEC method has been thoroughly studied in a multicenter study (2).

The clinical relevance of susceptibility testing for NTM is undetermined. Because of the lack of standardization for testing NTM with BACTEC, this procedure should be performed only in specialized laboratories that have significant experience in testing these organisms and thorough understanding of the test limitations.

II. SPECIMENS

Growth of slow-growing mycobacteria on solid medium, such as Middlebrook agar or egg-based media, or liquid medium, such as Middlebrook 7H9 broth or BACTEC 12B medium (growth index [GI] of ≥ 500)

III. MATERIALS

Same as those required for susceptibility testing of *M. tuberculosis*

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

Include a culture of *M. avium* that is well characterized and has been tested several times for antimicrobial susceptibility.

V. PROCEDURE

A. In the case of *M. kansasii* follow the procedure for the susceptibility testing of *M. tuberculosis* (1). The procedure for susceptibility testing of *M. avium* complex is very different from that used for *M. tuberculosis* and is strictly experimental. In a multicenter study, BACTEC 460 susceptibility testing of *M. avium* with amikacin, ciprofloxacin, clofazimine, cycloserine, ethambutol, ethionamide, rifampin, and streptomycin yielded reproducible results (6), and the procedure established in this publication should be followed. Since *M. avium* grows

V. PROCEDURE (continued)

Observe standard precautions.

relatively rapidly in BACTEC 12B medium, standardization of the inoculum for susceptibility testing is very critical.

- B.** For *M. avium* three concentrations of a test drug are used since there is variation from strain to strain for susceptibility to any antimicrobial agent (6).
- C.** Inoculum preparation
- 1.** Liquid medium
Use an actively growing seed culture in BACTEC 12B medium. Prepare a seed vial by subculturing growth from the following.
 - a.** BACTEC 12B medium with a GI of 500 to 999. Add 0.1 ml to a vial of fresh 12B medium.
 - b.** 7H9 broth when turbidity reaches that of a McFarland no. 1 standard. Add 0.1 ml to a vial of fresh 12B medium.
 - 2.** Solid medium
 - a.** Prepare a suspension with a turbidity comparable to that of a McFarland no. 1 standard, and add 0.1 ml to a vial of fresh 12B medium.
 - b.** For *M. avium* complex, select as many translucent colonies as possible from 7H10 and 7H11 agar.
 - 3.** Incubate in a $37 \pm 1^\circ\text{C}$ incubator in the dark.
 - 4.** Test BACTEC 12B subculture daily on the BACTEC 460 instrument. Once the GI reaches 999 (usually 24 to 48 h), use as the inoculum source within 24 h.
 - 5.** Dilute BACTEC 12B suspension with BACTEC diluting fluid as follows.
 - a.** *M. kansasii* (1:20 dilution): 0.5 ml of suspension in 9.5 ml of diluting fluid
 - b.** *M. avium* complex (1:100 dilution): 0.1 ml of suspension in 9.9 ml of diluting fluid
 - c.** For *M. kansasii* further dilute the inoculum suspension for the control vial 1:100 by adding 0.1 ml of the standardized suspension to 9.9 ml of BACTEC diluting fluid. In the case of *M. avium*, inoculate drug-containing vial and the control vial with 1:100-diluted culture. Use another growth control by diluting the inoculum further 1:100 and inoculating into a 12B vial, control 2 (1:10,000).
- D.** Inoculation and incubation
- 1.** Gas BACTEC 12B vials on BACTEC 460 instrument.
 - 2.** Prepare a standardized test culture suspension as described above. Mix the inoculum suspension well, and use a tuberculin syringe to add 0.1 ml of the standardized suspension to each of the 12B vials containing antimicrobial agent. For *M. avium* inoculate into the growth control as well (control 1).
 - 3.** Subculture a few drops of the inoculum suspension onto a blood agar plate and a 7H10 or 7H11 agar plate to check for purity.
 - 4.** Inoculate 0.1 ml of the well-mixed 1:100-diluted suspension into the control vial (*M. avium*, control 2).
 - 5.** Disinfect the rubber septum on the top of each vial with a cotton swab or gauze pad soaked with an appropriate disinfectant, and then disinfect it with an alcohol swab.
 - 6.** Incubate all vials in a $37 \pm 1^\circ\text{C}$ incubator in the dark.
- E.** Daily BACTEC testing schedule
- 1.** Examine purity plates.
 - 2.** Test vials daily at approximately the same time (± 2 h) each day.
 - 3.** Test for a minimum of 4 days (5 days of incubation).
 - 4.** Once the GI in the control for the *M. kansasii* vial is ≥ 30 , interpret results.
 - 5.** If the GI of the control does not reach 30 within 10 days of incubation or reaches 30 in less than 3 days, consider the test uninterpretable.

It is imperative that these cultures be handled in a biosafety hood.

V. PROCEDURE (continued)

6. For *M. avium* the MIC is interpreted when the GI of the 1:100 control (control 2) is 20 or more for three consecutive days and the GI of the undiluted control (control 1) reaches 999. These requirements have to be met between days 4 and 8 of incubation (the day of inoculation is considered day 1).

VI. RESULTS AND INTERPRETATION

- A. Interpret results of *M. kansasii* as described for *M. tuberculosis*. For *M. avium* the MIC is the lowest concentration of a test drug which inhibits 99% of the bacterial population. In the presence of the lowest concentration of a drug, the daily GI increases (Δ GI) are less than those in the 1:100-diluted control (control 2) and the final GI in the drug-containing vial is not greater than 50 at the time of interpretation.
- B. Translucent colonies of *M. avium* complex are more resistant than the opaque variants. Therefore, when they are present, use translucent colonies for susceptibility testing (5).
- C. The synergistic effect of several drugs against *M. avium* complex has been tested using the BACTEC system (3).

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

For isolates other than *M. kansasii*, include this note in the report: "To date, no studies have proven that in vitro results correlate with clinical efficacy."

VIII. LIMITATIONS

- A. Clinical correlation of in vitro susceptibility test results for NTM has not been determined.
- B. It is not known which of the two susceptibility test procedures, BACTEC or the conventional method, yield results for NTM that correlate best with the clinical results. However, it has been suggested that testing of *M. avium* complex be performed by a MIC method (2, 6).
- C. There are no standard recommendations for QC of the BACTEC procedure when testing NTM.
- D. Because of variation in susceptibilities of different strains within the same species, it is difficult to develop a test procedure using a single concentration of an antimicrobial agent. Thus, more than one concentration of antimicrobial agent should be tested.

7.8.4

BACTEC 460TB System—Direct Susceptibility Test for *Mycobacterium tuberculosis*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Direct susceptibility testing of smear-positive specimens of *Mycobacterium tuberculosis* by using the BACTEC method is not widely used and has not been cleared by the Food and Drug Administration. It has been reported to yield rapid and reliable results (1). Direct susceptibility testing may be performed on all acid-fast

smear-positive specimens irrespective of the degree of smear positivity. Results are available in 4 to 21 days, depending on the number of viable organisms in the original specimen (1). Direct susceptibility test results may take longer (5 to 21 days; average, 10 to 12 days) than indirect test

results. Direct tests are usually set up on the same day that primary isolation media are inoculated, and identification results are often available concurrently with direct susceptibility results. Indirect testing must be performed to confirm all results obtained by direct testing.

II. SPECIMENS

Use concentrated, digested and decontaminated, smear-positive specimens.

III. MATERIALS

Include QC information on reagent container and in QC records.

All the materials and supplies are the same as for the indirect susceptibility testing, except that BACTEC 460 PANTA (polymyxin B, amphotericin B, nalidixic acid, trimethoprim, and azlocillin) antimicrobial mixture is needed to suppress contamination.

ANALYTICAL CONSIDERATIONS

IV. PROCEDURE

Observe standard precautions.

The test procedures are the same as for indirect susceptibility testing, except for the following.

- A. Test only streptomycin, isoniazid, rifampin, and ethambutol.
- B. Add 0.1 ml of BACTEC PANTA antimicrobial supplement to control and drug-containing BACTEC 12B vials prior to inoculation.
- C. Inoculate 0.1 ml of the well-mixed acid-fast bacillus (AFB) smear-positive sediment directly into the drug-containing BACTEC 12B vials.
- D. Prepare a 1:10 dilution of the initial inoculum by using BACTEC diluting fluid (0.1 ml of inoculum plus 0.9 ml of BACTEC diluting fluid), mix well, and inoculate 0.1 ml into the control vial. The inoculum is diluted 1:10 rather than 1:100 because usually the specimen contains a low number of AFB.
- E. Incubate in a $37 \pm 1^\circ\text{C}$ incubator, and test BACTEC vials every 2 to 3 days for a maximum of 3 weeks. For specimens with numerous acid-fast bacteria on smear, test daily.

IV. PROCEDURE (*continued*)

- F. Once the growth index (GI) in the control is ≥ 10 , test vials daily.
- G. Interpret results when the GI of the control is ≥ 20 .
- H. Occasionally, the organism in the control vial may fail to grow adequately even though resistance is observable in drug vials. Do not report these results.

V. RESULTS AND INTERPRETATION

Usually, results are unequivocally susceptible or resistant because of the smaller number of mycobacteria in the inoculum and the longer incubation time. A GI in the drug vial that is close to the GI in the control vial (within 20%) suggests a 10% resistant population, as the control was diluted 1:10. Report as partially resistant.

POSTANALYTICAL CONSIDERATIONS

VI. REPORTING RESULTS

- A. Report “susceptible” or “resistant” based on the GI interpretation and add the following statement: “Results obtained by direct specimen testing.”
- B. If borderline results are obtained, report the following: “Based on direct testing, isolate appears partially resistant to (respective drug); confirmatory testing to follow.”
- C. Do not report results until isolate is confirmed as *M. tuberculosis*.

VII. LIMITATIONS

- A. The direct testing method does not include a mechanism for standardizing the number of organisms in the test inoculum.
- B. Although initial readings are made every 2 to 3 days, vials must be tested daily once a GI of ≥ 10 is obtained. Consequently, a daily BACTEC testing schedule must be followed.
- C. Only results for *M. tuberculosis* are reportable.
- D. Susceptibility tests are set up before mycobacterial identification is established, and sometimes isolates other than *M. tuberculosis* are tested unnecessarily. Confine testing to specimens highly suspicious for *M. tuberculosis*.
- E. Direct susceptibility testing has not been extensively validated.

REFERENCE

- 1. Libonati, J. P., C. C. Stager, J. R. Davis, and S. H. Siddiqi. 1988. Direct drug susceptibility testing of *M. tuberculosis* by the radiometric method. *Diagn. Microbiol. Infect. Dis.* **101**:41–48.

7.8.5

BACTEC MGIT 960 SIRE— Nonradiometric Susceptibility Testing for *Mycobacterium tuberculosis*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The BACTEC MGIT 960 SIRE kit is a nonradiometric antimicrobial susceptibility system for testing *Mycobacterium tuberculosis* from isolated culture. It provides susceptibility results for streptomycin (STR), isoniazid (INH), rifampin (RIF) and ethambutol (EMB) in approximately the same time frame as the BACTEC 460TB system. The BBL MGIT 7-ml mycobacteria growth indicator tube (MGIT tube) contains a modified Middlebrook 7H9 broth, which supports the growth and detection of mycobacteria. The MGIT tube contains a fluorescent

compound embedded in silicone on the bottom of a 16- by 100-mm round-bottom tube. The fluorescent compound is sensitive to the presence of oxygen dissolved in the broth. The initial concentration of dissolved oxygen quenches the emission of fluorescence from the compound, and little fluorescence can be detected. Later, actively growing and respiring microorganisms consume the oxygen, which allows the compound to fluoresce.

The BACTEC MGIT 960 SIRE kit is a 4- to 13-day qualitative test. The test is

based on growth of the *M. tuberculosis* isolate in a drug-containing tube compared to a drug-free tube (growth control). The MGIT 960 instrument continuously monitors tubes for increased fluorescence. Analysis of fluorescence in the drug-containing tube compared to the fluorescence of the growth control tube is used by the instrument to determine susceptibility results. The BACTEC MGIT 960 instrument automatically interprets these results and reports a susceptible or resistant result.

II. SPECIMENS

Susceptibility tests are performed from pure cultures of *M. tuberculosis*.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Materials provided

1. BACTEC MGIT 960 SIRE kit containing one vial of each lyophilized drug and eight vials of SIRE supplement (40 tests per drug per kit)
2. BACTEC MGIT 960 STR 4.0 kit containing one vial of lyophilized drug and two vials of SIRE supplement (20 tests per kit)

3. BACTEC MGIT 960 INH 0.4 kit containing one vial of lyophilized drug and two vials of SIRE supplement (20 tests per kit)

B. Materials required and not provided

1. BBL MGIT 7-ml tubes
2. Ancillary culture media, reagents
3. Laboratory equipment as required for this procedure

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

A. Strains

1. Test QC strains, *M. tuberculosis* ATCC 27294, upon receipt of a new shipment or lot number of MGIT 960 SIRE kit vials
2. Maintain QC stock strains at -70°C .
3. The QC AST set should be prepared according to the "Inoculation Procedure for Susceptibility Test" instructions for the drug kits being tested.

IV. QUALITY CONTROL (continued)

4. Observation of the proper results within 4 to 13 days, as shown below, indicates that the BACTEC MGIT 960 SIRE kits are ready for use in testing patient isolates. If the proper results are not observed, repeat the test.

Strain	Growth control	MGIT STR	MGIT INH	MGIT RIF	MGIT EMB	MGIT STR 4.0	MGIT INH 0.4
<i>M. tuberculosis</i> ATCC 27294	Positive	Susceptible	Susceptible	Susceptible	Susceptible	Susceptible	Susceptible

B. Troubleshooting

1. The same QC organism should be run once each week when susceptibility testing is performed.
2. If the batch QC fails, do not report patient results for the drug(s) that failed for that testing period. Repeat the QC for the drug(s) and patient isolates affected by the initial QC failure. If the repeat QC does not perform as expected, do not report patient results. Send specimen to reference laboratory for evaluation.

V. PROCEDURE

It is imperative that these cultures be handled in a biosafety hood.

A. Specimen preparation

1. Preparation of isolate from solid media
 - a. Add 4 ml of Middlebrook 7H9 broth or MGIT broth to a sterile tube with cap containing glass beads.
 - b. Scrape with a sterile loop several colonies and suspend in 7H9 broth.
 - c. Vortex the suspension for 2 to 3 min to break up the large clumps. The suspension should exceed a 1.0 McFarland standard turbidity.
 - d. Allow suspension to sit for 20 min.
 - e. Transfer the supernatant to another sterile tube with cap, and let it sit for an additional 15 min.
 - f. Transfer the supernatant to another tube. Adjust suspension to a 0.5 McFarland standard.
 - g. Dilute 1 ml of the adjusted suspension in 4 ml of sterile saline (1:5 dilution).
2. Preparation from a positive BACTEC MGIT 7-ml tube
 - a. A positive 7-ml MGIT tube should be used the day after it becomes positive on the BACTEC MGIT 960 instrument (day 1), up to and including the fifth day (day 5) after instrument positivity.
 - b. A tube that has been positive for more than 5 days should be subcultured to a fresh 7-ml MGIT tube containing BACTEC MGIT 960 growth supplement and tested on the BACTEC MGIT 960 instrument until positive and used from 1 to 5 days following positivity.
 - c. If the tube is a day 1 or 2 positive, mix well and proceed.
 - d. If the tube is a day 3, 4, or 5 positive, mix well and dilute 1 ml of positive broth in 4 ml of sterile saline and proceed with diluted suspension.

B. Inoculation procedure for BACTEC MGIT 960 SIRE kit susceptibility test

1. Label five 7-ml MGIT tubes for each test isolate. Label one as GC (growth control), one as STR, one as INH, one as RIF, and one as EMB. Place the tubes in the correct sequence in the appropriate-size AST set carrier.
2. Aseptically add 0.8 ml of MGIT SIRE supplement to each tube.
3. Aseptically pipette 100 μ l of 83- μ g/ml MGIT STR solution to the appropriately labeled MGIT tube.
4. Aseptically pipette 100 μ l of 8.3- μ g/ml MGIT INH solution to the appropriately labeled MGIT tube.

V. PROCEDURE (*continued*)

5. Aseptically pipette 100 µl of 83-µg/ml MGIT RIF solution to the appropriately labeled MGIT tube.
6. Aseptically pipette 100 µl of 415-µg/ml MGIT EMB solution to the appropriately labeled MGIT tube.
7. No antimicrobial agents should be added to the MGIT growth control tube.

Drug	Drug concn (µg/ml) after reconstitution ^a	Vol (µl) added to MGIT tubes	Final concn (µg/ml) in MGIT tubes
MGIT STR	83	100	1.0
MGIT INH	8.3	100	0.1
MGIT RIF	83	100	1.0
MGIT EMB	415	100	5.0

^a Reconstitute using 4 ml of sterile distilled and deionized water.

C. Growth control tube preparation and inoculation

1. Aseptically pipette 0.1 ml of the organism suspension into 10 ml of sterile saline to prepare the 1:100 growth control suspension.
2. Mix the growth control suspension thoroughly. Inoculate 0.5 ml of the 1:100 growth control suspension into the MGIT tube labeled “GC.”

D. Inoculation of drug-containing tubes

1. Aseptically pipette 0.5 ml of the organism suspension into each of the four remaining drug tubes (STR, INH, RIF, and EMB).
2. Tightly recap the tubes. Mix tubes thoroughly by gentle inversion three or four times.
3. Enter the AST set into the MGIT 960 using the AST set entry feature (refer to the *BACTEC MGIT 960 User's Manual*, “AST Instructions”).
4. Streak 0.1 ml of the organism suspension onto a TSA with 5% sheep blood plate. Enclose in a plastic bag. Incubate at 35 to 37°C.
5. Check the blood agar plate at 48 h for bacterial contamination. If the blood agar plate shows no growth, then allow AST testing to proceed. If the blood agar plate shows growth, discard the AST set (refer to the *BACTEC MGIT 960 User's Manual*, “AST Instructions”) and repeat testing with pure culture.

E. Inoculation procedure for BACTEC MGIT STR 4.0 and INH 0.4 kits

It is recommended that if resistance occurs at the critical concentration of a test drug, a susceptibility test be performed with a higher concentration of the drug, especially for INH.

1. Label enough 7-ml MGIT tubes for the test isolate to have a MGIT growth control and a MGIT drug tube for each antimicrobial agent tested. Place the tubes in the correct sequence in the appropriate-size AST set carrier (*see BACTEC MGIT 960 User's Manual*, “AST Instructions”).
2. Aseptically add 0.8 ml of BACTEC MGIT SIRE supplement to each tube.
 - **NOTE:** It is important to use the supplement supplied with the kit.
3. Aseptically pipette, using a micropipette, 100 µl of the drug solution to the appropriately labeled MGIT tube. It is important to add the correct drug to the corresponding tube. No antimicrobial agents should be added to the MGIT growth control tube.

Drug	Concn (µg/ml) of drug after reconstitution ^a	Vol (µl) added to MGIT tubes	Final concn (µg/ml) in MGIT tubes
MGIT STR 4.0	332	100	4.0
MGIT INH 0.4	33.2	100	0.4

^a Reconstitute using 2 ml of sterile distilled and deionized water.

V. PROCEDURE (continued)**F. Growth control tube preparation and inoculation**

1. Aseptically pipette 0.1 ml of the organism suspension into 10 ml of sterile saline to prepare the 1:100 growth control suspension.
2. Mix the growth control suspension thoroughly.
3. Inoculate 0.5 ml of the 1:100 growth control suspension into the MGIT tube labeled "GC."

G. Inoculation of drug-containing tubes

1. Aseptically pipette 0.5 ml of the organism suspension into each of the drug tubes.
2. Tightly recap the tubes. Mix tubes thoroughly by gentle inversion three or four times.
3. Enter the AST set into the MGIT 960 using the AST set entry feature (refer to the *BACTEC MGIT 960 User's Manual*, "AST Instructions").
4. Ensure that the order of the tubes in the AST set carrier conforms to the set carrier definitions selected when performing the AST set entry feature.
5. Streak 0.1 ml of the organism suspension onto a TSA blood agar plate. Enclose in a plastic bag. Incubate at 35 to 37°C.
6. Check the blood agar plate at 48 h for bacterial contamination. If the blood agar plate shows no growth, then allow AST testing to proceed. If the blood agar plate shows growth, discard the AST set (refer to the *BACTEC MGIT 960 User's Manual*, "AST Instructions") and repeat testing with pure culture.

VI. RESULTS AND INTERPRETATION

- A. Susceptible: when the fluorescence in the drug-containing tube is less than that of the growth control tube, then the BACTEC MGIT 960 interprets the result as susceptible.
- B. Resistant: when the fluorescence in the drug-containing tube is equal to that of the growth control tube, then the BACTEC MGIT 960 interprets the result as resistant.
- C. When certain conditions occur that may affect test results, the MGIT 960 instrument reports as an error (X) and there is no susceptibility interpretation.

POSTANALYTICAL CONSIDERATIONS**VII. REPORTING RESULTS**

- A. Report "susceptible" or "resistant" based on the BACTEC MGIT 960 instrument's interpretation.
- B. Do not report if the BACTEC MGIT 960 instrument interpretation result is an error (X).
- C. Include test method, drug, and concentration.

VIII. LIMITATIONS

- A. The BACTEC MGIT 960 susceptibility test does not interpret the degree of susceptibility of the isolate being tested. Results are reported as either S (susceptible) or R (resistant) for the drug and concentration tested.
- B. The BACTEC MGIT 960 SIRE test was developed with critical concentrations for STR, INH, RIF, and EMB that are slightly lower than the critical concentrations used in the method of proportion in order to avoid false susceptibility. Testing of the higher concentrations, as recommended, will enhance the ability to detect isolates with low-level resistance.
- C. The BACTEC MGIT 960 susceptibility tests can be performed only using the BACTEC MGIT 960 instrument. The AST sets cannot be read manually. Use only pure cultures of *M. tuberculosis*. Cultures that are contaminated or that may contain multiple species of mycobacteria may give erroneous results and

VIII. LIMITATIONS (*continued*)

- should not be tested. Direct testing from clinical specimens is not recommended. Suspensions made from solid media must be allowed to settle for the prescribed times prior to standardization. Inoculum preparations made from solid media should be visually compared to a 0.5 McFarland turbidity standard; failure to do so may give inaccurate results or cause an AST set error.
- D.** Failure to use the 1:5 dilution of the organism suspension, when indicated, to inoculate the drug-containing tubes may give inaccurate results.
 - E.** Failure to use a 1:100 dilution of the organism suspension for the inoculation of the growth control tube may give inaccurate results or cause an AST set error.
 - F.** Failure to reconstitute the drugs with the appropriate volume of sterile distilled and deionized water may give inaccurate results.
 - G.** Thorough mixing of inoculated tubes is important. Failure to mix the tubes adequately can lead to false-resistant results.
 - H.** Failure to load the tubes of the AST set into the AST set carrier in the proper sequence may give inaccurate results. Failure to select the appropriate set carrier drug definition may result in invalid or inaccurate results.
 - I.** Failure to load the AST set into the instrument correctly will result in an anonymous condition that must be resolved within 8 h. If the condition is not resolved within 8 h, the AST set must be discarded and set up again.
 - J.** Failure to use the SIRE supplement in the AST set may give inaccurate results. *Do not* add BACTEC MGIT 960 growth supplement to the AST set.

BACTEC MGIT 960 PZA— Susceptibility Testing for *Mycobacterium tuberculosis*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The BACTEC MGIT 960 PZA kit is a 4- to 21-day qualitative test used for pyrazinamide (PZA) susceptibility testing of *Mycobacterium tuberculosis* from culture using the BACTEC MGIT 960 system. The testing for PZA requires modification from the general methods because the drug is active in vitro only at lower pH values (1). The MGIT 960 PZA medium contains a modified Middlebrook 7H9 broth at a reduced pH of 5.9.

The mycobacteria growth indicator tube (MGIT tube) contains a fluorescent compound embedded in silicone on the

bottom of a 16- by 100-mm round-bottom tube. The fluorescent compound is sensitive to the presence of oxygen dissolved in the broth. The initial concentration of dissolved oxygen quenches the emission of fluorescence from the compound, and little fluorescence can be detected. Later, actively respiring microorganisms consume the oxygen, which allows the compound to fluoresce. The test is based on growth of the *M. tuberculosis* isolate in a drug-containing tube compared to a drug-free tube (growth control). The BACTEC

MGIT 960 instrument continually monitors tubes for increased fluorescence. Analysis of fluorescence in the drug-containing tube compared to the fluorescence of the growth control tube is used by the instrument to determine susceptibility results. The BACTEC MGIT 960 instrument automatically interprets these results using predefined algorithms (which compare growth in the drug-containing tube to that in the growth control tube), and the susceptible or resistant result is reported by the instrument.

II. SPECIMENS

Susceptibility tests are performed from pure cultures of *M. tuberculosis*.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. BACTEC MGIT PZA medium (20 to 25°C)
7 ml of PZA broth in a polypropylene tube with a fluorescent indicator in the bottom

B. BACTEC MGIT 960 PZA kit (2 to 8°C)
1. two lyophilized vials of PZA
2. six vials of PZA supplement

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Upon receipt of a new shipment or lot number of BACTEC MGIT 960 PZA kits or BACTEC MGIT PZA medium, it is suggested that the control organism *M. tuberculosis* ATCC 27294 be tested.
- B. Observation of the proper results within 4 to 21 days indicates that the BACTEC MGIT 960 PZA reagents are ready for use in testing patient isolates. If the proper results are not observed, repeat the test.

IV. QUALITY CONTROL (continued)

- C. The same control organism should be run as batch QC once each week when susceptibility testing is performed. If the batch QC fails, do not report patient results for the drug that failed for that testing period. Repeat the QC for the drug and patient isolates affected by the initial QC failure. If the repeat QC does not perform as expected, do not report patient results.

V. PROCEDURE

It is imperative that these cultures be handled in a biosafety hood.

A. Preparation of the isolate from solid media

1. Add 4 ml of Middlebrook 7H9 broth or BBL MGIT broth to a sterile tube with cap containing glass beads.
2. Scrape with a sterile loop as many colonies as possible from any solid medium. Suspend the colonies in the Middlebrook 7H9 broth. The suspension should exceed a 1.0 McFarland standard.
3. Vortex the suspension for 2 to 3 min to break up the larger clumps.
4. Let the suspension sit for 20 min.
5. Transfer the supernatant fluid to a sterile tube with cap and let sit for another 15 min.
6. Transfer the supernatant to a third tube.
7. Adjust the suspension to a 0.5 McFarland standard.
8. Dilute 1 ml of the adjusted suspension in 4 ml of sterile saline (1:5 dilution).

B. Preparation from a positive BACTEC MGIT tube

1. A positive 7-ml MGIT tube should be used the day after it first becomes positive on the BACTEC MGIT 960 instrument (day 1), up to and including the fifth day (day 5) after instrument positivity. A tube which has been positive for more than 5 days should be subcultured to a fresh 7-ml MGIT tube containing BACTEC MGIT 960 growth supplement and tested on the BACTEC MGIT 960 instrument until positive, and it should be used from 1 to 5 days following positivity.
2. If the tube is a day 1 or 2 positive, then proceed.
3. If the tube is a day 3, 4, or 5 positive, then dilute 1 ml of the positive broth in 4 ml of sterile saline (1:5 dilution) and proceed with the diluted suspension.

C. Inoculation procedure for BACTEC MGIT 960 PZA susceptibility test

1. Label two 7-ml MGIT PZA tubes for each test isolate. Label one as GC (growth control) and one as PZA. Place the tubes in the correct sequence in the two-tube AST set carrier (*see BACTEC MGIT 960 User's Manual, "AST Procedure"*).
2. Aseptically add 0.8 ml of BACTEC MGIT PZA supplement to each tube.
 NOTE: It is important to use the correct supplement.
3. Aseptically pipette, using a micropipette, 100 µl of 8,000-µg/ml BACTEC MGIT PZA drug solution to the appropriately labeled BACTEC MGIT tube. No drug solution should be added to the MGIT growth control tube.

Drug	Concn of drug after reconstitution	Vol added to MGIT tubes for test	Final concn in MGIT tubes
MGIT PZA	8,000 µg/ml	100 µl	100 µg/ml ^a

^a Equivalent to CDC-recommended critical drug concentrations.

D. Growth control tube preparation and inoculation

1. Aseptically pipette 0.5 ml of the organism suspension into 4.5 ml of sterile saline to prepare the 1:10 growth control suspension.
2. Mix the growth control suspension thoroughly. Inoculate 0.5 ml of the 1:10 growth control suspension into the MGIT tube labeled "GC."

V. PROCEDURE *(continued)***E. Inoculation of drug-containing tube**

1. Aseptically pipette 0.5 ml of the organism suspension into the drug tube.
2. Tightly recap the tubes and mix well.
3. Enter the AST set into the BACTEC MGIT 960 instrument using the AST set entry feature (refer to the *BACTEC MGIT 960 User's Manual*). Ensure that the growth control tube is in the first left tube position. Select PZA as the drug in the two-tube AST set carrier definition when performing the AST set entry.
4. Streak 0.1 ml of the organism suspension onto a TSA with 5% sheep blood plate. Enclose in a plastic bag. Incubate at 35 to 37°C.
5. Check the blood agar plate at 48 h for bacterial contamination. If the blood agar plate shows no growth, then allow AST testing to proceed. If the blood agar plate shows growth, discard the AST set (refer to the *BACTEC MGIT 960 User's Manual*) and repeat testing with pure culture.

VI. RESULTS AND INTERPRETATION

The BACTEC 960 instrument monitors the fluorescence in the growth control and drug-containing tubes until the test is ready to report. At this point the instrument interprets the results and reports as resistant or susceptible. Resistance is reported at the 10% proportion level, unlike SIRE interpretation, which is done at the 1% level.

The instrument will report an error (X) when certain conditions occur and results are not interpretable. In such a situation, the test should be repeated.

POSTANALYTICAL CONSIDERATIONS**VII. REPORTING RESULTS**

Report "susceptible" or "resistant" as interpreted by the instrument.

Do not report if the instrument interprets results with the error (X).

Do not report if the culture is found not pure.

Monoresistance to PZA is rare. Verify results if found monoresistance by checking purity, identification of *M. tuberculosis*, and other parameters.

VIII. LIMITATIONS

- A. The NCCLS recommends the BACTEC 460TB method for PZA susceptibility testing as a reference method (2). The nonradiometric BACTEC MGIT 960 PZA kit provides the susceptibility result in approximately the same time frame as the BACTEC 460TB system. The MGIT 960 PZA kit, like the BACTEC 460TB, uses a PZA concentration of 100 µg/ml, to achieve comparable results.
- B. Growth on the solid medium should be fresh (within 14 days). Inoculum preparations made from older cultures without the use of a 0.5 McFarland turbidity standard and the appropriate dilutions may give inaccurate results.
- C. Failure to use a 1:10 dilution of the isolate for the inoculation of the growth control tube may give inaccurate results.
- D. Failure to use the BACTEC MGIT 960 PZA supplement in the PZA AST set may give inaccurate results. Do not add BACTEC MGIT 960 SIRE supplement or BACTEC MGIT 960 growth supplement to the PZA AST set.

7.8.7

VersaTREK (Formerly ESP Culture System II)—Indirect Susceptibility Testing for *Mycobacterium tuberculosis*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The VersaTREK, formerly the ESP Culture System II (Trek Diagnostic Systems, Inc., Westlake, Ohio), has been adapted for the performance of antimycobacterial susceptibility testing to the first-line agents rifampin, isoniazid (INH), and ethambutol with clinical isolates of *Mycobacterium tuberculosis* (1, 2). Streptomycin and Pyr-

azinamide have not been Food and Drug Administration (FDA) cleared for antimycobacterial susceptibility testing with the VersaTREK as of this writing. A standardized suspension of *M. tuberculosis* is inoculated into drug-containing ESP Myco bottles and a drug-free control bottle. The bottles are placed into the ESP

Culture System II instrument and monitored for growth. The test is terminated 3 days after the control bottle signals positive. Any drug-containing bottle becoming positive within that time indicates resistance of the test isolate to that drug at the tested concentration.

II. SPECIMENS

The VersaTREK system has been cleared by the FDA for use with pulmonary and extrapulmonary specimens, including blood, for indirect susceptibility testing with rifampin, INH, and ethambutol.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Materials provided by manufacturer

Storage of the following is at room temperature except when otherwise indicated.

1. Myco bottles (7H9 broth with Casitone and glycerol)
2. Myco growth supplement (oleic acid, bovine serum albumin, glucose, and catalase) (4 to 8°C in the dark)

3. Connectors

4. Lyophilized drugs or drug powder (4 to 8°C)

B. Materials required but not provided

1. Tubes with sterile saline and sterile glass beads
2. Tuberculin syringes with fixed needles
3. Middlebrook 7H11 plates
4. TSA blood agar plates
5. Sterile filter packs

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

A. Strains

1. *M. tuberculosis* H37Rv (ATCC 27294)
2. *M. tuberculosis* ATCC 35838 (rifampin resistant)
3. *M. tuberculosis* ATCC 35837 (ethambutol resistant)
4. *M. tuberculosis* ATCC 35831 (streptomycin resistant) (optional)
5. *M. tuberculosis* ATCC 35822 (INH resistant)
6. Store stock culture suspensions at -70°C .

IV. QUALITY CONTROL*(continued)***B. Expected results**

1. *M. tuberculosis* (H37Rv) is fully susceptible to all first-line antituberculosis drugs tested.
2. Run the control weekly or each day of test, whichever is more frequent.
3. Optional but recommended: strains resistant to each of the four antituberculosis drugs (monoresistant strains) are run monthly. After preparing a new batch of drugs, both the H37Rv strain and the corresponding monoresistant strain must be run before using that batch of drug.

V. PROCEDURE**A. Rehydration of INH, rifampin, and ethambutol**

1. Add 25 ml of sterile distilled water to each of the three drug-containing bottles. Swirl to dissolve the contents. Dilute each bottle 1:1 with sterile distilled water. This will result in a final volume of 50 ml. These bottles should be labeled as to their final drug concentration as outlined in Table 7.8.7-1.
2. Remove 5 ml of the rehydrated INH solution and add to a sterile tube containing 15 ml of sterile distilled water. Label as described above (0.1 µg/ml).
3. To a second lyophilized vial of ethambutol, add 40 ml of sterile distilled water. Swirl to dissolve. Dilute 1:1 with sterile distilled water. This will result in a final volume of 80 ml. Label this solution “5 µg/ml ETH.”
4. Aliquot the stock drug solution into cryovials (approximately 1.1 ml each) and freeze in labeled tubes at –70°C. These tubes may be used for 6 months after rehydration.

B. Preparation of streptomycin stock solutions (optional; not FDA approved)

1. Streptomycin powder is obtained from Sigma Chemical Company (St. Louis, Mo.), catalog no. S9137.
2. Prepare 50 ml of a 1.2-mg/ml stock solution of streptomycin in distilled water according to the following formula:

$$\text{Weight (mg)} = \frac{50 \text{ ml} \times 1,200 \text{ µg/ml}}{\text{Assay potency (µg/mg)}}$$

The assay potency is found on the label of each container of streptomycin powder. The powder must be weighed on an analytical balance capable of weighing milligram quantities of the antimicrobial powder.

3. Mix the stock solution until completely dissolved and sterilized by filtration through a 0.45-µm-pore-size sterile disposable filter.
4. Aseptically pipette 1.1-ml aliquots into sterile cryotubes and store at –70°C.
5. Prior to use, thaw an aliquot and prepare a 1:10 dilution in sterile distilled water. This will result in a final concentration of 8.0 µg/ml when 1 ml of this dilution is added to a Myco bottle.

Table 7.8.7-1 Drug concentrations

Drug	Vol of sterile, distilled water	Dilution with sterile, distilled water	Final concn (µg/ml) in ESP bottle
INH	25 ml	1:1	0.4
	5 ml of + 15 ml of water	1:1	0.1
Rifampin	25 ml	1:1	1.0
Ethambutol	25 ml	1:1	8.0
	40 ml	1:1	5.0

V. PROCEDURE (continued)

It is imperative that these cultures be handled in a biosafety hood.

6. Take 5 ml of the 1:10 dilution and add it to 15 ml of sterile distilled water. This will result in a final concentration of 2.0 µg/ml in the Myco bottle.

C. Preparation of drug and control bottles

1. Add 1.0 ml of growth supplement to each of eight Myco bottles. This can be done up to 24 h in advance if the supplemented bottles are kept at 2 to 8°C. Prior to use, these bottles must be allowed to come to room temperature.
2. Add 1.0 ml of each of the seven drug stocks to appropriately labeled supplemented ESP Myco bottles.
3. Add 1.0 ml of sterile distilled water to the control bottle.

D. Preparation of inoculum

1. Growth from solid media
 - a. Prepare a suspension of the test organism in tubes containing sterile saline and glass beads from growth obtained from slants or plates.
 - b. Vortex well, and allow the larger particles to settle for at least 30 min. Remove the upper half of suspension to a sterile tube and adjust, with sterile saline, to a turbidity matching that of a 1.0 McFarland standard.
 - c. Dilute 1:10 with sterile saline. This suspension serves as the inoculum.
2. Growth from seed bottles or primary bottles
 - a. Myco bottles which have been seeded with the test organism or directly from a positive ESP bottle known to contain *M. tuberculosis* may be used as the source of the inoculum.
 - b. A seed bottle can be prepared by inoculating a supplemented Myco bottle with a suspension of organism obtained from solid media, as may be the case with an older referred culture, or from a positive bottle.
 - c. For a Myco bottle to be used as the inoculum source it cannot be refrigerated and *must be* used within 72 h of it giving a positive signal. Store the bottle at room temperature prior to use as the inoculum source.
 - d. Vortex the bottle for 1 to 2 min.
 - e. Disinfect the septum with an alcohol prep pad.
 - f. Remove 1.0 ml of medium from the Myco bottle and add to 9.0 ml of sterile inoculum source.
 - g. Mix carefully to obtain a homogenous suspension. This can now serve as the inoculum source.

E. Inoculation of bottles

1. Add 0.5 ml of inoculum to each of the drug-containing and control bottles.
2. Inoculate a 7H11 agar plate with a few drops of the inoculum to serve as a purity check.
3. Invert the bottle several times to mix the contents.
4. Disinfect each bottle septum with an alcohol prep pad.
5. Place a connector onto each bottle.

F. Bottle accessioning and reading

1. Accession each bottle into the Myco system using the specimen number and the contents of the bottle, i.e., "EMB 5."
2. When the control bottle signals positive, remove bottle from the system and confirm the presence of acid-fast bacilli (AFB) by performing a Kinyoun stain.
3. Record the time, to the nearest whole day, when the control bottle becomes positive. A time to detection (TTD) of 3.4 days = 3 days; a TTD of 3.8 days = 4 days.
4. The drug-containing bottles should be left on the instrument for 3 days after the control bottle signals positive.

V. PROCEDURE (*continued*)

5. Drug-containing bottles becoming positive either before the control bottle or within 3 days of the control bottle must be removed from the system and smeared, Gram and carbol fuchsin stained, and subcultured onto a blood agar and 7H11 agar plate. The blood agar plate must be incubated at 35°C and 5% CO₂ as per standard protocol.

VI. RESULTS AND INTERPRETATION

- A. Susceptible: any drug-containing bottle which fails to signal within 3 days of the control indicates that the test organism is susceptible to that drug at that concentration.
- B. Resistant: any drug-containing bottle with a TTD within 3 days of the control and confirmed to have AFB and no bacterial contamination indicates that the test organism is resistant to that drug at the concentration.
- C. Recommendation: any organism showing resistance to one or more drugs must have that resistance confirmed by the performance of another test method and must be tested against the second-line antituberculosis agents (New York state health code requirement).

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

Test results are reported as either susceptible (S) or resistant (R) according to the TTD of a drug-containing bottle as indicated above. Report results for each drug concentration tested.

VIII. LIMITATIONS

- A. Seed bottles or primary bottles or any liquid medium used as the inoculum source must always be checked for purity.
- B. The presence of contaminants or mixed mycobacterial species may lead to a false-resistant result.

7.8.8

VersaTREK (Formerly ESP Culture System II)—Indirect Susceptibility Tests with Pyrazinamide for *Mycobacterium tuberculosis*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Pyrazinamide (PZA) is now routinely used in first-line therapy for the treatment of infections with strains of *Mycobacterium tuberculosis*. Therefore, susceptibility testing of clinical isolates of *M. tuberculosis* is required. PZA-resistant strains have been observed in patients with multidrug-resistant strains but only rarely in patients with monoresistant strains of *M. tuberculosis*. PZA monoresistance in an *M. tuberculosis* complex isolate is often an indication that the isolate is actually *Mycobacterium bovis* (2). However, routine biochemical testing must be employed to confirm the identification.

The VersaTREK (ESP Culture System II) Myco system (Trek Diagnostic Systems, Inc., Westlake, Ohio) is currently utilized for testing of susceptibility of isolates of *M. tuberculosis* to the first-line antimycobacterial drugs (1). This system has the decided advantage of being able to use a primary culture bottle as the inoculum source for the test (3). This greatly reduces the time required to generate a final result. The same culture bottle can be used as the inoculum source in the PZA assay. PZA requires an acidic pH to retain activity so

the assay utilizes a buffer to rehydrate the PZA and is added to the control bottle to provide an acidic environment. As with the other first-line agents, the first isolate of *M. tuberculosis* is tested against PZA and retested if *M. tuberculosis* is isolated from the same patient ≥ 2 months from the date of the initial isolate. The VersaTREK system has not been cleared by the Food and Drug Administration for indirect susceptibility tests with PZA for *M. tuberculosis*.

II. SPECIMEN

The VersaTREK system has not been cleared by the FDA for use with pulmonary and extrapulmonary specimens, including bloods for indirect susceptibility testing with PZA.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Materials provided by manufacturer

1. PZA Test kit
1. PZA, 112,500 μg
2. PZA rehydration buffer
3. Myco bottles
4. Growth supplement
5. Connectors

B. Materials required but not provided

1. 1-ml syringes with fixed needles
2. Glass slides

3. Kinyoun stain

4. Middlebrook 7H11 agar plate
5. Sheep blood agar plate
6. 1.5-ml cryotubes
7. Tubes with 9 ml of sterile isotonic saline
8. Tubes with 2 ml of sterile isotonic saline with sterile glass beads

ANALYTICAL CONSIDERATIONS**IV. QUALITY CONTROL**

M. tuberculosis H37Rv is run each day of the test as a PZA-susceptible control. It is recommended that an isolate of *M. bovis* ATCC 19210 be included each time a new batch of PZA is prepared and monthly after that.

V. PROCEDURE**A. Preparation of the drug**

1. Add 25 ml of rehydration buffer to the vial of PZA. Swirl until completely dissolved and dispense 1.1-ml aliquots into the cryotubes. Freeze at -70°C .
2. For each isolate to be tested remove one cryotube from the freezer and allow to thaw completely. Mix gently before use.

B. Preparation of the Myco bottles

Use a 1-ml syringe with a fixed needle to add the following to each Myco bottle.

1. Add 1.0 ml of growth supplement to each of two Myco bottles.
2. Add 1.0 ml of rehydrated drug to the test bottle.
3. Add 1.0 ml of rehydration buffer to the control bottle.

C. Preparation of the inoculum

1. From a primary bottle
 - a. A positive Myco bottle containing an isolate confirmed as belonging to the *M. tuberculosis* complex may be used as the inoculum source.
 - b. This bottle must be used within 72 h of the positive signal.
 - c. Vortex the Myco bottle for 2 to 3 min.
 - d. Remove a 1-ml aliquot from the Myco bottle and add to 9.0 ml of sterile isotonic saline. Mix completely.
 - e. Add 0.5 ml of the diluted suspension into both the control and test ESP Myco bottles.
2. From a seed bottle

If a primary Myco culture bottle is beyond the 72-h threshold, a seed bottle must be prepared from the primary bottle.

 - a. Vortex the ESP Myco bottle for 2 to 3 min.
 - b. Remove a 0.5-ml aliquot from the primary bottle and add to a Myco bottle that has been supplemented with 1.0 ml of growth supplement,
 - c. Place the seed bottle into the VersaTREK instrument and incubate until a positive signal is obtained. Proceed as described above.
3. From growth on solid media
 - a. Transfer growth from the solid medium into a tube containing sterile isotonic saline with glass beads. Vortex for 3 min. Allow to stand for 30 min for the larger particles to settle out.
 - b. Remove the supernatant and adjust to match that of a 1.0 McFarland standard with sterile isotonic saline.
 - c. Using this suspension dilute 1:10 with sterile isotonic saline. Use this as the inoculum source. Proceed as described above.

D. Purity check

An aliquot of the inoculum suspension regardless of the source must be inoculated onto a Middlebrook 7H11 plate and onto a blood agar plate to check for isolate purity.

E. Bottle placement

1. Wipe the septum of each bottle with 70% isopropyl alcohol. Place a connector onto each bottle.
2. Accession into the VersaTREK (ESP) computer system. Indicate the patient name and chart number and delineate the control from the test bottle.
3. Place into the indicated location in the VersaTREK (ESP) instrument.

It is imperative that these cultures be handled in a biosafety hood.

VI. RESULTS AND INTERPRETATION

- A. All positive bottles must be smeared and stained by the Kinyoun method to confirm the presence of mycobacteria and rule out contamination. In addition, check the blood agar purity plate for signs of contamination prior to interpreting the test results.
- B. The drug-free control bottle should signal positive within 3 to 7 days of being placed into the instrument. If the bottle signals positive prior to 2.5 days, the inoculum was too heavy, or the bottle is contaminated and the test must be repeated. Any control bottle requiring more than 10 days to give a positive signal would also invalidate the test.
- C. An isolate is considered resistant to PZA if the drug-containing bottle gives a positive signal within 3 days of the control bottle signaling positive.
- D. An isolate is considered susceptible to PZA if the drug-containing bottle fails to give a positive signal within the 3-day period.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

The results are reported as either susceptible (S) or resistant (R) to PZA.

VIII. LIMITATIONS

- A. This procedure has been validated with isolates of *M. tuberculosis* complex only.
- B. When performing the test from a primary bottle or a seed bottle prepared from a primary bottle care must be taken when reporting a resistant result. Mixed mycobacterial infections can lead to false resistance. In cases of resistant results the result must be kept preliminary until the growth from the purity plate can be observed.
- C. Any PZA-monoresistant strain of *M. tuberculosis* must be confirmed. The nitrate reduction and niacin accumulation tests must be performed to rule out *M. bovis*. If the strain is confirmed as *M. tuberculosis*, the PZA susceptibility test must be repeated.

8.1

Introduction and General Considerations

Fungi are significant, sometimes overlooked, human pathogens. Infections range in severity from merely cosmetic to life threatening. Over the last decade, in particular, the spectrum of agents responsible for infection has altered in response to changes in the susceptible population, notably, increases in immunocompromised subjects and greater use of antifungal agents. Fortunately, awareness of the role of opportunistic fungi in disease is growing, but with that awareness the clinical laboratory must be prepared to identify a range of fungal species. In addition, new antifungal agents less toxic than amphotericin B and variously administered have increased the requirement to identify po-

tential pathogens to the species level. (It is no longer acceptable in most situations to report a yeast that does not produce germ tubes as “yeast, not *Candida albicans*.”) While amphotericin B is effective against many invasive fungal pathogens, newer drugs with a narrower spectrum of efficacy are available. Resistance to these drugs is sometimes a species characteristic and may also be isolate dependent for other species. This section brings together the contributions of well-respected mycologists, whose expertise should help laboratories become more adept at identifying fungi, recognizing the significance of an isolated organism, and performing susceptibility testing.

Discussion of results between the clinical mycologist and the anatomic pathologist, cytopathologist, or neuropathologist often facilitates interpretation of culture significance. In some fungal diseases (e.g., histoplasmosis and coccidioidomycoses), the histopathology services may provide the first diagnostic evidence of the disease while the clinical laboratory provides confirmation of the etiologic entity. The appearance of the fungal organism in the tissue material, along with patient history and symptomatology, provides the best guidance to the likely etiology, but this should be confirmed whenever possible by mycological analysis.

I. CLASSIFICATION

Fungal taxonomy is an evolving process. Nomenclatural changes also continue to have significant implications for understanding fungi in the biological community, fungal disease, and the treatment of disease. We have endeavored to mention developments in molecular taxonomy, but as these methods are not commercialized and are still primarily research investigation based, we have limited our presentation to more of an overview of the methods available.

II. SAFETY

It is imperative that these cultures be handled in a biosafety hood.

Safety measures, as described elsewhere in this handbook, should always be followed in a clinical mycology laboratory. Every mould should be considered a potential pathogen and should be manipulated only in a biological safety cabinet. If a mould is seen on a bacteriology plate, the plate should be taped closed or sealed with parafilm around the edge to prevent accidental release of infectious particles. Plates may also be sealed with Shrink-Seals (Remel), but we have found these to be cumbersome. The plate must be transported to the mycology area. Manipulation of fungal organisms requires that certain unique or less routine safety measures be followed.

III. LEARNING MORE

Medical mycology and clinical mycology continue to grow and expand. We expect that the information provided in this section will not be without omissions, and laboratorians will need to find other sources of information. A number of useful reference texts and papers are cited in this section. A source of timely information is the Internet. Some useful websites on clinical mycology are provided below.

8.2

Specimen Selection, Collection, and Transport

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Suitable specimen selection, proper specimen collection, and rapid specimen transport must be performed to ensure the successful isolation of the etiological agent of a fungal infection. To establish or confirm the diagnosis of a suspected fungal infection, it is essential for the clinician to provide the laboratory with adequate specimens for evaluation. Also, it is essential for the laboratory to have guidelines for the clinician regarding minimum specimen volumes and appropriate specimen transport (e.g., a laboratory manual or web page). The microbiology laboratory should be notified if an unusual pathogen or an organism that can be a significant laboratory hazard is suspected, as some require special handling or special stains.

Examples of unusual fungal and bacterial pathogens, respectively, include *Malassezia* spp. (some species require the addition of olive oil to culture media) and *Nocardia* spp. (which are more easily detected on a modified acid-fast stain [see section 6 of this handbook]). Examples of potential laboratory hazards include *Coccidioides* spp. and *Histoplasma capsulatum*. Additionally, the microbiology laboratory should be contacted prior to certain procedures, as some specimens for fungal culture may require bedside inoculation onto appropriate culture media (e.g., corneal scrapings).

Communication between the laboratory and the physician about a patient's

travel history may be helpful in the determination of what specimen to collect or what test to order. The patient's travel history may suggest a likely etiological agent, such as *Coccidioides* spp., which is endemic in the southwestern United States; *H. capsulatum*, which is endemic in North America (tending to be associated with the major river valleys [Ohio, Mississippi, and Missouri]; and *Penicillium marneffei*, which is endemic in Southeast Asia and southern China. If there is any question about how to select, collect, or transport a specimen, the clinician should contact the microbiology laboratory for assistance.

II. TRANSPORT OF SPECIMENS FOR FUNGAL CULTURE

Observe standard precautions.

■ **NOTE:** In general, transport media are not recommended unless the specimen can be completely retrieved from the medium. For site-specific collection guidelines, refer to Table 8.2–1.

A. General considerations

1. Collect specimens aseptically and place in sterile, leakproof containers.
2. Deliver the specimen to the laboratory within 2 h.
3. Rapid transport is critical to ensure the survival and isolation of fastidious organisms and to prevent overgrowth by more hardy bacteria.
4. Process the specimen within 2 h of receipt or store appropriately.
5. If processing is going to be delayed, incubate normally sterile specimens (e.g., blood, bone marrow, CSF, or deep lesion material) at 37°C (or 35°C if a 37°C incubator is not available). Refrigerate at 4°C specimens that are potentially contaminated with bacterial microbiota (e.g., dermatological specimens, transtracheal aspirates, ear [internal] aspirates, and conjunctiva cultures).

■ **NOTE:** *H. capsulatum* does not survive for long periods under refrigeration or on dry ice (3). Limited studies have shown significantly decreased

Table 8.2–1 Site-specific selection and collection guidelines

Specimen source	Fungal agent ^a	Acceptable collection and transport procedures ^b	Comments
Abscess/drainage/ wound	Yeasts Filamentous fungi Aerobic actinomycetes	Aspirate sample and transport in a syringe without needle. Submit in a sterile screw-cap container. Collect sample with aerobic swab transport system. Non-cotton-tip swabs are recommended.	Sample advancing margin of lesion. If specimen is collected at surgery, also submit a portion of the abscess wall. Several swabs, if possible, should be sent to the laboratory to allow for a Gram stain and a KOH or calcofluor white stain (<i>see</i> procedure 8.3).
Blood	<i>H. capsulatum</i> <i>C. neoformans</i> <i>Candida</i> spp. <i>Malassezia</i> spp.	Lysis-centrifugation device (Isolator [Wampole]) (1, 4) Automated blood culture systems (BACTEC [Becton-Dickinson]; BacT/Alert [Organon Teknika]) 8 ml of blood in tube containing SPS (e.g., yellow Vacutainer tube no. 4960 contains 1.7 ml of 0.35% SPS; final concentration with blood, 0.05%) Biphasic vented BHI medium	Most <i>Candida</i> spp. can be recovered in bacterial blood culture systems. If using an automated blood culture system, review manufacturer's guidelines to determine which fungi are detected. Samples for cryptococcal antigen, histoplasma antigen, or galactomannan antigen testing may be useful.
Bone marrow	<i>H. capsulatum</i> <i>C. neoformans</i>	Lysis-centrifugation device (Isolator) 5 ml in a green-top (heparin) tube 5 ml of bone marrow in tube containing SPS (e.g., yellow Vacutainer tube no. 4960; contains 1.7 ml of 0.35% SPS) Bedside inoculation onto appropriate fungal medium Automated blood culture systems (BACTEC; BacT/Alert)	If using an automated blood culture system, review manufacturer's guidelines to determine which fungi are detected.
Catheter (7)	<i>Malassezia</i> spp. <i>Candida</i> spp.	Place 5 cm of the distal end into sterile screw-cap container.	A standardized method for identifying catheter-related fungal infection has not been developed.
Catheter exit site		Using aerobic swab transport system, collect sample from infected skin site surrounding the intravenous line.	Fungal blood cultures should also be submitted.
Eye (9) Corneal scrapings	<i>Candida albicans</i> <i>C. neoformans</i> Numerous filamentous fungi have been isolated in fungal keratitis. These include <i>Fusarium</i> , <i>Aspergillus</i> , <i>Acremonium</i> , <i>Paecilomyces</i> , <i>Penicillium</i> , <i>Pseudallescheria</i> , <i>Curvularia</i> , <i>Alternaria</i> , <i>Phialophora</i> , and <i>Bipolaris</i> spp.	Use direct inoculation onto appropriate fungal medium. The physician should contact the laboratory to obtain medium prior to corneal scraping procedure.	Agar plates are inoculated by lightly touching both sides of the spatula in a row of separate C streak marks.
Conjunctiva		Use bedside inoculation onto appropriate fungal medium or aerobic swab transport system.	Sample both eyes (even if one is uninfected) prior to applying anesthetic. The uninfected eye can act as a control to compare agents isolated from the infected eye.
Intraocular fluid		Collect in a sterile screw-cap container.	If intraocular washings, fluid should be concentrated prior to plating.

Table 8.2–1 (continued)

Specimen source	Fungal agent ^a	Acceptable collection and transport procedures ^b	Comments
Hair/nails	<i>Trichophyton</i> spp. <i>Epidermophyton</i> spp. <i>Microsporium</i> spp. <i>Candida</i> spp. <i>Trichosporon</i> spp.	After selecting infected area, remove at least 10 hairs and scrape scalp scales if present, scrape infected nail area, or clip infected nail. Use bedside inoculation onto appropriate fungal medium or transport in a clean envelope or between two clean glass slides taped together (transport slides in slide carrier).	Humidity in a closed system may cause the sample to be overgrown by bacteria.
Respiratory sites	Yeast and filamentous fungi Aerobic actinomycetes	Collect three early-morning sputa resulting from a deep cough. Collect bronchoalveolar lavage, transtracheal aspirate, bronchial brushings. Induced sputum. Transport specimens in a sterile screw-cap container.	24-h sputum collections are not acceptable for fungal culture.
Skin/intertriginous areas	<i>Trichophyton</i> spp. <i>Epidermophyton</i> spp. <i>Microsporium</i> spp. <i>Candida</i> spp. <i>Malassezia</i> spp. <i>Sporothrix schenckii</i>	To reduce the likelihood of bacterial contamination, the skin surface should be disinfected with 70% alcohol. The specimen should be collected from the edge of the lesion and inoculated directly onto fungal medium or placed in a clean envelope or between two clean glass slides taped together (transport slides in a slide carrier).	Humidity in the closed system may cause the sample to be overgrown by bacteria.
Sterile fluids (CSF, pleural, pericardial, joint, peritoneal)	<i>H. capsulatum</i> <i>C. neoformans</i>	Collect a minimum of 2 ml in a sterile container. In general, the more fluid obtained for culture, the better the chance of isolation of any fungal pathogen.	If CSF, samples for cryptococcal antigen testing may be useful.
Tissues/biopsy specimens	Yeast and filamentous fungi Aerobic actinomycetes	Collect tissue and transport in sterile screw-cap container with a small amount of nonbacteriostatic saline to prevent drying. <i>Never transport in formalin.</i>	
Urine	Yeast <i>C. immitis</i> <i>H. capsulatum</i> <i>B. dermatitidis</i>	First morning clean-catch urine in sterile screw-cap cup Catheterized specimen in sterile screw-cap cup Urine collected in a sterile screw-cap cup following prostatic massage <i>Note:</i> Patients with blastomycosis or cryptococcosis may have prostatic infection.	Most <i>Candida</i> spp. will grow on bacterial culture media. 24-h urine collections and Foley catheter urine specimens are not acceptable. Samples for histoplasma antigen testing may be useful.

^a The anatomic site of the fungal infection can be an indicator of what mycotic agent to suspect, but in an immunocompromised patient population, virtually any fungus can be an opportunistic pathogen.

^b Veterinary specimens should be collected and transported in the same manner as human specimens. SPS, sodium polyacrylate sulfonate.

II. TRANSPORT OF SPECIMENS FOR FUNGAL CULTURE (continued)

viability for *H. capsulatum*, *C. immitis*, *Blastomyces dermatitidis*, and *Aspergillus fumigatus* stored at room temperature or on dry ice. *Rhizopus arrhizus* is also known to be difficult to recover from delayed specimens (6). Therefore, specimens suspected of containing one of these agents should be processed immediately. While it is not documented whether freezing by methods other than dry ice would reduce viability, it is likely that freeze-thaw damage associated with any method of freezing would be sufficient to cause a problem.

6. The laboratory should establish minimum volume requirement guidelines. For some fungal infections, the fungal load may be low. Inadequate amounts of specimen may yield false-negative results. In order to maximize the chance of recovering organisms in sterile fluids, it is recommended that as much specimen as possible be sent for culture. If the volume received is not adequate for the tests requested, the physician should be contacted to prioritize test requests.
 7. Laboratorians should develop criteria for fungal culture frequency in collaboration with their infectious-disease consultants. Multiple specimens from the same site may not always be processed. In general, with the exception of biopsy specimens, one fungal culture per site per day, not to exceed three per week, should be adequate for the recovery of fungi. Exceptions to these guidelines should be made only after the physician of record consults the laboratory director. All biopsy specimens should be processed.
 8. In general, swabs for the collection of material from open wounds or draining lesions are not recommended because these sites are frequently contaminated with environmental microorganisms.
 9. When possible, to increase the chance of recovery of a fungal organism, the specimen should be collected before an antifungal agent is administered.
- B. Shipping guidelines** (see section 15 of this handbook for a more detailed discussion about shipping)
1. For off-site delivery specimen transport guidelines, refer to the International Air Transport Association (IATA) *Dangerous Goods Regulations*, 44th edition (2), and the U.S. Department of Transportation and the International Civil Aviation Organization (ICAO) regulations. The IATA and ICAO have established two categories of specimens, diagnostic and infectious substances. Both specimen types require specific packaging and handling procedures. The shipper must decide in which category specimens belong. In general, IATA considers specimens that are sent for initial and confirmatory testing for the presence of an infectious pathogen to be infectious substances. Specimens sent for routine presurgical and blood bank screens are considered diagnostic substances.
 2. When preparing a specimen for transport, always check the specimen transport guidelines of the receiving laboratory. Specimen transport temperatures follow the same principle as if processing is going to be delayed. Attempt to ship clinical specimens overnight for early morning delivery when possible. Clinical specimens preferably should not be shipped over weekends or holidays. Normally sterile specimens (e.g., blood, bone marrow, CSF, and deep-lesion material) are shipped at room temperature. Overnight shipping on dry ice is the only practical alternative for refrigeration. However, this level of freezing may compromise fastidious organisms (e.g., some dermatophytes, *Malassezia* spp., and *H. capsulatum*). Thus, specimens that are potentially contaminated with bacterial microbiota (e.g., dermatological specimens, transtracheal aspirates, ear [internal] aspirates, and conjunctiva cultures) should also be shipped at room temperature. All specimens should have same-day or overnight delivery.

III. SELECTION OF SPECIMENS FOR FUNGAL CULTURES

Observe standard precautions.

- A. For some organisms, ancillary antigen studies may provide information that is useful in the diagnosis and/or confirmation of systemic mycosis.
1. Cryptococcal antigen testing of CSF and serum specimens can be useful for the diagnosis of *Cryptococcus neoformans* infections. Laboratorians should substitute antigen testing for the less sensitive India ink procedure for the detection of *C. neoformans* meningitis.
 2. If *H. capsulatum* is suspected, histoplasma polysaccharide antigen (HPA) detection on serum or unpreserved urine can be a useful indicator of systemic infection. Additionally, there is evidence that following HPA levels can help to predict relapse in patients on therapy.

▣ **NOTE:** False-positive HPA assays have occurred with patients with blastomycosis, paracoccidioidomycosis, and *P. marneffeii* infections. No cross-reactivity has been found in patients with coccidioidomycosis, cryptococcosis, candidiasis, or aspergillosis (5, 8).
 3. The sensitivities and specificities of antigen detection methods for fungi other than those tests mentioned above are still being evaluated.
- B. Other guidelines for specimen selection, collection, and transport include the following.
1. The specimen must be properly labeled with the patient's name and other relevant demographic information (see section 2 of this handbook for information regarding specimen labeling).
 2. The specimen should not be contaminated on the outside with sample debris or other potentially hazardous materials.
 3. Radioactive specimens should be labeled so that proper waste disposal can be performed.
 4. Specimens in syringes should not be sent to the laboratory with needles attached but should be transferred to a sterile tube. If there is little material in the syringe, the physician should draw a small amount of sterile nonbacteriostatic 0.85% NaCl or sterile broth through the syringe and then transfer the specimen to a sterile tube. Alternatively, if transferring it from the syringe will compromise the specimen, the physician should draw a small amount of sterile nonbacteriostatic 0.85% NaCl or sterile broth through the syringe, remove the needle, and then cap the syringe with a sterile cap prior to transporting it to the laboratory.

8.3

Specimen Examination

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The microscopic examination of clinical specimens for the presence of fungi plays an important part in the laboratory diagnosis of most mycoses. Microscopic examination may provide a rapid indication of the cause of an infection, allowing the prompt initiation of appropriate antifungal therapy. It is also important to establish whether the fungus is present in the specimen prior to culture, as some organisms may also occur as laboratory contaminants. Furthermore, the results of micro-

scopic examination may influence the choice of culture media.

An initial macroscopic examination of the specimen is also important. This will enable the selection of particular parts of the sample for microscopic examination in the case of tissue or sputa, particularly those that are obviously caseous, purulent, or necrotic. Tissue from a suspected mycetoma should be teased apart in order to check for the presence of grains. Hair specimens may be examined by Woods

lamp for fluorescence, which will indicate infection caused by some species of dermatophyte.

When the specimen is too small to allow full examination, culture usually takes precedence over microscopic examination. The exceptions are nail samples, for which there is a high rate of culture failure (ca. 30%), and cases of suspected pityriasis versicolor, where microscopy of skin scrapings is adequate.

II. SPECIMEN PROCESSING FOR MICROSCOPIC EXAMINATION

Pretreatment of clinical specimens is often required in order to concentrate fungal cells or in order to see the fungal material more clearly. Details of the various methods of pretreatment used for different clinical materials are described in procedure 8.4.

III. MATERIALS

A. Stain reagents (*see* item V below and Appendixes 8.3-1 and 8.3-2)

B. Supplies

1. Glass slides, coverslips, and pipettes
2. Microscope equipped with low-power ($\times 100$) and high-power ($\times 400$) magnification

3. Microscope equipped with UV fluorescence for use with the calcofluor stain (excitation filter, $\lambda_{300-412\text{ nm}}$; emission filter, $\lambda_{500\text{ nm}}$)

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

Include QC information on reagent container and in QC records.

- A. Perform macroscopic and microscopic examination of all stains for the presence of contaminating organisms or artifacts.
- B. Ensure that all commercially prepared reagents have not passed their expiration dates.

V. PROCEDURES

Observe standard precautions.

Staining for direct microscopic examination**A. Potassium hydroxide (KOH) mount**

KOH dissolves proteinaceous tissues, including keratin, and renders them transparent. This enables fungi to be visualized more easily. A KOH wet mount is essential for skin, hair, nail, and tissue specimens and may be useful for the examination of mucous membrane swabs, urine, liquified sputa, and other respiratory specimens. Brain biopsy specimens are best evaluated with Gram stain, as KOH produces misleading artifacts. As high concentrations of KOH are caustic, hand protection is recommended.

1. This reagent is typically 10 to 30% (wt/vol) potassium hydroxide. The high KOH content facilitates rapid digestion of the keratin.
2. Place the material to be examined on a glass slide, add a drop of KOH, and place a coverslip on top. Warming the slide on a heating block or over the pilot flame of a Bunsen burner or incubating it at 30°C for 20 min can accelerate digestion of tissue by the KOH (do not boil!). Keratinous tissue specimens should be left at room temperature for 20 to 30 min to allow digestion and “clearing” of the keratin.
3. Prior to examination, squash the preparation firmly, for example, with a mounting needle or covered marker pen, and remove excess KOH with a paper tissue. This enhances viewing, particularly in the case of nail specimens; however, hair specimens should also be viewed prior to being squashed to aid differentiation of endothrix and ectothrix infections.
4. Specimens may be examined by bright-field, dark-field, or phase-contrast microscopy. Examine first at $\times 100$ magnification, focusing on possible fungal cells at $\times 400$. In the case of bright-field examination, stopping down the field diaphragm and racking down the condenser often improve the contrast of fungal cells against the background. Dermatophytes in skin or nail are seen as branching hyphae or arthrospores and often appear slightly greenish in color, with hyphae running across the colorless host cells. Most hyphae will be parallel sided and around 2 μm in width. Yeasts are present as budding cells, pseudohyphae, or yeast mycelium. In infections caused by dermatiaceous fungi, the hyphae are often brown. Artifacts, such as fibers, may be distinguished from hyphae by the lack of septa, tapering ends, and size differences.
5. KOH mounts may be stored overnight, preferably in moist chambers at 4°C, but eventually even fungal hyphae are degraded by KOH.

B. KOH-DMSO mount

Dimethyl sulfoxide (DMSO) is sometimes added to the KOH reagent in order to enhance clearing of specimens without heating or incubation. This is usually required only for keratinous or fibrous tissue.

1. Place specimen on slide, add a drop of KOH-DMSO, add coverslip, and squash preparation.
2. Examine immediately, as specimens in DMSO degrade quickly.

C. KOH-calcofluor mount

Calcofluor binds to the chitinous cell walls of fungi and fluoresces under UV light. This allows small amounts of fungus to be easily detected, aids visualization of microscopic morphology, and may also facilitate microscopic examination of specimens. It may also assist in rapid screening of specimens by inexperienced operators. Most specimens are suitable for this method.

1. Place specimen on slide, add 1 drop of calcofluor reagent and 1 drop of 10 or 20% KOH, add a coverslip, and squash preparation firmly.

V. PROCEDURES (*continued*)

2. Examine with fluorescent microscope using UV light source and appropriate filters. Using emission filters, fungi appear yellow-green; without filters, fungi will fluoresce bright white.

D. India ink method

The capsule of *Cryptococcus neoformans*, while virtually invisible by normal microscopy, will exclude ink particles, resulting in a halo-like appearance around the cells. Preparations of CSF in India ink will allow the presumptive identification of capsulated cryptococcal cells. This stain is suitable to use on specimens of body fluids, CSF, and urine. If the stain is prepared using formalin, hand protection and adequate ventilation are recommended. Physicians should be informed that the India ink method is less sensitive than antigen testing for the diagnosis of cryptococcal meningitis.

1. Addition of a drop of detergent may aid maintenance of dispersed ink particles in this reagent. The India ink should be replaced regularly, because moulds can grow in the solution. Alternatively, 10% (wt/vol) nigrosine in 10% formalin, heated to dissolve the nigrosine and filtered, can be used.
2. After centrifugation, place a drop of sediment (CSF, urine, or body fluid) onto a slide, add a small drop of ink, and mix with the sediment, using the coverslip. Place a coverslip on top.
3. Examine by light microscopy. If the preparation is too dark, add a drop of water on one side of the coverslip and draw across by applying blotting paper to the other side of the coverslip, forming an ink gradient.
 - ☑ Cryptococcal cells can be differentiated from white blood cells present in CSF by the presence of a halo and by budding in some of the yeast cells. Care must be exercised, as some strains of cryptococci can be nonencapsulated; therefore, it is important to ensure that the yeast cell is in focus when interpreting the presence or absence of a capsule.

E. Giemsa stain for *Histoplasma capsulatum*

The small yeast cells of *H. capsulatum* can be highlighted by Giemsa staining of peripheral blood or bone marrow smears.

1. Giemsa stain solution (commercial preparation) should be diluted as directed by the manufacturer prior to use, typically 1:10 or 1:20 in 65 mM potassium phosphate buffer or distilled water.
2. Fix smear in 100% methanol for 1 min, drain alcohol, and dry.
3. Flood slide with diluted Giemsa stain and stain for 5 min; wash slide with copious water and air dry (do not blot).
4. Examine slide by light microscopy. Phagocytosed yeast cells stain light to dark blue and will be surrounded by a clear halo.

F. Microscopic morphologies seen in specimens

Figure 8.3–1 lists the different clinical specimens, the fungal morphologies that may be present in these materials, and the possible etiologic agents.

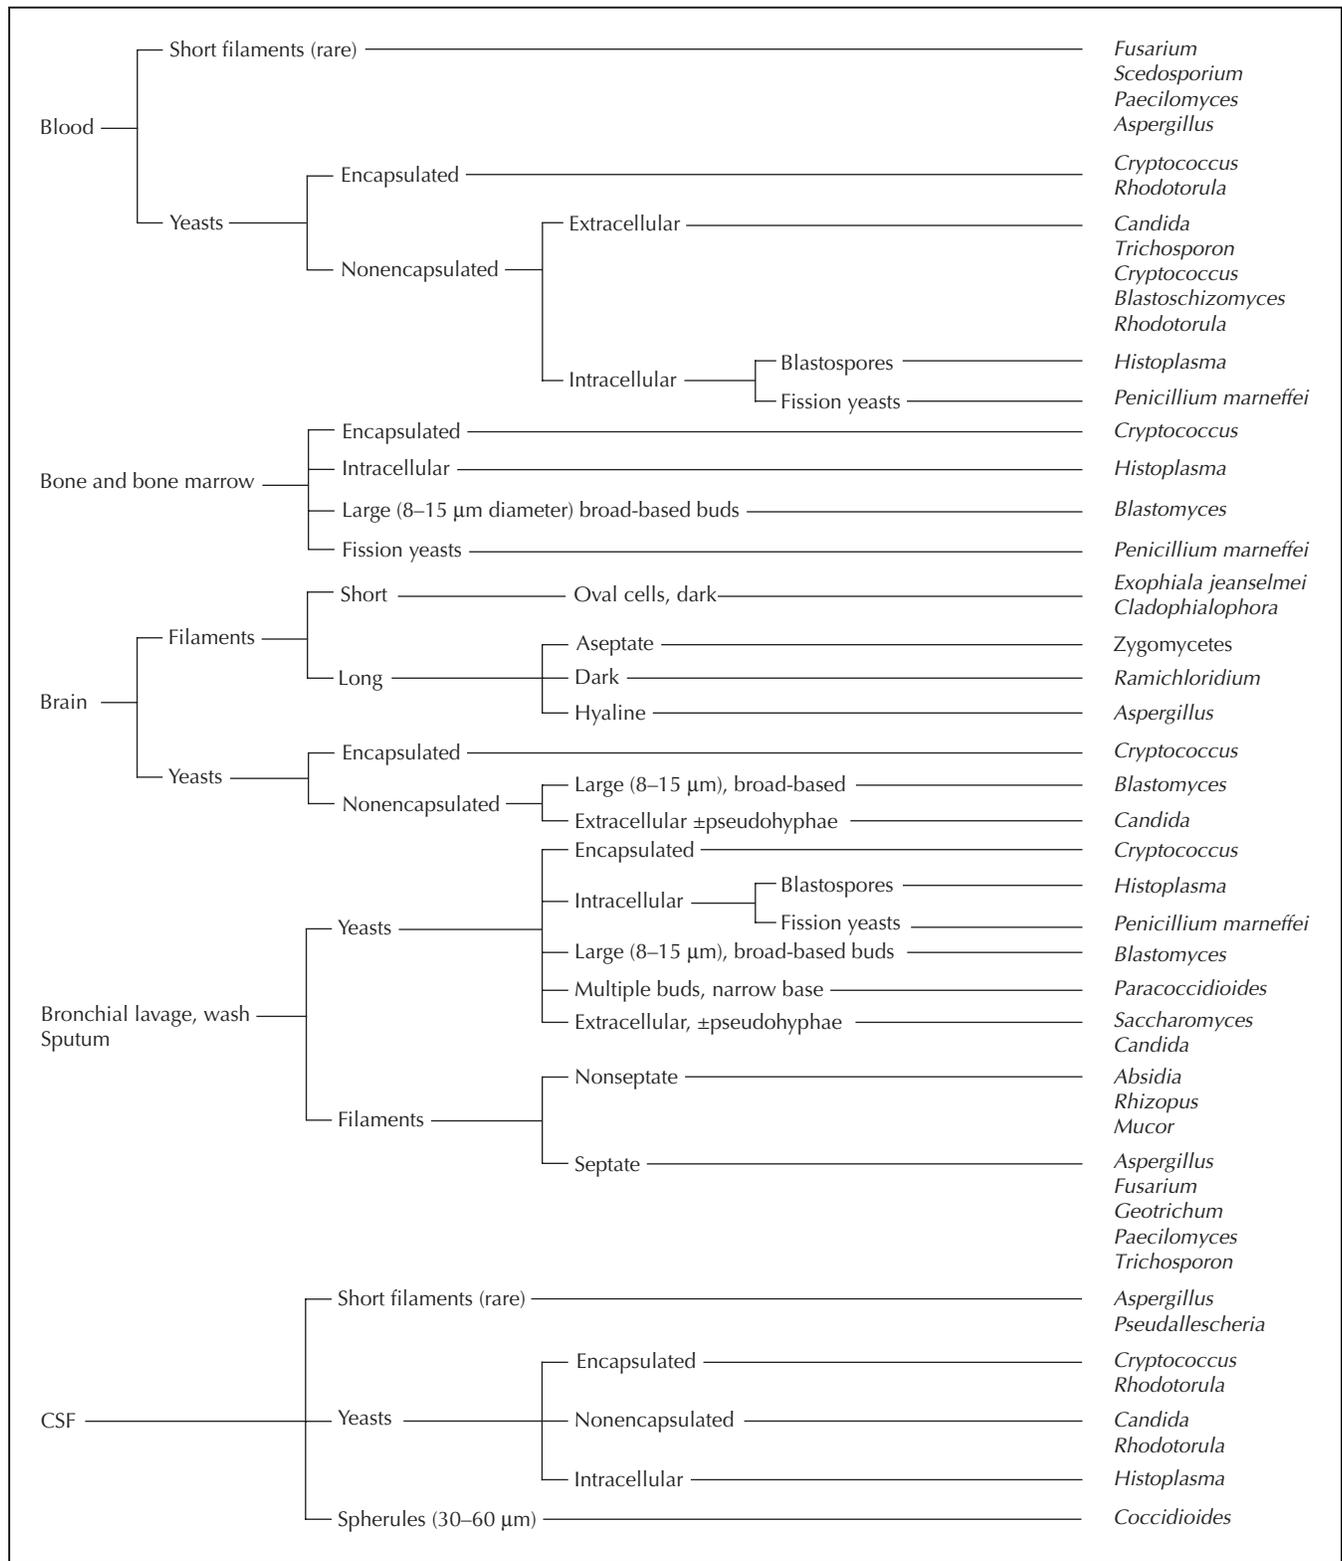

Figure 8.3–1 Most common possible fungal etiologies and morphologies seen in specimens (assuming appropriate stain was used to visualize organism [e.g., calcofluor white] or unstained to see pigment) (continued).

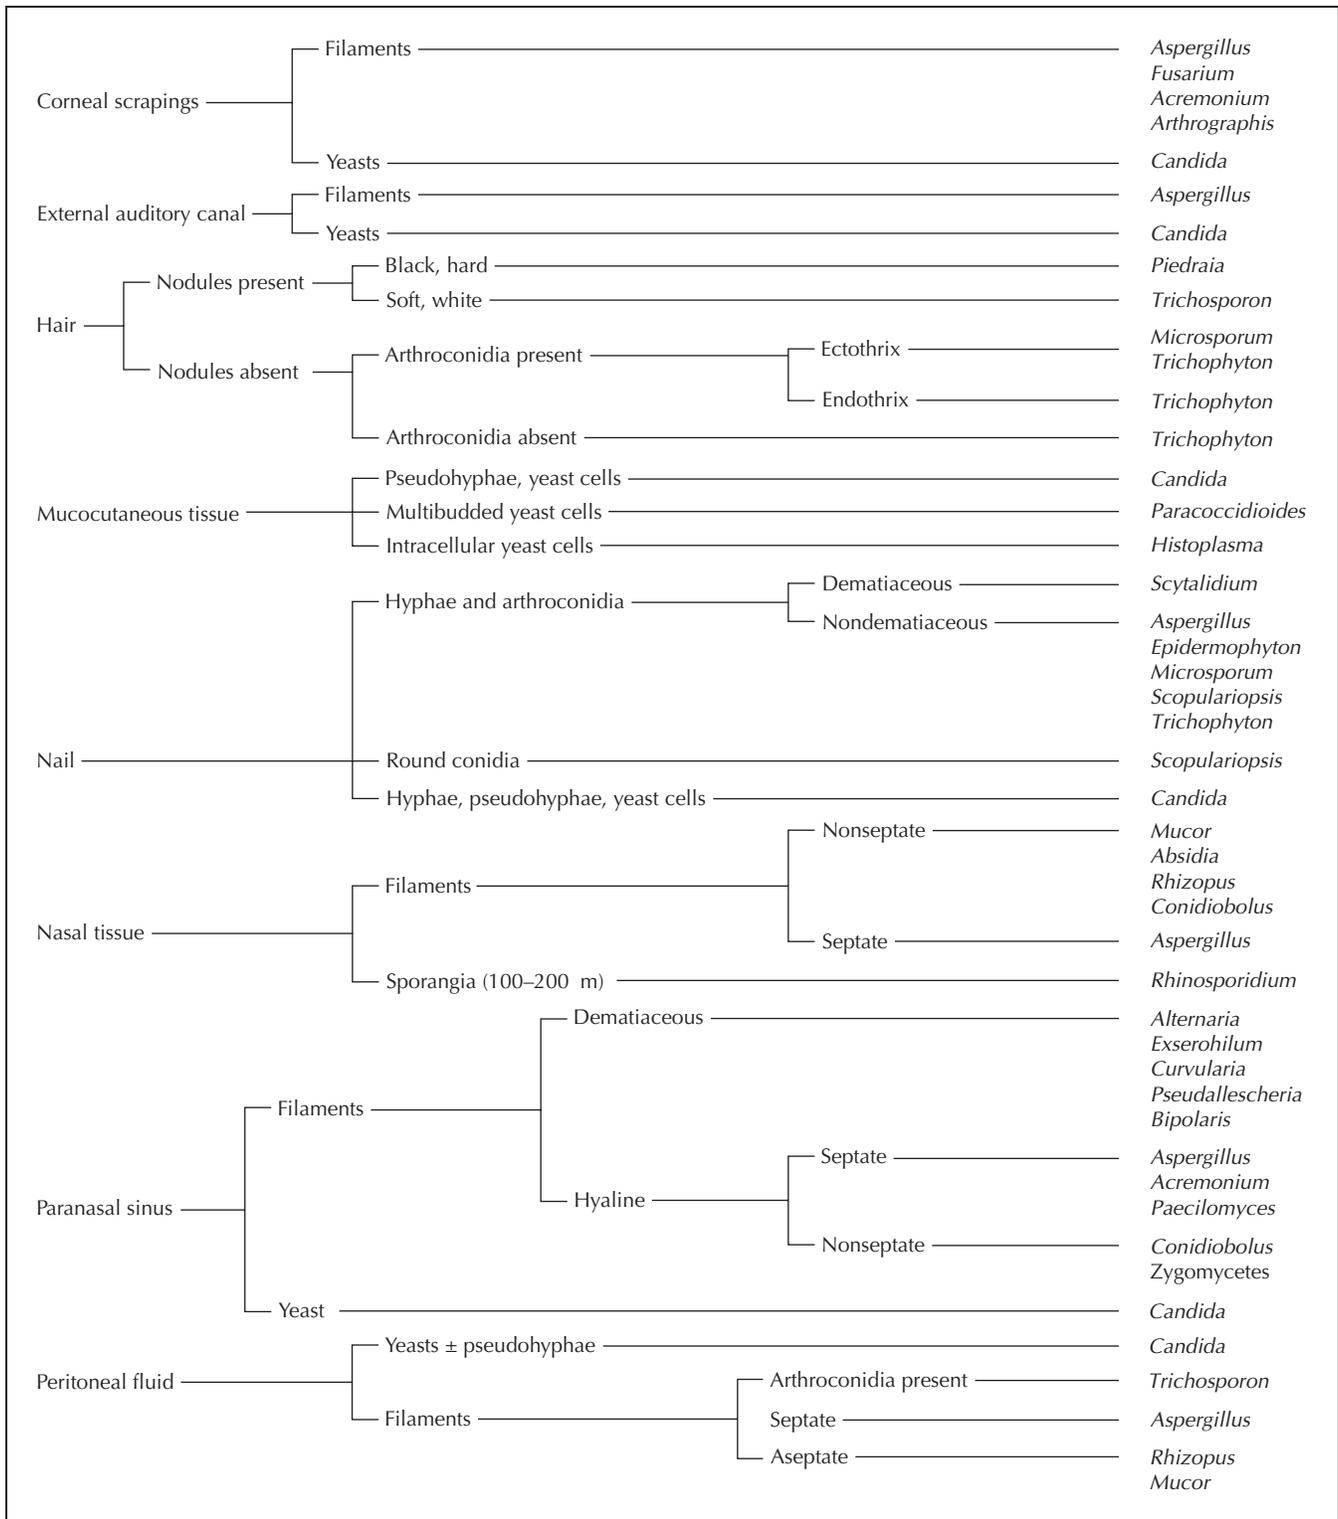

Figure 8.3–1 (continued)

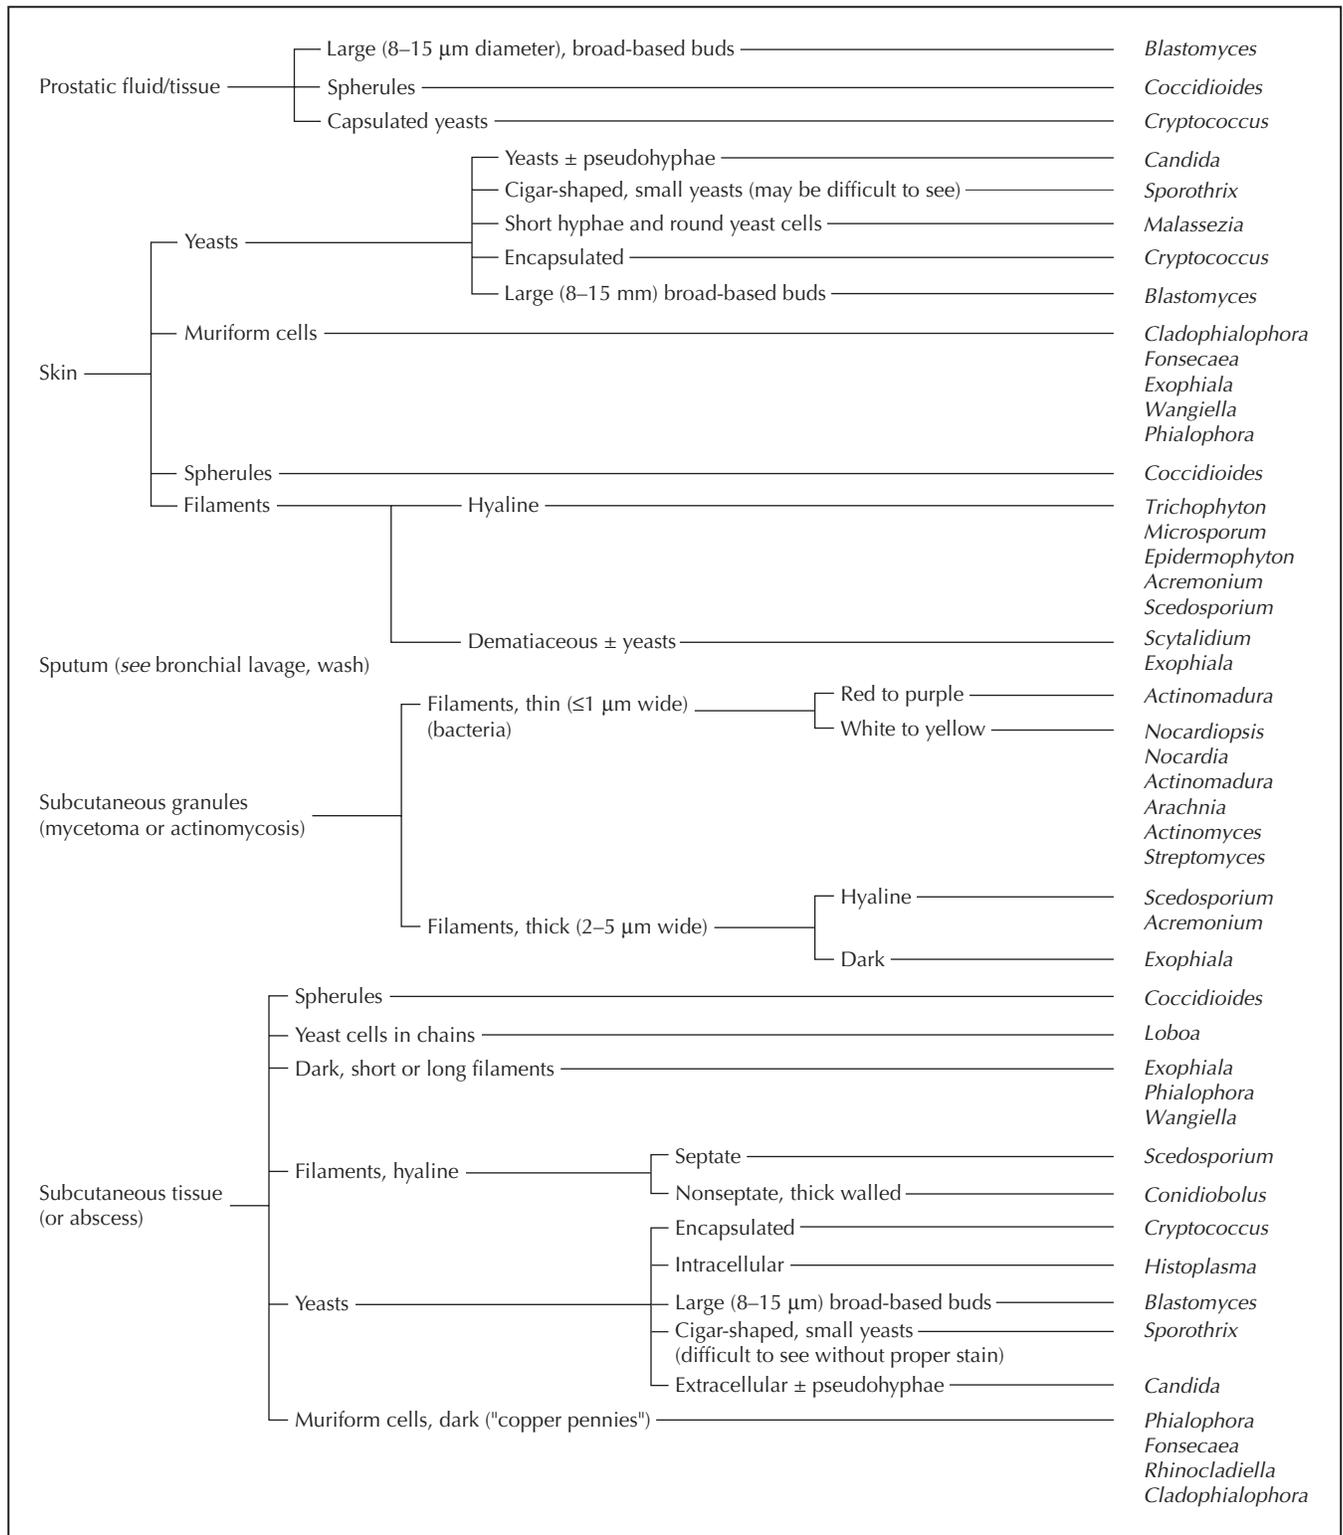

Figure 8.3–1 (continued)

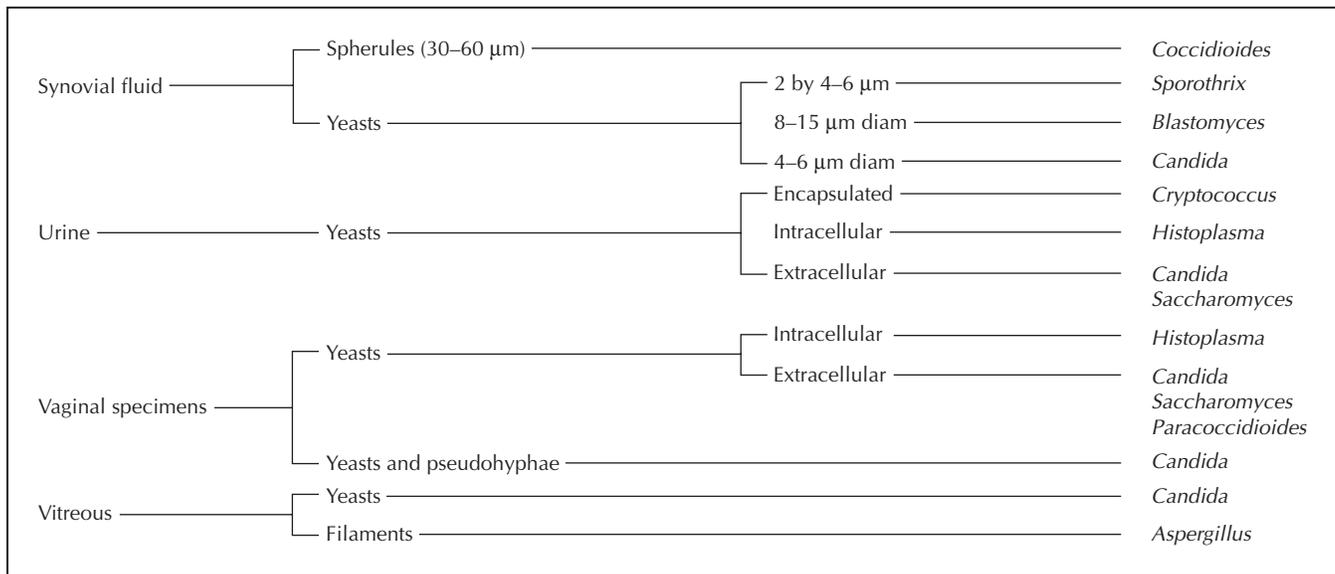

Figure 8.3–1 (continued)

POSTANALYTICAL CONSIDERATIONS

VI. REPORTING RESULTS

A. General considerations

Prompt reporting of the results of microscopic examination for fungi is often important for the speedy diagnosis of infections. Results from cultures may not be known for several days, and visualization of tissue invasion by fungal structures may provide a more reliable result than culture in some cases. Experienced laboratory personnel will have confidence in the differentiation of true fungal cells from artifacts and, in some cases, may be able to determine the type of fungus.

B. Slide preparations

The following are suggested reports based on smear evaluation. Laboratories may wish to add more definitive reports or comments if personnel have sufficient expertise.

1. No fungus seen
2. Budding yeast cells seen
3. Encapsulated yeast cells seen
4. Yeasts with pseudomycelium seen
5. Mycelium seen

C. Dermatological specimens

Due to the slow growth of dermatophyte fungi and the sensitivity and specificity of microscopy, treatment for dermatophyte infections is frequently initiated on the preliminary report of the microscopic examination. Reporting the quantity of fungal material seen is unnecessary, and the presence or absence of fungal mycelium or arthroconidia is usually all that is required. The reporting of scalp infections as endothrix or ectothrix hair lesions is often useful, since it may be predictive of the causative species and can help in management of the infection.

The presence of yeast cells, pseudohyphae, or yeast mycelium in skin and nail specimens should be reported, though the assessment of their clinical significance is less straightforward. Diagnosis of pityriasis versicolor can be reli-

VI. REPORTING RESULTS

(continued)

ably made on the basis of the characteristic combination of round yeasts and short hyphae of *Malassezia* spp., the so-called “spaghetti-and-meatballs” appearance.

D. Respiratory and sterile body specimens

The examination of sputa and bronchial and alveolar washings may reveal fungal mycelium, yeast cells, or pseudohyphae. The presence of fungal mycelium is important in the diagnosis of aspergillosis and other pulmonary infections caused by moulds and must be reported urgently in immunocompromised patients. The presence of yeasts, pseudohyphae, or yeast mycelium is usually a reflection of oropharyngeal candidosis, since pulmonary candidosis is rare.

The presence of any fungal cells in sterile fluids, such as blood, CSF, peritoneal dialysate, or vitreous humor, and in biopsy specimens from deep tissues should be reported rapidly to clinicians as clear evidence of a fungal infection.

Reagent Preparation

I. KOH

KOH is prepared as 10 to 30% (wt/vol) potassium hydroxide in water or in 20% (vol/vol) glycerol, which helps prevent the KOH mount from drying out. This reagent is sometimes mixed 4:1 or 1:1 with Parker Super Quink permanent black ink, which is helpful in staining some pathogens, such as *Malassezia* and *Scopulariopsis*.

II. KOH-DMSO

KOH-DMSO is prepared as 20% (wt/vol) KOH in 40% (vol/vol) DMSO in distilled water.

III. CALCOFLUOR WHITE

Calcofluor white consists of 0.1% (wt/vol) calcofluor white, either M2R (Polysciences Inc.; also sold as Blankophor BA [Bayer]) or Fluorescent Brightener 28 (Sigma), in distilled water or with 0.05% Evans Blue as a counterstain. Commercial ready-to-use preparations are also available. Store in the dark at 25°C. Use along with 10 to 20% KOH.

8.4

Processing Specimens for Fungal Culture

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

When a specimen is suspected to contain a fungal etiologic agent, it should be processed for fungal culture, regardless of direct microscopic findings. Recovery of fungal pathogens in culture provides definitive diagnosis of mycotic disease, identifies the etiologic agent of infection, and allows evaluation of in vitro susceptibility to antifungal agents. In the event that there is insufficient material for both micros-

copy and culture, all of the specimen should be used for culture, since this is the more sensitive procedure for detection of fungi. Methods of specimen processing and culture are designed to retain the viability of the fungus and to obtain the maximum yield of organisms from clinical specimens. The choice of media for the isolation of fungi from clinical material is

based primarily on the most likely species to be found in a particular site or under a recognized clinical condition. Selective media are included when other microorganisms, particularly bacteria, might also be present in the specimen. Specimens should be processed as soon as possible after receipt. Some specimens may require pretreatment prior to culture.

II. SPECIMENS

- A. Specimens should be submitted in closed containers without preservatives.
- B. All specimens submitted to the laboratory are initially examined macroscopically, and representative parts are selected for further investigation. Specimens such as sputum and tissue are examined for any obvious signs of purulence, caseation, blood, or necrosis, and these areas are selected for microscopy and culture.
- C. When specimens are submitted to the laboratory, the following information should be obtained in addition to pertinent demographic information.
 1. Source and/or anatomical site
 2. How and when it was collected
 3. Formulation of transport medium (if any)
 4. How it was transported
 5. How long it was in transit
- D. Communication with the clinician about details of the patient's area of residence, travel history, contact with animals, and previous therapy with antibacterial, antifungal, or immunosuppressive cytotoxic agents may also help guide the laboratory toward processing the specimen for a particular fungal pathogen. Such information is often not easily obtained from the submitting physician. It is best if a request for this information is made at the time the specimen is submitted, perhaps on the (paper or electronic) request form.

II. SPECIMENS (*continued*)

- E.** Specimens may be obtained from both sterile and nonsterile body sites or sources.
1. Examples of specimens collected from sources usually considered sterile include the following.
 - a. CSF
 - b. Blood
 - c. Bone marrow
 - d. Surgical tissue
 - e. Body fluids
 - f. Catheterized urine
 2. Examples of specimens obtained from sources considered nonsterile include the following.
 - a. Sputum
 - b. Tracheal aspirate
 - c. Bronchial wash and brush
 - d. Midstream urine
 - e. Gastric lavage fluid
 - f. Hair, skin, and nail samples
 - g. Superficial wound swabs
 - h. Throat, mouth, or nasopharynx mucocutaneous materials
 - i. Ear material
 - j. Vaginal or cervical material
 - k. Feces
- F.** Specimens received on swabs are inferior to samples of tissue or fluid, but they should not be rejected for culture unless the swab is dry. Rejection criteria for other specimens are described in sections 2 and 3 of this handbook. Other unsuitable specimens include material received in fixative, 24-h urine, specimens received in leaking containers, and specimens comprised of insufficient material. In these circumstances, the laboratory should communicate with the physician and ask that a specimen be recollected if possible.

III. MATERIALS**A. General supplies and equipment**

1. Sterile plastic pipettes
2. Sterile cotton swabs
3. Sterile scalpel blades and forceps
4. Microscope slides and coverslips
 - a. With etched center well
 - b. With frosted ends
5. Class II biosafety cabinet
6. Bacteriometer
7. Inoculating loops
8. Latex gloves and mask
9. Puncture-resistant biohazard discard container
10. Potassium hydroxide
11. India ink

B. Media for fungal culture

1. The selection of suitable media for the recovery of fungi is primarily a function of the specimen type and suspected fungal pathogen(s). See Fig 8.3–1 above for specimen type and microscopic indications of potential etiologic agents. A combination of several different media is used for culturing most specimens.

Media are dispensed in either screw-cap tubes (25 by 150 mm) or 100-mm-diameter petri dishes. Plated media are useful because of the large surface area available. However, because plated media are vented to the atmosphere, the layer of poured medium must be thick to resist dehydration during prolonged incubation. Lids should be secured with gas-permeable tape or Shrink-Seals (Remel) to prevent exogenous contamination and to protect personnel from pathogenic moulds. Tubed media have a reduced surface area for fungal isolation but provide maximum safety and resistance to dehydration and contamination.

2. In general, there are two categories of media employed for the recovery of fungi from clinical specimens. General-purpose media, such as Sabouraud dextrose (glucose) agar (SDA) and BHI agar, support the

III. MATERIALS (continued)

growth of most fungi found in clinical material and are used as primary isolation media. Selective agents, such as chloramphenicol, gentamicin, and cycloheximide, may be incorporated into these media to inhibit the growth of bacteria or saprobic fungi that may be found in nonsterile specimens. The second

category of media is used for subculture and identification of fungi. On these media, particular growth characteristics or sporulation patterns are encouraged. Examples include corn meal agar and potato flake agar. Some features of commonly used fungal media are listed in Table 8.4–1.

Table 8.4–1 Media for the isolation and identification of fungi^a

Medium	Intended use	Remarks
SDA	Originally formulated for dermatophyte growth and pigment production. General-purpose medium used for primary isolation.	Emmons modification contains 2% glucose and is slightly acidic (pH 6.9). Overlay with olive oil for growth of <i>Malassezia furfur</i> .
BHI	Enriched medium for recovery of yeast, especially <i>Cryptococcus neoformans</i> . Can be used for mould-yeast conversion in some dimorphic fungi	Addition of sheep erythrocytes and/or antibiotics optional
Sabhi agar	Enriched medium for recovery of yeast	Addition of sheep erythrocytes and/or antibiotics optional
Mycosel or mycobiotic agar (Becton Dickinson)	Commercial selective medium for primary isolation of fungi. Inhibits bacteria and saprobic fungi.	SDA with chloramphenicol and cycloheximide. Will inhibit some pathogenic fungi. Note that chloramphenicol-resistant bacteria will grow on this medium.
IMA	Enriched selective medium	Contains chloramphenicol and gentamicin
Potato dextrose agar and potato flake agar	Promotes sporulation of moulds	Ideal medium for slide culture preparation
Malt extract agar	May enhance recovery of zygomycetes	
Yeast extract phosphate medium (Remel)	Selective medium for dimorphic fungi	Must add concentrated ammonium hydroxide to surface
Cornmeal agar	Chlamydoconidium formation in <i>Candida albicans</i> ; pigment production in <i>Trichophyton rubrum</i>	
Dermatophyte test medium	Selective recovery and presumptive identification of dermatophytes	Dermatophyte turns medium pink to red. Bacteria and saprobic fungi turn medium yellow. <i>Caution:</i> Some non-dermatophytes also turn the medium red.
Czapek-Dox agar	Reference medium for identification of <i>Aspergillus</i> spp.	
Caffeic acid agar or birdseed (niger seed) agar	For detection of <i>C. neoformans</i>	
Candida ID (bioMérieux), CHROMagar	Selective and differential medium for <i>Candida</i> spp.	Characteristic color development identifies some species.

^a With few exceptions, or unless specifically noted, all of the media listed in this table are available from BD Biosciences, Hardy Diagnostics, and Remel. Czapek-Dox and malt extract agar plates and slants are not available from BD Biosciences. Formulations for the nonproprietary media are provided in other procedures within section 8, as well as in the *Handbook of Microbiological Media* (1).

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

Include QC information on reagent container and in QC records.

- A. Ensure that media to be used are within their expiration period.
- B. Follow laboratory procedure or manufacturer's instructions for preparation of inocula using automated equipment (e.g., lysis centrifugation).
- C. Inspect calibrated loops regularly to ensure that they remain in good condition and free from damage.

V. PRETREATMENT OF SPECIMENS FOR MYCOLOGICAL EVALUATION

It is imperative that these cultures be handled in a biosafety hood.

This topic concerns only deviations from treatments described in other sections of this handbook or with issues specific to mycology.

A. Liquefaction or homogenization of sputum

The use of mucolytic agents, such as *N*-acetyl-L-cysteine or Sputolysin, on viscous samples of sputum is of unproven value for the recovery of most fungi. However, these agents should be used, along with centrifugation, on sputa submitted for detection of *Pneumocystis carinii*.

B. Mincing of tissues

Tissue samples are minced with a sterile scalpel blade and forceps. The procedure may be performed in a sterile petri dish to which a few drops of sterile distilled water have been added. Do not use mechanical tissue homogenizers or a mortar and pestle, as these can adversely affect the recovery of fungi such as zygomycetes because of damage to fragile hyphal structures.

VI. INOCULATION OF MEDIA

It is imperative that these cultures be handled in a biosafety hood.

- A. Transfer a maximum amount of the clinical specimen to culture medium, but retain some for preparation of smears for direct microscopic examination. Refer to procedure 8.2 for refrigeration and freezing of specimens.
- B. The number of media inoculated may be dependent on the specimen type and amount. Both nonselective (SDA and BHI) and selective (inhibitory mould agar [IMA], Mycosel, and Mycobactin) media should be included, and specialized media may be required for specimens in which difficult-to-grow etiologic agents (see Fig. 8.3–1 above) are suspected. Selective media may be omitted if the specimen is free of contaminating microbiota. See Table 8.4–1 for the selection of media for isolation and identification of fungi.
- C. Specific specimen types
 1. Blood
 - a. Automated blood culture systems may provide specialized media for the recovery of fungi from blood. These media can be incorporated into testing protocols as indicated by the manufacturer.
 - b. Lysis centrifugation (Isolator; Wampole) has proven to be a superior method for the recovery of some fungi from blood, especially *Histoplasma capsulatum*. The blood sample is processed according to the manufacturer's instructions, and 3 to 5 drops of sediment are inoculated and streaked onto enriched medium. If some of the sediment remains after all desired media have been inoculated, it can be distributed onto additional plates of medium to ensure that the entire concentration is cultured.
 2. Body fluids (CSF; urine; pericardial, pleural, and peritoneal fluids; ascites)
 - a. Centrifuge quantities of >2 ml.
 - b. Up to 0.5 ml may be inoculated and streaked onto each type of medium.
 - c. Urine may be inoculated and streaked with a calibrated loop if quantitation is desired.

VI. INOCULATION OF MEDIA*(continued)*

- d. Inoculate CSF onto media free of cycloheximide (inhibitory to *Cryptococcus neoformans*). Supernatant from the sample preparation may be aseptically removed and used for antigen testing.
3. Bone marrow aspirates
 - a. Inoculate and streak 3 to 5 drops onto each plate of medium.
 - b. Lysis centrifugation using the pediatric (1.5-ml) Isolator may enhance recovery.
4. Bronchial brushings
 - a. Vortex brush in sterile distilled water.
 - b. Inoculate 3 to 5 drops onto each plate of medium.
 - c. Place brush on surface of selective medium.
5. Tissue

Mince and place several pieces on each plate of medium. Include inhibitory medium if bacterial contamination is suspected.
6. Exudates, pus, and drainage specimens

Exudates, pus, and drainage specimens should be carefully examined with a dissecting microscope for the presence of granules. If found, granules should be teased out with a dissecting needle and crushed between two glass slides. The slides may be examined microscopically for the presence of fungal elements.
7. Specimens on swabs

Swab specimens may be eluted into a small volume of sterile water, and the water may be used to inoculate media. Swabs may also be directly applied to the surface of the agar.
8. Hair, skin, and nails
 - a. Samples of hair should be first examined with a Wood's light, and any fluorescent parts should be included in the culture. The strands are cut into 1-mm lengths with sterile scissors and then applied with sterile forceps to selective medium.
 - b. Nail and skin samples are cut into small pieces with sterile scissors and placed directly on the agar surface using sterile forceps. They should be pressed into the agar slightly.

VII. INCUBATION AND EXAMINATION OF FUNGAL CULTURES

It is imperative that these cultures be handled in a biosafety hood.

- A. Fungal cultures are incubated at 30°C for a minimum of 4 weeks. Plates should be examined daily for the first 7 days and at least twice per week thereafter.
- B. Specimens from genital sites or mucosal surfaces submitted for isolation of *Candida* spp. may be discarded after 7 days.
- C. When *H. capsulatum* or *Blastomyces dermatitidis* is suspected, 6 to 8 weeks of incubation may be required.

VIII. SAFETY CONSIDERATIONS

It is imperative that these cultures be handled in a biosafety hood.

Personnel working in the mycology laboratory should be aware of the potential dangers when working with fungal organisms and exercise appropriate safety measures.

- A. Processing of specimens for fungal culture is done in a biosafety level 2 facility using standard precautions for protection against infectious agents.
- B. All clinical material is processed under a class II biosafety cabinet that is monitored and maintained regularly for proper function.
- C. Disposable gloves and protective clothing are worn during processing. Gloves should be wiped with dilute bleach between specimens.
- D. When *H. capsulatum* or *Coccidioides immitis* is suspected, all isolates should be maintained on slants to prevent aerosolization when cultures are manipulated.

VIII. SAFETY CONSIDERATIONS
(continued)

- E.** Seal all plated media with gas-permeable tape or Shrink-Seal before removing them from biosafety cabinet.
- F.** All excess clinical materials are discarded in biohazard bags secured with tape and placed in containers designated for disposal of biomedical waste.
- G.** All laboratory surfaces that come in contact with specimens or cultures should be decontaminated with 10% bleach that is made fresh each day.

8.5

Examination and Evaluation of Primary Cultures

PREANALYTICAL CONSIDERATIONS

I. EXAMINATION OF FUNGAL GROWTH ON PRIMARY MEDIA

It is imperative that these cultures be handled in a biosafety hood.

▣ **NOTE:** Manipulate cultures in biosafety cabinet.

Primary plates are read daily for the first week, every other day for the second week, and twice weekly for the remaining 2 weeks. The use of 4 weeks of incubation has been challenged by some groups because few new positive cultures develop in the fourth week. I have noted that clinically significant positive cultures are sometimes seen in the fourth week, suggesting the need to retain this incubation period. In areas of endemicity of systemic dimorphic pathogens, incubation for 5 weeks should be considered, as occasional isolates of *Histoplasma capsulatum* and *Blastomyces dermatitidis* may require that much time to form evident colonies. In cases of eumycetoma, the etiologic agent may not be evident on culture until the fifth or sixth week. When growth appears, differentiate between yeast and filamentous forms (moulds) that may require microscopic examination. Use wet mounts or stain with lactophenol cotton blue (*see* item V.B below). If the isolate suggests an actinomycete, examine with Gram stain and with a modified acid-fast stain. (Procedures for the identification of aerobic actinomycetes are given in procedure 6.1, items V.D.1 and V.D.2.)

Several key characteristics of a fungus may be obtained from primary cultures. For the yeasts, these include the presence of a capsule, budding characteristics (single, multiple, or catenated), size, morphology, and colony color. If CHROMagar or another chromogenic medium was used in the primary setup, a presumptive identification of a yeast may be possible (*see* item VI.A below) (1). For moulds, helpful features include colony characteristics (obverse and reverse), sporulation characteristics, the presence of septa, and hyphal or conidial color (e.g., phaeoid moulds). For the moulds, *see* procedures 8.7 and 8.9.

Blood cultures or fluid cultures incubated in broth which have fungal elements upon Gram staining (*see* section 3) should be subcultured onto appropriate media. If yeasts are seen, then the subculture medium battery should include CHROMagar or similar differential medium, and it should also include an India ink stain if yeast morphology is suspicious for *Cryptococcus* spp.

II. PREPARATION OF CULTURE MATERIAL FOR MICROSCOPIC EXAMINATION

Once colony formation has occurred, the organism should be viewed microscopically. For some fungi (e.g., zygomycetes), intact colonies should be viewed initially with a dissecting microscope because it provides a good indication of growth characteristics. The following list includes the general methods for colony preparation and staining.

A. Yeast

1. Wet prep (with or without Tween 20)
2. Stains
 - a. Lactophenol cotton blue (LPCB)
 - b. India ink

B. Moulds

1. Wet prep (with Tween 20)
2. Scotch tape (or pinworm paddle)
3. Tease prep
4. Slide culture
5. Stains
 - a. LPCB
 - b. Ascospore

III. MATERIALS

A. General

Slides, coverslips, dissecting needles, loops, pipettes, and cello tape

B. Stains and reagents

1. 0.05% Tween 80 in sterile distilled water (50 μ l of Tween 80 in 99.95 ml of water; sterilize by autoclaving)
2. LPCB (available from Remel and other suppliers)

3. India ink (available from Remel and other suppliers)

C. Media

1. Sabouraud's dextrose agar
2. CHROMagar
3. Other agars suitable for ascospore production (*see* procedures 8.4 and 8.8)

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

Include QC information on reagent container and in QC records.

A. Stains

1. Each lot of reagent should be tested to ensure that it stains adequately. For example, a tease preparation of *Penicillium* sp. hyphae in LPCB should stain the cell walls blue. There is no specific strain of *Penicillium* sp. for QC. Laboratorians should, however, select a strain and use it for all subsequent QC evaluations of LPCB. QC for India ink is described in item IV of procedure 8.3.
2. Check stain for presence of extraneous material (fungal elements, etc.).

B. Organisms

Different batches of media can result in variation in the colony characteristics of organisms. Therefore, inoculate a control plate with organisms known to display specific colony features. For CHROMagar, *Candida albicans* ATCC 10231, *Candida krusei* ATCC14243, and *Escherichia coli* ATCC 25922 are recommended by the manufacturer.

C. Media

Ensure that all media are used before their expiration date. See section 14 of this handbook for a general discussion of QC.

V. MICROSCOPIC EXAMINATION OF YEASTS AND MOULDS

It is imperative that these cultures be handled in a biosafety hood.

A. Yeast colony examination with 0.05% Tween 80 wetting agent

The addition of Tween 80 helps reduce bubble formation and prevent infectious conidia from escaping. The procedure is as follows.

1. Place a drop of 0.05% Tween 80 onto a slide.
2. With a loop, touch the surface of the suspicious colony, being sure that some fungal material is on the loop. Gently rub the material in the drop of Tween.
3. Place a coverslip on top of the drop and examine with a microscope.

B. LPCB solution

LPCB is an excellent stain for examination of fungal material. The phenol kills the fungi, and the lactic acid increases preservation. Cotton (china) blue stains chitin and cellulose. The procedure is as follows.

1. Place a drop of LPCB onto a slide.
2. Remove a piece of fungal material, using a dissecting needle, and place into the drop of stain. Tease the mycelial hyphae apart using sterile dissecting needles.
3. Place a coverslip on top and examine microscopically.

C. India ink

The India ink test helps to demonstrate the presence of a capsule on an organism. (see item 8.3.V.D above).

D. Gram stain

See procedure 3.2.1.

POSTANALYTICAL CONSIDERATIONS

VI. TESTS USEFUL FOR YEAST IDENTIFICATION FROM PRIMARY CULTURES

A. CHROMagar

CHROMagar contains enzymatic substrates that are linked to chromogenic compounds. When specific enzymes cleave the substrates, the chromogenic substrates produce color. The action of different enzymes by yeast species results in color variation useful for the presumptive identification of some yeasts. Colony variation is seen for some species (1). The medium is best suited for *C. krusei*, *C. albicans*, *Candida tropicalis*, and *Trichosporon* spp. The medium should not be used alone to make a definitive identification of a yeast; it contains chloramphenicol to inhibit bacterial contamination in primary specimens.

1. Applications

CHROMagar is useful for the detection of mixed infections (especially in wounds, blood, and urine) and as an additional test to resolve difficult identifications.

2. Procedure

- a. Primary specimens should be plated by procedures typical for the specimen.
- b. Subcultures should be streaked for isolation.
- c. Incubate at 35°C in the dark for 48 to 72 h (not less than 48 h). Exposure to higher or lower temperatures for a prolonged period will alter the final color production and lead to possible incorrect presumptive identification of some *Candida* spp.
- d. Use only isolated colonies to determine the organism's characteristics for purposes of presumptive identification.
- e. *Do not use the isolated colonies to perform subsequent screening tests for identification or for biochemical identification systems.* Subculture onto a nonselective medium before performing additional identification tests on the isolate.

VI. TESTS USEFUL FOR YEAST IDENTIFICATION FROM PRIMARY CULTURES (continued)

Table 8.5–1 General list of yeast species or genera based on colony color^a

White, cream, or tan	Brown or black	Salmon, pink, or red
<i>Blastoschizomyces</i>	<i>Aureobasidium</i>	<i>Rhodotorula</i>
<i>Candida</i>	<i>Phaeoannellomyces elegans</i>	<i>Sporobolomyces</i>
<i>Cryptococcus</i>	<i>Phaeoannellomyces werneckii</i> ^b	
<i>Geotrichum</i> ^d	<i>Phaeococcomyces exophialae</i> ^c	
<i>Hansenula</i>	<i>Ustilago</i>	
<i>Kloeckera</i>		
<i>Malassezia</i>		
<i>Prototheca</i> ^d		
<i>Saccharomyces</i>		
<i>Trichosporon</i>		
<i>Ustilago</i>		
Teleomorphs ^e		
<i>Debaryomyces</i>		
<i>Kluyveromyces</i>		
<i>Pichia</i>		

^a Based on growth on Sabouraud glucose agar (Emmon's modification), potato dextrose agar, malt extract agar, or BHI agar. Note that all *Malassezia* spp. except *Malassezia pachydermatis* require exogenously supplied lipid (e.g., olive oil) for growth.

^b Previously *Exophiala werneckii*.

^c A second anamorphic (asexual) form (i.e., synanamorph) of *Wangiella dermatitidis*.

^d Not a yeast but produces yeastlike colonies on mycological media.

^e Sexual genera associated with some species of the anamorphic genera.

B. Other tests

Only a few tests are available to identify a yeast when it is first isolated. Colony color (pigment) (Table 8.5–1) and microscopic morphology are helpful. The tests described below provide only presumptive identification (an exception is the Accu-Probe for *Cryptococcus neoformans* [Gen-Probe], which is described in procedure 8.9). Subculture of the yeast colony onto appropriate media will lead to yeast identification (see procedure 8.8). Isolates from medically significant specimens must be identified to the species level. Stopping at the presumptive identification step could lead to inappropriate therapy.

VII. SUBSEQUENT TESTING

Based on the type of organism and special characteristics, several tests may be performed to obtain an identification of a primary culture (Table 8.5–2). If the fungal colonies are not well separated from bacterial colonies or there is insufficient material for testing, subculture the organism (see procedures 8.4 and 8.7). The identification schemes shown in Fig. 8.5–1 and 8.5–2 utilize pigment (Table 8.5–1), microscopic morphology (see Table 8.3–1 above) and presumptive test results (Table 8.5–2; described in procedure 8.6.)

VIII. INTERPRETATION

CHROMagar

A. *C. albicans*

A medium-size (2- to 3-mm diameter), green, smooth, matte colony with a very slight green halo in the surrounding medium. Note that *Candida dubliniensis* produces a similar colony, but it is typically darker green.

B. *C. tropicalis*

A medium-size, smooth, matte colony which is blue to blue-gray with a paler pink edge. The colony may have a dark-brown to purple halo which diffuses into the agar.

Table 8.5–2 Summary of subsequent tests

Primary growth	Key characteristic	Further tests ^a
Yeast	Capsulated	Caffeic acid disk, urease, rapid nitrate, serology
	Nonencapsulated	Urease, germ tubes, <i>C. albicans</i> screen, rapid trehalose, serology
	CHROMagar pigmentation or Other chromogenic media	Color chart Determine mixed infection. May allow presumptive identification of <i>C. krusei</i> , <i>Candida glabrata</i> , <i>C. albicans</i> . See manufacturer’s information for organism identification and limitations.
Mould	Nonseptate hyphae	Likely zygomycete; subculture to potato dextrose agar.
	Septate hyphae	Evaluate reproductive and hyphal characteristics. Subculture to one or more media (see subculture procedure 8.9). Accu-Probe if suspect systemic pathogen (<i>Histoplasma</i> , <i>Blastomyces</i> , <i>Coccidioides</i>)

^a These tests are described in procedures 8.6 and 8.7.

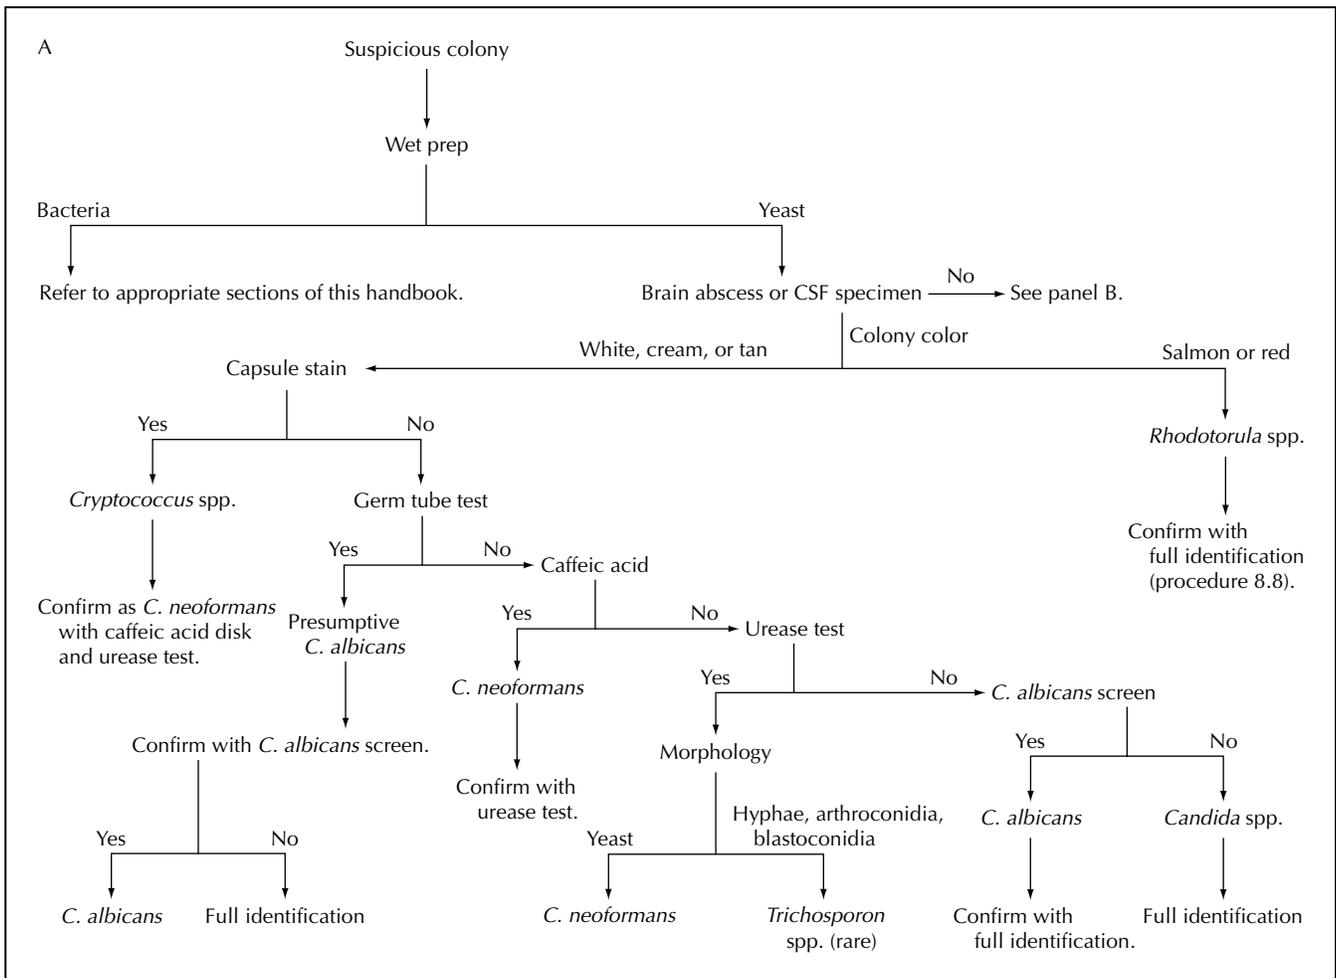

Figure 8.5–1 Flowchart for evaluating a possible yeast species on primary culture. (A) Identification procedure when yeast cells are found in brain abscess or CSF specimen. See Fig. 8.3–1 for common yeast agents isolated from different body sites. (B) Identification procedure for yeasts when the specimen is not brain abscess or CSF (continued).

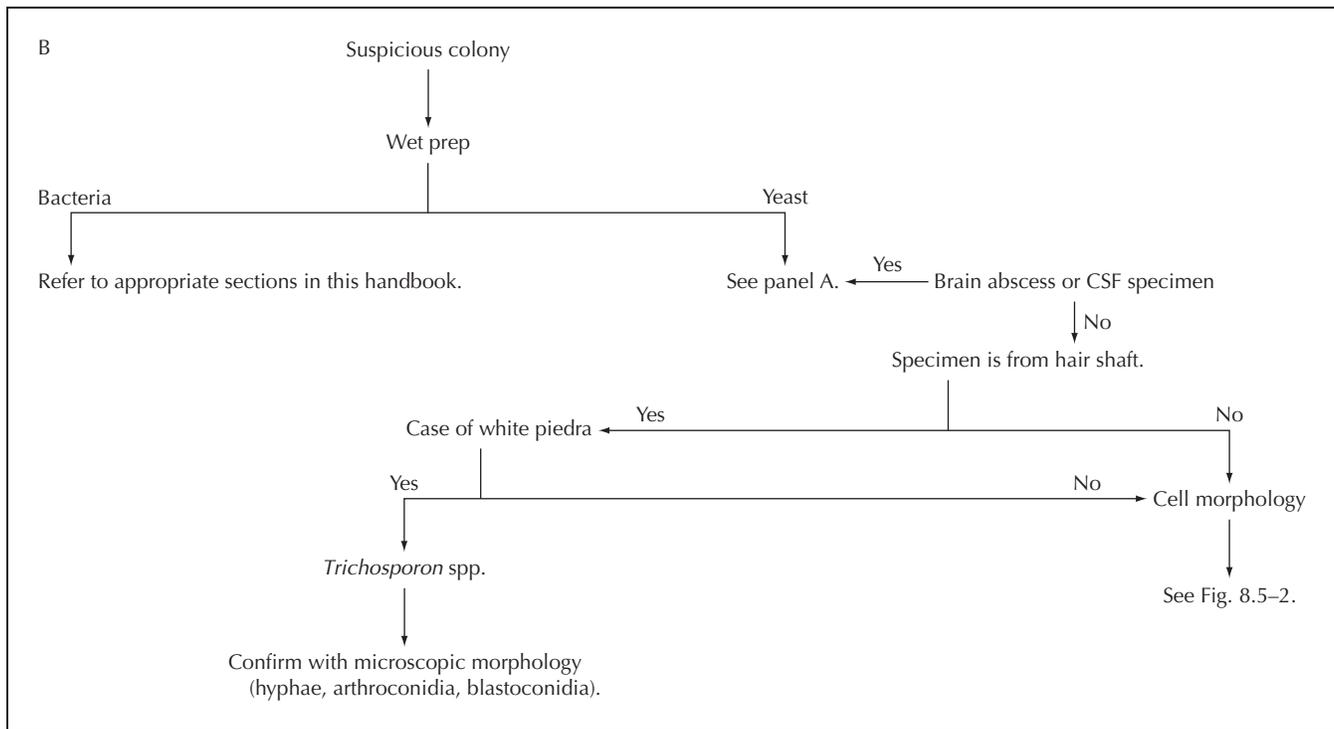

Figure 8.5-1 (continued)

VIII. INTERPRETATION

(continued)

C. *C. krusei*

A large (≥ 4 -mm-diameter), spreading, rough, pink colony with a pale-pink to white edge

- D.** Other yeasts produce colony characteristics that are useful to obtain a suggestive identification. According to Odds and Bernaerts (1), *Trichosporon* spp. (e.g., *Trichosporon beigeli*) produce a distinctive blue-green colony, particularly with prolonged incubation, when it becomes rough and crenated. The manufacturer does not include this isolate in its list of organisms that can be presumptively identified. Further testing is required to identify *Trichosporon* spp.
- E.** If the test is used to determine mixed infection in primary specimens, additional testing must be performed. If the test is used to help resolve a difficult identification, further tests may not be required.

IX. LIMITATIONS

A. CHROMagar

1. The CHROMagar test provides only presumptive identification of four yeasts (*C. albicans*, *C. tropicalis*, *C. krusei*, and *C. dubliniensis*). Individual clinical laboratories should test at least five isolates of each of the four species to become aware of the color variation that may occur. Strict adherence to the manufacturer's incubation conditions is imperative. Enzymatic reactivity is sensitive to temperature. Review the manufacturer's instructions before performing this test.
2. Other chromogenic media (e.g., Albicans ID [bioMérieux, Marcy l'Étoile, France], and CandiSelect [Sanofi Diagnostics, Marnes-la-Coquette, France]),

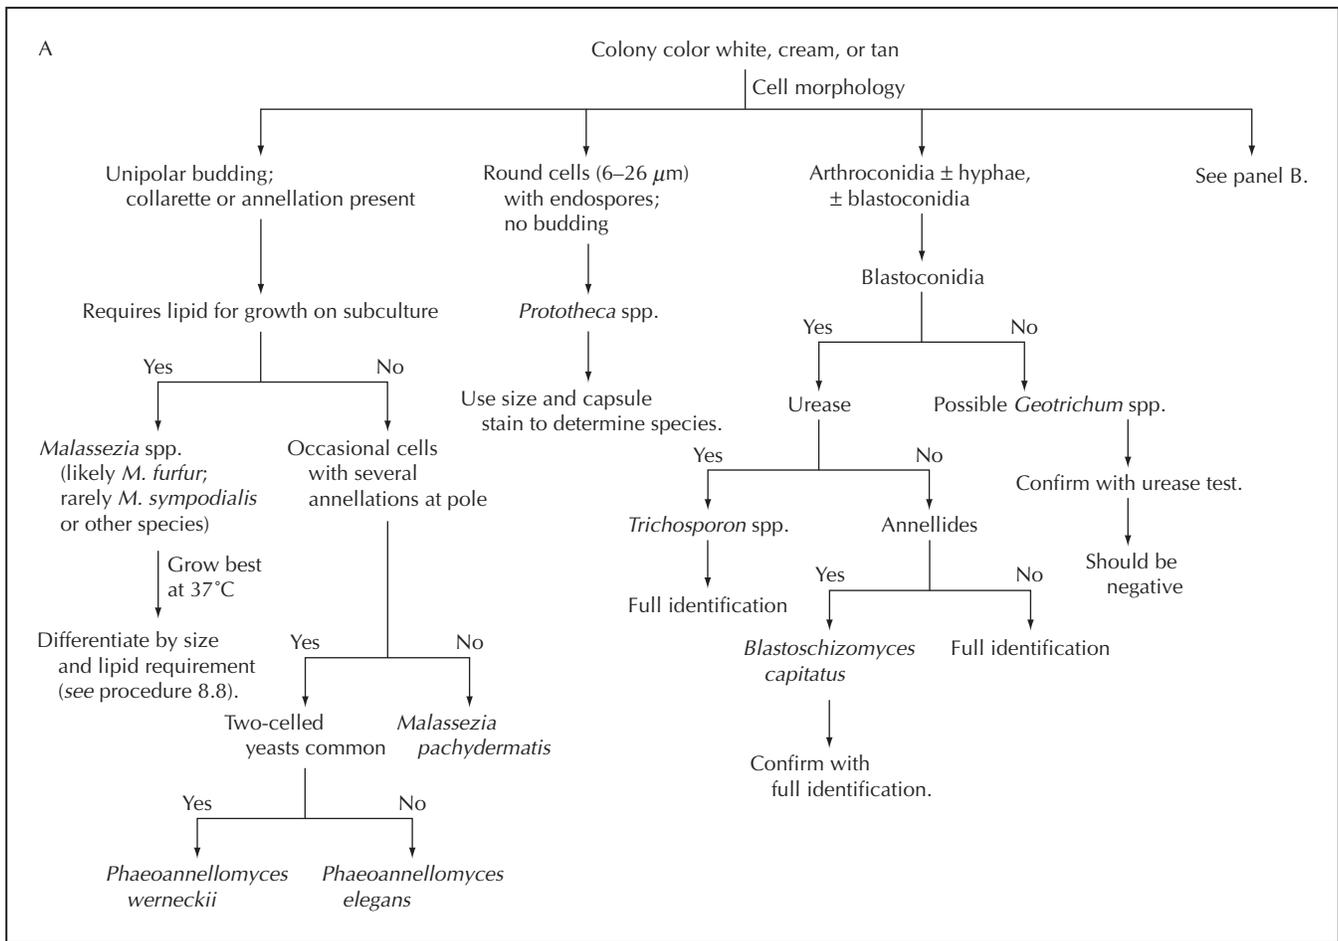

Figure 8.5–2 Simple tests to determine genera of yeast cells seen on primary culture. (A and B) Identification procedures when colony color is white, cream, or tan. (C) Identification procedure when colony color is salmon, pink, or red. (D) Identification procedure when colony color is brown or black (*continued*).

IX. LIMITATIONS (*continued*)

as well as fluorogenic media (e.g., Fluoroplate Candida [Merck, Darmstadt, Germany] and MUAG Candida agar [Biolife, Milan, Italy]) have been developed to provide presumptive identification of *C. albicans*, but these media could also be used to help detect mixed infections. The media will also produce positive color or fluorescence development with *C. dubliniensis*. Fluorogenic media have the additional problem that the fluorophore can diffuse into the medium and make non-*C. albicans* colonies appear positive. Until extensive studies have been performed, no chromogenic or fluorogenic medium should be used as the sole determinant of species identification.

B. India ink

When cryptococci are cultured, capsule production is generally reduced compared to what is seen with organisms in a specimen. Therefore, the India ink test may not provide much help to identify *C. neoformans* from a primary culture. Size, shape, and budding characteristics are usually more helpful and should suggest to the laboratorian the need to perform a rapid presumptive test, such as the caffeic acid test (*see* procedure 8.6).

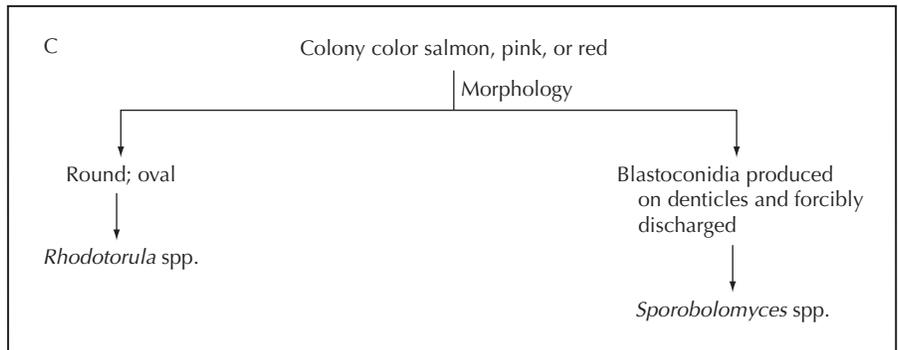

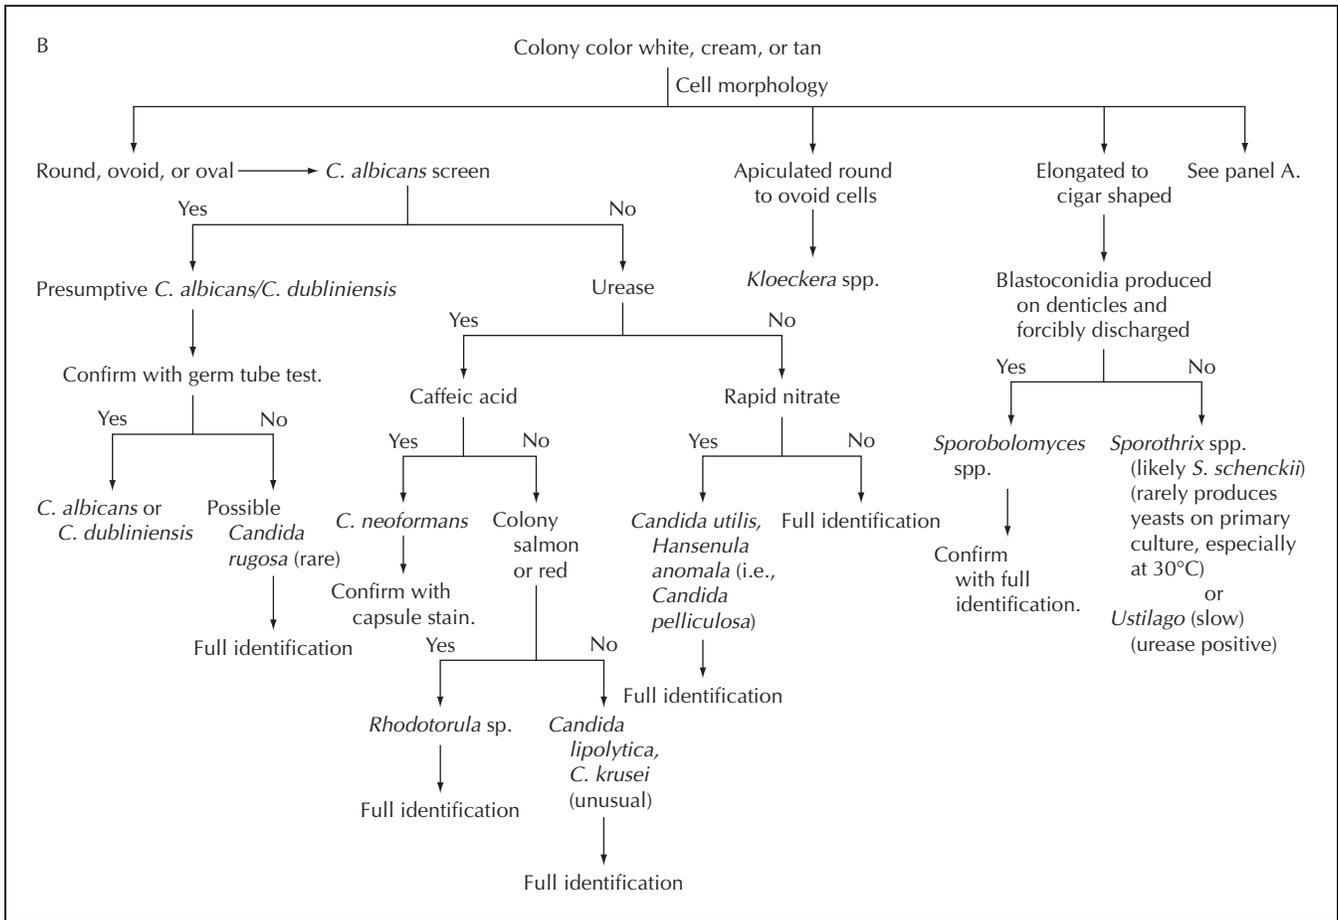

Figure 8.5–2 (continued)

X. REPORTING

General

The tests described in this procedure are intended to provide preliminary or presumptive information (such as mould, yeast, dematiaceous, encapsulated) about the identity of an organism recovered from a specimen. As such, reporting should indicate that the species identification information is not definitive and that additional testing is needed to obtain more definitive identification information (e.g.,

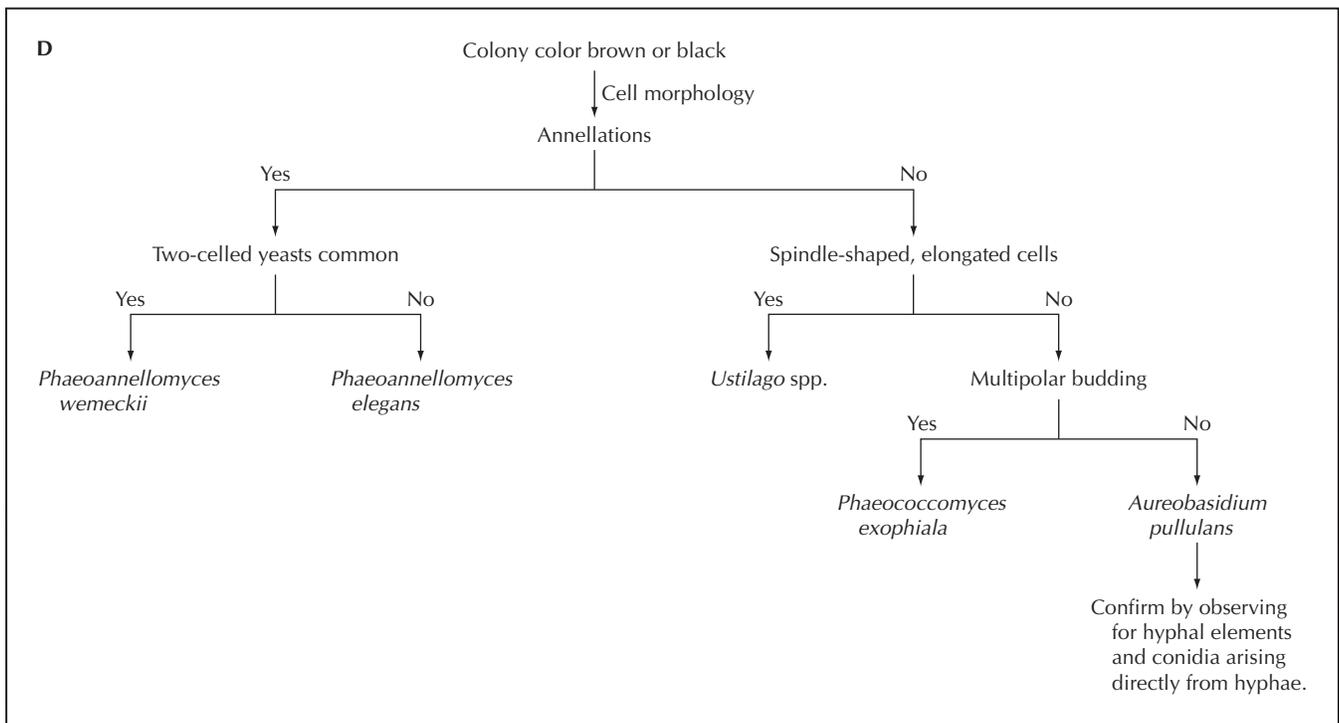

Figure 8.5–2 (continued)

X. REPORTING (continued)

“presumptive [species]; further testing needed for definitive identification”). Significant isolates should always be identified to the species level. When the significance is in doubt, the presumptive report should be sufficient. It is possible to identify some moulds (such as some dermatophytes and aspergilli) to the species level from primary cultures. When this occurs, there is no need to assign any preliminary nature to the identification. Whether all significant moulds should be identified to the species level is controversial. However, with the advent of new antifungals and the different susceptibilities of species within a genus to different antifungals (within a class and among classes), identification to the species level should be strongly considered.

One of the more controversial issues regarding primary cultures is quantitation. While for yeasts, quantitation is generally reported using criteria similar to those used in bacteriology for deciding clinical significance, the situation is different for moulds because they grow as contiguous cells which may break off into fragments. Such fragmentation could lead to the appearance of a higher fungal burden than is actually present in the tissue. Similarly, the recovery of a single colony of a potentially pathogenic mould does not necessarily mean that the fungal burden in the specimen is low (i.e., that the single colony represents a contaminant). Sample bias, sample preparation, and other factors can contribute to the recovery of so few colonies from an infected site. When available, it is helpful to correlate what was recovered on primary culture with what was seen with histopathology.

☑ One problem with the bacteriological quantitation approach for yeasts is that yeast cell volume is much greater than the volume of bacteria, so the space occupied by a given number of yeast cells will typically exceed by >10-fold the space occupied by the same number of bacteria. This raises the issue that 2+ of yeasts on a primary isolation plate is not equivalent to 2+ of bacteria (that is, the yeast is occupying more tissue space).

APPENDIX 8.5–1

Medium and Reagent Preparation
A. Yeast colony examination using water and Tween 80

125-ml flask	
distilled water	100 ml
Tween 80	0.05 ml

Add 0.05 ml of Tween 80 to 100 ml of distilled water. Autoclave at 121°C for 15 min. Store at room temperature for 3 months.

B. Lactophenol cotton blue

Available from several sources (for example, Remel no. 40-028, Lactophenol Aniline Blue). Store at room temperature for up to 6 months.

C. CHROMagar

Source: Hardy Diagnostics (catalog no. G34)

8.6

Presumptive Identification Tests for Yeasts Isolated on Primary Culture

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

All of the tests described in this procedure (Table 8.6–1) are considered presumptive because they do not test a characteristic of a species that is unique to that species. Some of the tests do have high specificity values, which would make the test sufficient for the purposes of medical management of some clinical situations (e.g., intertriginous candidiasis due to *Candida albicans*) but insufficient for others (e.g., fungemia due to *C. albicans*). Presumptive tests also are generally restricted in the range of species they determine. The results of two different physiological tests with high specificity for a particular species may be appropriate for identifying the species presumptively. However, there are

instances when two different species elicit identical positive reactions in both tests. Mycologists and clinical microbiologists must be aware of these obfuscations. For example: *C. albicans*, by far the most frequently encountered *Candida* sp. in the clinical setting, and *Candida dublinensis* are both germ tube positive and positive for the enzymes β -galactosaminidase and L-proline aminopeptidase (4).

As with more definitive tests, care must be taken to be sure that the tests are performed on yeasts cultured on the appropriate media and under the appropriate conditions. Results obtained with a presumptive test must be consistent with other information regarding the yeast (e.g.,

colony color and cell morphology) and the clinical specimen from which the yeast was isolated. Thus, presumptive tests should be performed only on isolates that have morphological and cultural characteristics consistent with the use of a given test. For a review of current presumptive tests, see Freydière et al. (3). It is important to remember that mixed yeast infections do occur, such as in fungemia. The presumptive tests below assume that yeast inocula are from pure cultures or from single colonies. Tests such as the *C. albicans* screen and the *Candida* check require multiple colonies in the preparation of the inoculum. Mixed cultures will therefore cause erroneous results.

Table 8.6–1 Presumptive identification tests for yeasts on primary culture

Test	Item no. ^a	Organism
CHROMagar	8.5.VI.A	<i>C. krusei</i> , <i>C. albicans</i> , <i>C. tropicalis</i> , <i>Trichosporon</i> spp.
Germ tube	8.6.IV.A	<i>C. albicans</i>
<i>C. albicans</i> screen	8.6.IV.B	<i>C. albicans</i>
Rapid urease	8.6.IV.C	<i>Cryptococcus</i> spp., <i>Rhodotorula</i> spp., <i>Trichosporon</i> spp., (variable), <i>C. krusei</i> (variable), <i>Malassezia pachydermatis</i> , <i>Candida lipolytica</i> (i.e., basidiomycetous yeasts)
Rapid nitrate reductase	8.6.IV.D	<i>C. albidus</i> (+), <i>C. neoformans</i> (–), <i>C. terreus</i> (+)
Caffeic acid disk	8.6.IV.E	<i>C. neoformans</i>
Rapid trehalose assimilation	8.6.IV.F	<i>C. glabrata</i>
India ink	8.3.V.D	<i>Cryptococcus</i> spp.

ANALYTICAL CONSIDERATIONS

III. QUALITY CONTROL

- A. Germ tube test**
- The following yeasts should be included each time the test is performed.
1. Germ tube positive, *C. albicans* ATCC 14053
 2. Germ tube negative, *Candida tropicalis* ATCC 66029
- B. Preformed-enzyme test (*C. albicans* screen or CA-50)**
- Randomly select two tubes from each lot of kits received and conduct the test using *C. albicans* ATCC 14053 (positive for β -galactosaminidase and L-proline aminopeptidase) and *Cryptococcus laurentii* ATCC 18803 (negative for both enzymes).
- C. Urease disk test**
- Test each new numbered lot using the following controls.
1. Positive control, *Cryptococcus neoformans* ATCC 66031
 2. Negative control, *C. albicans* ATCC 60193
 3. Reagent control, uninoculated
- D. Nitrate swab rapid test**
- The medium is tested on receipt, using control strains, and each time a test is conducted. Use *C. neoformans* (ATCC 66031) as a negative control and *Cryptococcus albidus* (ATCC 10231) as a positive control.
- E. Caffeic acid disk test for *C. neoformans* screen**
- Each new lot of disks should be tested and should yield a brown pigment with *C. neoformans* (positive) and no pigment with *C. albicans* (negative). The disks should be white; discard if discolored.
- F. Rapid trehalose test**
- Each test should include the positive control, *Candida glabrata* ATCC 2001, producing a color change to yellow, and a negative control, *C. albicans* ATCC 10231, which produces a color change to blue or green.
- G. Serologic identification of *Candida* and *Cryptococcus* spp.**
- There are no established control organisms for the serologic identification kit, but it is recommended that the following species be used for the *Candida* check kit to demonstrate positive and negative reactions for each factor serum.
1. *Candida parapsilosis*, factor sera 1, 5, 13, and 13b positive
 2. *Candida guilliermondii*, factor sera 1, 4, and 9 positive

III. QUALITY CONTROL (continued)

3. *Candida kefyr*, factor sera 1 and 8 positive

4. *C. glabrata*, factor sera 1, 4, 6, and 34 positive

For the *Cryptococcus* check kit, use single isolates of *C. neoformans* of serotypes A, B, C, and D (available from various commercial culture collections).

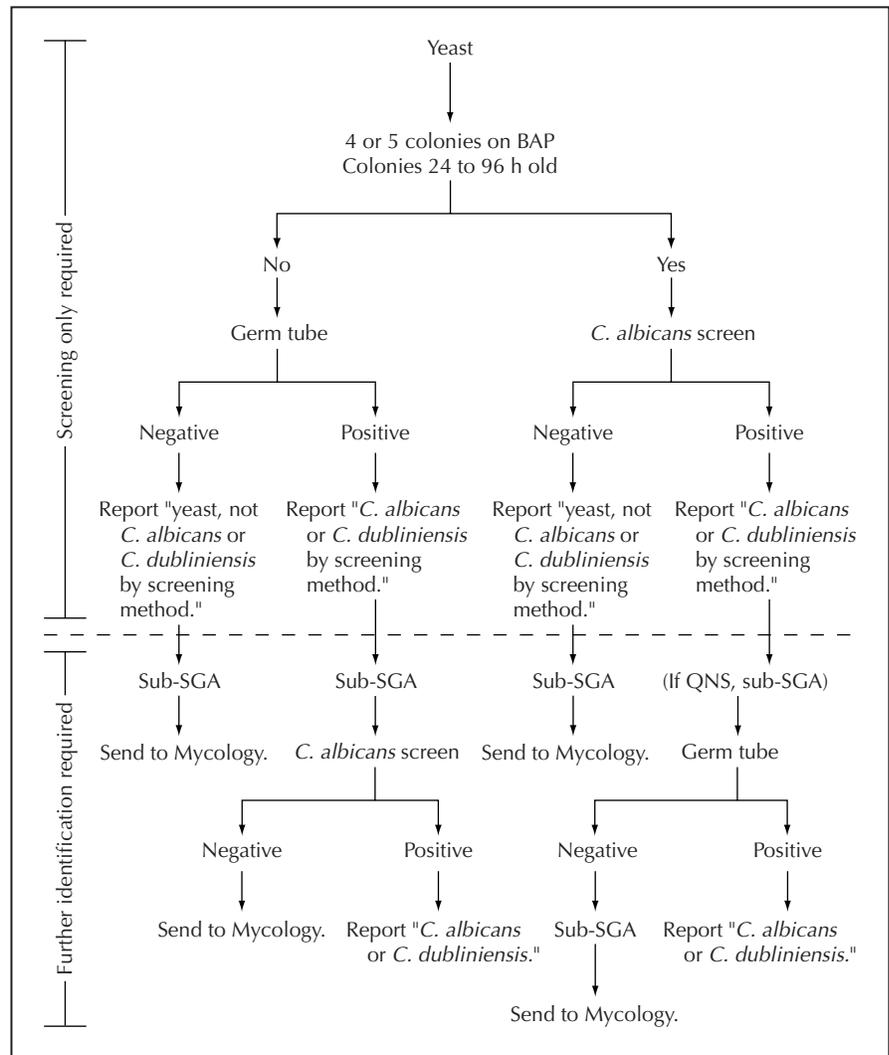

Figure 8.6–1 Algorithm for identification of *C. albicans* and *C. dubliniensis* on primary culture. Follow specimen guidelines for significance for specimens submitted for routine bacteriology cultures. When a protocol requires screening tests or identification for yeast, proceed as outlined in this diagram. If the yeast is from a sterile body fluid or blood, two tests must be positive to identify *C. albicans* or *C. dubliniensis* (e.g., if the *C. albicans* screen was positive, perform a germ tube test). Note that *C. dubliniensis* is a rare bloodstream pathogen (usually associated with catheters). To discriminate between *C. albicans* and *C. dubliniensis*, use growth at 45°C (presumptive, as not all isolates of *C. albicans* tolerate this temperature and not all isolates of *C. dubliniensis* are inhibited by it) or, more definitively, assimilation tests (see procedure 8.8). If yeasts are seen in a blood culture bottle, subculture the bottles to CHROMagar to check for purity. SGA, Sabouraud glucose agar; QNS, quantity not sufficient.

IV. PROCEDURES

See Appendix 8.6–1 for reagents.

A. Germ tube test

The germ tube test provides one of the most rapid approaches to the *presumptive* identification of *C. albicans* and *C. dubliniensis* (Fig. 8.6–1).

Procedure

1. Lightly touch a yeast colony with a wooden applicator stick.
2. Suspend the yeast cells in an appropriately labeled tube of fetal bovine serum.
3. Incubate at $37 \pm 1^\circ\text{C}$ for 2.5 to 3 h.
4. Place a drop of the suspension on a microscope slide.
5. Place a coverslip over the suspension.
6. Examine under high power for the presence or absence of germ tubes. A germ tube appears as a short lateral extension from the yeast cell and does not have a constriction (septum) where it meets the yeast cell. A constriction where the lateral extension meets the yeast cell is produced by pseudohyphae or budding cells. A minimum of five germ tubes should be observed before calling the isolate positive.

B. Preformed-enzyme tests

C. albicans produces two exoenzymes, L-proline aminopeptidase and β -galactosaminidase, when grown on appropriate media. The detection of these enzymes with a 30-min chromogen-coupled substrate-impregnated disk affords *presumptive* identification of *C. albicans*. A commercial kit, the *C. albicans* Screen (Carr-Scarborough; also sold by Murex as CA-50), which utilizes the impregnated disk, is available. Presumptive identification of *C. albicans* based on only one of the two preformed enzymes mentioned above or on β -D-glucosidase leads to an unacceptably low level of sensitivity. This test, in combination with the germ tube test, has been used to confirm an isolate as *C. albicans* (4). However, *C. dubliniensis* will produce the same results. Fortunately, the latter organism has only infrequently been detected in specimens obtained from sites other than the oropharynx. Laboratorians should be mindful that *C. dubliniensis* may be obtained from blood, urine, vaginal, and other specimens, especially when the patient is immunocompromised or appears refractory to azole therapy. Laboratorians should also be mindful that rare isolates of other *Candida* spp., especially *C. tropicalis*, can produce germ tubes in the germ tube assay, although few germ tubes are present and they are more constricted at the bases. The enzyme test will help distinguish these isolates from *C. albicans*.

1. Procedure

- a. Use only pure 18- to 24-h cultures of the control organisms grown on Sabouraud dextrose agar and only pure cultures of the test organisms grown on blood agar, Sabouraud dextrose agar, Mycosel, or potato dextrose agar.
- b. Remove a disk from the vial and place it in one of the tubes provided. Add 1 drop of sterile demineralized (deionized) water.
- c. With an applicator stick, pick up a heavy visible “paste” of the yeast and rub it onto the disk. Incubate at 35°C for 30 min.
- d. After incubation, add 1 drop of 0.3% NaOH and examine against a white background for a distinct yellow color. No color is considered negative.
- e. Add 1 drop of cinnamaldehyde reagent. Development of a pink to red color within 1 min is a positive PRO (L-proline aminopeptidase) test. No color or a slight yellow color is a negative test.

2. Results

The development of a distinct yellow color upon the addition of 0.3% NaOH is a positive test for β -galactosaminidase. No yellow color indicates the ab-

IV. PROCEDURES (continued)

sence of the enzyme. The development of a red color within 1 min after adding cinnamaldehyde reagent is a positive test for L-proline aminopeptidase. No color change or development of a slight yellow color is a negative test.

C. Urease disk test for the differentiation of yeast

The urease disk test is a rapid detection test to distinguish basidiomycetous yeasts (e.g., *Cryptococcus*) from ascomycetous yeasts. Urease splits urea to form ammonia and carbon dioxide, which raises the pH and causes a color shift in the phenol red indicator from amber to pinkish red. When an organism appears urease negative but there is a strong suspicion that the organism should be urease positive, a more definitive urease test should be performed (e.g., urea agar slants).

1. Procedure

- a. Emulsify a colony of the yeast in 0.5 ml of sterile distilled water in a 16-by 125-mm tube.
- b. Add one urea disk.
- c. Incubate at 28°C
 - **NOTE:** Room temperature may not be 28°C and therefore should not be used.
- d. Check at 4 h and daily up to 72 h.

2. Results

- a. Positive, turns to pink to red in color
- b. Negative, no color change
- c. Urease activity by species

^a Variable depending on strain

D. Nitrate swab rapid test for yeast nitrate reduction

Nitrate reduction can be used to differentiate species of *Cryptococcus*. *C. neoformans* does not reduce inorganic nitrate. *C. albidus* and *Cryptococcus terreus* are nitrate positive. Organisms that reduce nitrate do not necessarily assimilate nitrate; however, the opposite is true (if they assimilate nitrate, they must reduce it).

Cotton swabs impregnated with KNO₃-Zephiran are used to test yeasts for the ability to form nitrite from nitrate (the presence of nitrate reductase). The formation of nitrite is detected by the addition of a color reagent. The reaction (color changes) occurs on the cotton swab.

Not all nitrate reductase-positive organisms listed in Table 8.8–4 below will produce a positive result, presumably due to insufficient enzyme production. However, the rapid test can sometimes provide laboratorians with an indication of an isolate's identity. The test is also useful when species discrimination cannot be made based on more elaborate tests (such as standard yeast identification panels). The organisms which produce a positive result with the rapid nitrate

IV. PROCEDURES (continued)

test are not frequently isolated in the laboratory, so incorporation of this test into the laboratory's test menu may not be cost-effective.

1. Procedure

- a. Positive and negative controls are run each time the test is done.
- b. Sweep the KNO₃-Zephiran-impregnated swab across several (four or five) colonies. Swirl the swab against the inside wall of a sterile empty tube to insure good contact of the organisms with the substrate.
- c. Incubate the swab in the tube at 45°C for 10 min, or 20 to 30 min at 35°C.
- d. Remove the tubes from the incubator; place the swab in a tube containing 2 drops each of nitrate reagents A and B.
- e. Observe the swab for the development of a pink to red color, indicating a positive test. A positive test result should be visible within 3 to 5 min.

2. Results

a. Positive test

The development of a pink to red color on the swab indicates nitrate has been reduced to nitrite.

b. Negative test

No color development on the swab indicates a negative test result. Zinc powder is not added to confirm that the result is a true negative, as residual nitrate is nearly always present.

E. Caffeic acid disk test for *C. neoformans* screen

Caffeic acid and ferric citrate are the substrates for the phenol oxidase enzyme, produced only by *C. neoformans*. This enzymatic reaction produces melanin, which is absorbed by the yeast cell wall, resulting in a brown pigmentation.

1. Procedure

- a. Place the disk on the cornmeal agar plate for rehydration. (Do not use a medium containing glucose; it will inhibit the phenoloxidase activity.)
- b. Inoculate the disk with several yeast colonies. A heavy inoculum is critical.
- c. Inoculate the plate for yeast morphology.
- d. Replace the lid, and incubate the plate at 35 to 37°C in ambient air.
- e. Examine at 30-min intervals for up to 4 h for the production of a brown pigment on the disk, indicating a positive test result.

2. Results

- a. The production of a brown pigment after incubation at 35°C indicates phenoloxidase activity in the yeast cell wall.

(1) If a brown pigment is observed, report "presumptive for *Cryptococcus neoformans*" and proceed to full yeast identification procedure, including API confirmation (see procedure 8.8).

(2) If there is no brown pigment but *C. neoformans* is strongly suspected, proceed with yeast identification workup. Include a birdseed (niger seed or thistle seed) agar plate.

- b. After 48 h, read the plate for yeast morphology and record results.

F. Rapid trehalose test for *C. glabrata*

When heavily inoculated and incubated at 42°C, rapid trehalose assimilation broth detects in 3 h the trehalose assimilation associated with *C. glabrata*. This reaction is used for the presumptive identification of *C. glabrata*. Isolates which are germ tube and pseudohypha negative and are microscopically small (compared to organisms such as *C. albicans*) may be *C. glabrata*, and therefore this rapid test may provide presumptive identification. It is important to note that this test should not be used in place of standard methods to detect trehalose assimilation of other yeast species. Other tests which specifically evaluate trehalose assimilation or fermentation and can be used to presumptively identify *C. glabrata* are available (e.g., Hardy Diagnostics Trehalose Fermentation with

IV. PROCEDURES (continued)

Durham Tube and Remel Yeast Fermentation Broth with Durham Tube). As with the Remel Rapid Trehalose Assimilation Broth test, incubation occurs at 42°C, as this provides better selectivity for *C. glabrata* versus other species. However, the two fermentation tests require prolonged incubation (24 h) and therefore compromise the ability to provide useful information rapidly to physicians. False-positive results occur with each of the trehalose tests (2), but confusion can be reduced by correlating the trehalose test results with other characteristics of the yeast isolate, as mentioned above (i.e., germ tube formation and small size).

1. Procedure

- a. Allow the number of tubes (stored at 2 to 8°C) needed for testing to come to room temperature.
- b. Prepare a cloudy suspension of the yeast isolate in an appropriately labeled tube of broth.
- c. Incubate the tubes at 42°C.
- d. Monitor the tubes for up to 3 h for a color change to yellow.

Caution: Incubation beyond 3 h may result in false-positive results.

2. Results

a. Positive test

A color change to yellow within 3 h of incubation

b. Negative test

Blue, blue-green, or green color after 3 h of incubation

G. Serologic identification of *Candida* and *Cryptococcus* spp.

Candida and *Cryptococcus* spp. produce polysaccharide antigens that are exposed on the cell surface and that vary among serotypes and species. Specific agglutination antisera that have been produced in rabbits and adsorbed to remove nonspecific antibodies can be used to identify serotypes and species of *Candida* and serotypes (or variants) of *C. neoformans*. The value of discriminating among the variants of *C. neoformans* (between *C. neoformans* var. *gatti* [serotypes B and C], *C. neoformans* var. *grubii* [serotype A], and *C. neoformans* var. *neoformans* [serotype D]) for the purposes of therapeutic management and predicting the severity of disease is debatable (1). Host immune status appears to be the most critical determinant for disease development and progression. Therefore, only the serologic test for *Candida* spp. will be described. The method is similar for *Cryptococcus* spp.

1. Procedure

- a. Culture yeast isolate on GYEP (see Appendix 8.6–1, item J.3) agar for 48 h at 25°C.
- b. With a loop or applicator stick, transfer a small amount of the yeast colony onto the agglutination test tray.
- c. Add ~50 µl of specific factor serum or, for negative-control purposes, sterile saline.
- d. Roll the test tray to stir the cells and serum together for 1 to 2 min.
- e. Agglutination reactions are either negative, weak positive, moderately positive, or strong positive as indicated in the manufacturer's directions.
- f. No agglutination should occur with the negative control.
- g. Isolates that are positive for only factor sera 1, 4, 5, and 6 are either *C. albicans* serotype A or *C. tropicalis*. These can be differentiated by sucrose fermentation as described by the manufacturer. *C. tropicalis* ferments sucrose, while *C. albicans* serotype A does not.

2. Results

Isolates are identified to the species level based on which factor sera give positive agglutination. Refer to the manufacturer's package insert for reactive patterns.

It is imperative that these cultures be handled in a biosafety hood.

POSTANALYTICAL CONSIDERATIONS

V. INTERPRETATION**Preformed-enzyme test**

A positive test result, i.e., both enzymes present, is presumptive identification of *C. albicans* or *C. dubliniensis*. Rare isolates of *Candida rugosa* and *C. tropicalis* may be positive. Rule out these possibilities by performing a germ tube test.

VI. LIMITATIONS**A. Germ tube test**

Sabouraud dextrose agar is the best medium to isolate yeast for germ tube production; sheep blood agar is an acceptable substitute (our unpublished observations). It should be noted that some *C. tropicalis* isolates produce pseudohyphae, and some also produce germ tubes that require careful observation to discriminate from those of *C. albicans*. A good rule is to see at least five germ tubes before calling an organism positive, as rare tubes may be produced by other species. Frequently, isolates of *C. albicans* produce colonies described as “yeasts with feet” in recognition of a peripheral fringe. This occurs most commonly on serum-enriched media, such as sheep blood agar. These colonies should not be used for the germ tube test, as cells within the colony have produced pseudohyphae and germ tubes.

B. Preformed-enzyme test

The preformed-enzyme test requires several colonies to produce the needed inoculum paste. A mixed culture could cause a false-negative result. A heavy paste of the organism on the disk is necessary. Insufficient inoculum may result in a negative test result.

C. Nitrate swab rapid test

1. If pink to red yeasts are tested by this method, the upper part of the swab should be observed for the color change (to distinguish it from the yeast inoculum in the lower part of the swab).
2. Inoculate the swab with a heavy inoculum to insure a clear-cut reaction.

D. Caffeic acid disk test

The test described here is for rapid detection of phenoloxidase activity. If a false-negative result is suspected, the isolate could be subcultured onto agar medium containing caffeic acid or niger seed (thistle seed) extract. Detection of melanin production on such media depends on colony development; thus, the time to a positive result may be 24 to 72 h.

E. Serologic identification of *Candida* and *Cryptococcus* spp.

C. dubliniensis and *C. albicans* serotype A cannot be differentiated by the serologic method.

VII. REPORTING**General**

An algorithm for reporting germ tube tests is provided in Figure 8.6–1. If a combination of at least two of the tests described above does not provide a presumptive identification of *C. albicans*, *C. dubliniensis*, *C. glabrata*, or *C. neoformans*, then a full identification should be performed; these procedures are outlined in procedure 8.8.

The tests described in this procedure are designed to provide a presumptive identification, or at least information to guide the choice of subsequent identification tests. If a single presumptive test is used for preliminary reporting purposes, then the report should indicate that the identification is presumptive; for example, “yeast, presumptive *Cryptococcus neoformans*.” It may also be useful to provide the basis of the presumptive identification.

VII. REPORTING (continued)

Example: Yeast, presumptive *Cryptococcus neoformans* based on capsule production.

Please note that rare isolates of other yeast species may show capsule production.

APPENDIX 8.6–1

Medium Preparation, Storage, and Sources

A. Sterile calf serum

1. Purchased from BioWhittaker (catalog no. 14-401E).
2. 0.5-ml aliquots are stored at -10 to -30°C .
3. Outdate is 6 months from the date the serum is aliquoted.
4. Racks of aliquots in use are stored at 2 to 8°C .

B. Carr-Scarborough (*C. albicans* screen)

C. Murex (CA-50)

D. Differentiation Disks Urea

1. Purchased from Difco (catalog no. DF1625-33)
2. Expiration date established by manufacturer

E. Rapid nitrate swab (0.2% nitrate)

1. Purchased from Remel (catalog no. 20-355). If unavailable, cotton swabs impregnated with KNO_3 -Zephiran chloride may be used; however, performance of the test will be less satisfactory than with the commercial swabs. The KNO_3 -Zephiran chloride solution is described by Hopkins and Land (1).
2. Stored at 2 to 8°C
3. Expiration date established by manufacturer.

F. Nitrate reagent A (0.08% sulfanilic acid in acetic acid)

1. Purchased from Remel (catalog no. 21-239)
2. Stored at 2 to 8°C
3. Expiration date established by manufacturer.

G. Nitrate reagent B (0.06% *N*-dimethyl-1-naphthyl amine)

1. Purchased from Remel (catalog no. 21-242)
2. Stored at 2 to 8°C
3. Expiration date established by manufacturer

APPENDIX 8.6–1 (continued)

H. Caffeic acid disk for *C. neoformans* screen

1. Remel caffeic acid disk (catalog no. 21-128)
2. Stored at 2 to 8°C
3. Use manufacturer's expiration date.
4. Do not use if the color has changed. The disks should be white.
5. Remel cornmeal agar plates (catalog no. 01-330). Stored at 2 to 8°C. Use manufacturer's outdate.
6. Remel birdseed agar (catalog no. 01-192). Stored at 2 to 8°C. Use manufacturer's outdate.

I. Rapid trehalose assimilation broth tubes

1. Purchased from Remel (catalog no. 06-4856)
2. Stored in the original container at 2 to 8°C

J. *Candida* check kit; *Cryptococcus* check kit

1. Purchased from Iatron Laboratories, Inc., Tokyo, Japan
2. Stored in the original container at 2 to 8°C
3. GYEP agar

glucose	20 g
yeast extract	0.5 g
peptone	10 g
agar	15 g
distilled water	1 liter

Mix, autoclave for sterilization (typically 121°C for 15 min), and pour plates.

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

A pure culture is a prerequisite for the identification of a fungus. Fungi may be polymorphic, and any visible structures present must be demonstrated to be produced by one fungus, not several. Bacteria may also interfere with the development of key characteristics.

Characteristics of the mould, such as whether the hyphae are septate or aseptate, hyaline or dematiaceous; the color and topography of the colony; and production of reproductive structures, all provide information that helps with the identification of the isolate. Although the structures produced by the sexual state are the predom-

inant features for fungal classification and give the fungus the teleomorph name that takes precedence under the *International Code of Botanical Nomenclature*, they are not usually produced in the diagnostic-mycology laboratory. It is usually the vegetative state of the fungus that is isolated from clinical specimens. Moreover, moulds on primary culture are predominantly heterothallic and are therefore in the anamorph, or asexual, state when encountered in the diagnostic-mycology laboratory. It is the architecture of the spore-bearing apparatus of the asexual state that often provides the most important taxo-

nomical features. Filamentous fungi isolated in the laboratory must be accurately identified, and their significance must be assessed, before being reported to the clinician. Many of the fungi isolated are often regarded as contaminants; however, they must be seen as potential pathogens in the correct patient setting. It is therefore imperative to implement procedures that allow the isolate to be assessed as a potential pathogen and differentiated from a contaminant acquired during collection of the specimen, transport to the laboratory, or processing of the specimen in the laboratory.

II. CULTURE EXAMINATION

It is imperative that these cultures be handled in a biosafety hood.

The initial growth of some fungi might require up to 4 weeks of incubation. Occasional isolates of dimorphic, systemic pathogens require 5 to 6 weeks. Plates should be examined frequently during the incubation period. Cultures from specimens from deep sites should be examined daily for the first week and twice weekly for the subsequent 3 weeks. If a dimorphic, systemic pathogen is highly suspected, laboratorians may want to consider examining plates daily for 2 weeks. It should be borne in mind that prolonged incubation increases the risk of contamination, and control plates should be incubated concurrently. When growth appears, it should be examined both macroscopically and microscopically; however, the structures required for genus or species identification might not manifest until the organism has been subcultured onto a suitable medium.

■ *All mould cultures with the possible exception of cultures from clear-cut cases of dermatophytosis should be handled in a class II biological safety cabinet! Mounting reagents for microscopy should contain a disinfectant.*

A. Colony characteristics

The most commonly used agar media in the mycology laboratory are Czapek-Dox agar, malt agar, and glucose peptone agar (Sabouraud glucose agar is one variation of glucose-peptone agar). However, the original sources of agar, peptone, and other basic ingredients can subtly alter the appearance of some fungi on different media. It is preferable to subculture a referred organism onto an

II. CULTURE EXAMINATION

(continued)

agar with which you have become familiar to demonstrate the culture appearance of the fungus under the conditions of your laboratory. Several features should be taken into account when investigating the gross morphology of the culture. The macromorphology features for consideration and examination are the texture, topography, and color of the surface and reverse of the colony.

1. Colony texture

The range of textures of the colony can be described as fluffy (cotton wool-like), some aerial mycelium (velvety), flat (suede-like), and growing into the agar (submerged hyphae). The description of the topography as smooth, flat, roughened, raised, or folded is worth noting; other attributes which could be considered are the appearance of concentric rings of growth and smooth or feathered edges.

2. Growth rate

The rate of growth of a mould may not be reliable on initial culture, but after subculture onto standardized medium, it may be a useful characteristic, if the colony diameter is recorded.

3. Color

The color of the surface of the colony, the uniformity of that color, any color seen on the reverse of the colony, and the presence of diffusible pigments in the medium aid the description of the mould and are useful in the identification of the isolate.

B. Microscopic morphology

The presence of large structures, such as pycnidia, sclerotia or ascocarps, and synnemata (these terms are defined in procedure 8.9), are useful in identification, and their presence can be more easily detected by the use of a low-power dissecting microscope. Also, this microscope can be used to visualize larger structures, such as rhizoids or stolons, to examine the method of spore production, and it is useful for seeing the wetness of the spores (whether they are held in globules of liquid), which can often be difficult to see on microscopical examination and which are too small to be seen by the naked eye.

If fungus from an unknown site or origin is sent to the laboratory, especially from an area of the world where dimorphic fungi are endemic or from a patient who has visited such an area, then the isolate should be handled within the safety cabinet. Such information is typically not known to the laboratorian. Therefore, all moulds should be considered possible dimorphic pathogens until otherwise demonstrated. Mounts and subcultures of such fungi should also be prepared within the safety cabinet. The use of lactophenol as a mountant will kill the fungus and allow the preparations to be handled outside a safety cabinet.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Media

See procedures 8.4 and 8.9 for medium sources, components, and preparation.

B. Reagents and stains

See the individual procedures and Appendix 8.5–1 for sources and preparation.

C. Other supplies

Slides, coverslips, cellophane tape, laboratory loops, inoculation wire, and mounted needles

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

Include QC information on reagent container and in QC records.

- A. Ensure that all media used are within their expiration dates.
- B. Examine all reagents for the presence of contamination or extraneous material.
- C. To ensure that media support growth, color development, and fruiting structures, it is worthwhile to test new lots of media with appropriate control organisms or to compare the characteristics of moulds obtained from clinical specimens against those presented in illustrated texts (or guides) such as St. Germain and Summerbell (2) and Beneke and Rogers (1). However, one should be mindful that some variation in mould characteristics from strain to strain and from one lot of medium to another is likely; thus, organisms will not appear exactly as presented in the illustrated texts.

V. PROCEDURES

It is imperative that these cultures be handled in a biosafety hood.

A. Cellophane tape mount

Most types of transparent sticky tape work for the cellophane tape mount method, but they are not suitable for permanent mounts, as the tape will disintegrate with time. This method usually maintains the original distribution of fungal structures, so it is also suitable only for plate cultures. It is recommended that there be more than one culture, as the tape may contaminate the plate when the preparation is made.

1. Place a drop of lactophenol cotton blue on a clean slide.
2. Cut a short piece of tape and apply the gummed side to the surface of the mould using forceps.
3. Smooth the loop of tape onto the slide, trying to remove any air bubbles.
4. Examine microscopically, noting structures such as hyphae, conidia, spores, or fruiting structures.

B. Tease mount

The tease mount is probably the most common technique used for microscopic examination of fungi; it is a good simple technique but requires practice to obtain optimal results. Do not just drag the wire over the surface, or only spores will be removed. The idea is to see how the spores are attached and any other structures that are present. Poorly sporing isolates may require the preparation of several mounts. Carbol fuchsin is preferred to lactophenol cotton blue by some workers. If identification cannot be made from the tease preparation, it might be necessary to use a slide culture.

1. Place a drop of alcohol on a clean glass slide.
2. Using an inoculation wire, take a fragment from the culture approximately midway between the culture edge and center and place it in the alcohol. Gently tease the fungus apart using the wire and a dissecting (mounting) needle and endeavoring not to destroy any fragile structures. The alcohol serves as a wetting agent and helps to drive out the air bubbles.
3. Place a drop of lactophenol cotton blue on the fungus and add a coverslip by laying it along the edge of the liquid and lowering it with the tip of the dissecting needle to ensure there are no air bubbles.
4. After removal of any excess mountant with a tissue, the coverslip can be sealed with nail polish to preserve the preparation.
5. Examine microscopically, noting hyphae, conidia, spores, or fruiting structures.

C. Slide cultures

The slide culture technique is an invaluable weapon in the diagnostic armory. Its greatest benefit for identification is that it allows the mycologist to examine delicate fungal structures that are often disrupted during the preparation of a

It is imperative that these cultures be handled in a biosafety hood.

It is imperative that these cultures be handled in a biosafety hood.

V. PROCEDURES (continued)

cellophane tape mount or a tease mount. The slide culture preparation can be sealed and preserved as a record of the isolate.

■ **NOTE:** Slide cultures should not be prepared with isolates suspected to be *Blastomyces*, *Coccidioides*, *Histoplasma*, *Paracoccidioides*, or *Cladophialophora* (*Xylohypha*) *bantiana*, as the risk of infection is too great.

The agar selected should induce maximum spore production in the mould group to which the isolate is thought to belong. Two slide cultures should be prepared to allow examination after different incubation times. They should be prepared in a biological safety cabinet.

1. Prepare slide culture dishes by placing a clean, grease-free glass slide supported by a glass rod bent into a V shape in a glass petri dish. The dishes and contents are then sterilized.
2. Cut a block of agar ~0.5 cm square from a sterile plate and place it on the slide.
3. Pour a little sterile distilled water into the base of the dish, but not so much as to wet the agar cube; alternatively, a damp piece of sterile filter paper may be used. The water should be topped up regularly to prevent the agar drying out, but it should not be kept so humid that excessive condensation forms.
4. Inoculate around the edge of the cube with the tip of an inoculation wire, cover with a clean sterile coverslip, and incubate. It is imperative that the cube of agar be smaller than the coverslip, as hyphae grow onto the glass. The diagnostic structures are likely to be formed around the edges of the block.
5. Check regularly during incubation, and when growth is visible, carefully remove the coverslip with fine sterile forceps and place a drop of lactophenol cotton blue on the slide; invert the coverslip onto this edge first to drive out air bubbles. Care should be taken not to disturb the delicate fungal structures. Remove the block from the slide, drop on some lactophenol cotton blue, and then put on a new coverslip.
6. Before examination, wipe the underside and edges of the slide with disinfectant. Note the type of spores and how they are attached and the structures of any spore-bearing bodies.
7. There are variations of the slide culture technique which are also suitable. The important concerns are that there is a glass surface over which the hyphal elements may grow, that the glass surface can be covered with disinfectant, and that the glass surface can be easily viewed by microscopy.

D. Subculture, medium selection, and incubation conditions

If the organism cannot be identified from the primary culture or there is too much contamination for reliable identification, colonies of interest should be subcultured for purity and to induce characteristic features.

1. Subculture

Stab inoculation. Using a bent inoculation on wire, remove some of the fungus and stab it into the center of an agar plate. Incubate the plate at the appropriate temperature until there is sufficient growth for identification. If there is a mixture of fungi or contamination with fungi or bacteria, a streak inoculum of the fungal growth will aid separation from the contaminants for subsequent subculture for purification.

2. Medium selection

The standard laboratory media for subcultures are those that have been used for colony descriptions, such as Czapek-Dox medium for *Aspergillus*. Other common laboratory media used by mycologists include malt agar, glucose peptone agar, and potato dextrose agar. In general, moulds should be subcultured onto nutritionally limited medium, such as potato dextrose agar, and onto a rich medium. Common mycologic media and media that are particu-

It is imperative that these cultures be handled in a biosafety hood.

V. PROCEDURES (continued)

larly useful for specific groups of fungi, such as dermatophytes, black yeasts, coelomycetes, and dematiaceous moulds, are described in procedure 8.9.

There is a vast range of more specialized media developed for particular genera of fungi. Water agar is a minimal medium used to induce sporulation in zygomycetes such as *Apophysomyces* or *Saksenaea*. Dermatophyte test medium is useful in nonspecialized laboratories, as it turns red when a dermatophyte is cultured, and nutrient agar is recommended for the isolation of *Trichophyton verrucosum*. Further details of specialized media are given in procedure 8.9 and its appendixes.

3. Incubation temperatures

Most fungi will grow well if incubated at between 28 and 32°C. However, some species can tolerate higher growth temperatures, and this can be another useful aid to mould identification.

Two subcultures are made from the parent colony, labeled, dated, and incubated, one at 28 to 30°C and one at the higher test temperature. For the test to be valid, there has to be growth of the mould at the lower temperature.

Aspergillus fumigatus is the only *Aspergillus* sp. that will tolerate up to 50°C and will grow well at 45°C; *T. verrucosum* will grow faster at 37 than at 28°C, and *Trichophyton mentagrophytes* will tolerate 37°C. Studies of the mucoraceous fungi show that *Rhizomucor pusillus* will tolerate 50 to 55°C and that *Rhizopus* spp. will grow at 45°C, whereas *Mucor* will tolerate only up to 37°C.

4. Cycloheximide resistance

Cycloheximide resistance can be an indicator for identification, as several fungi, including *Aspergillus* and the mucoraceous moulds *Rhizopus*, *Absidia*, and *Mucor*, are sensitive to it. The inclusion of cycloheximide in agars used to isolate dermatophytes is useful, as most dermatophyte species and some of the dimorphic primary pathogens, *Blastomyces dermatitidis*, *Coccidioides immitis*, *Histoplasma capsulatum*, *Paracoccidioides brasiliensis*, and *Sporothrix schenckii*, are resistant to this antibiotic. At present, there is a worldwide problem with the supply of cycloheximide, and alternatives, e.g., primaricin, have not been evaluated with all these genera. More detail can be found in Table 8.9.–6 below.

Inoculate plates of medium with and without cycloheximide and incubate under identical conditions. Commercial plates typically contain 500 µg of cycloheximide/ml. Growth will be roughly equivalent on both plates if the organism is resistant and vastly reduced or lacking on the cycloheximide plate if the organism is sensitive.

It is imperative that these cultures be handled in a biosafety hood.

POSTANALYTICAL CONSIDERATIONS

VI. INTERPRETATION AND REPORTING

A. General considerations

Whether a mould should be identified to the genus or species level depends on the clinical status of the patient and the site from which the organism was isolated. The isolation of moulds from clinical specimens (*see* item B below) should be considered significant unless there is clear evidence that the mould is a contaminant. The most common fungal etiologies from a range of clinical specimens are shown in Fig. 8.3–1. The correlation of any morphological information from the direct examination with the characteristics of the fungus isolated in culture can aid identification and provide an indication of whether the isolate is likely to be a contaminant.

The reporting of any moulds isolated should, when appropriate, reflect the mycologist's opinion as to whether the mould is likely to be of clinical signif-

VI. INTERPRETATION AND REPORTING (continued)

icance. Reports may include wording such as “possible (or probable) contaminant.” The quantities of fungus grown may be reported with a comment added regarding the mycologist’s interpretation of the results, considering the specimen type, the processes performed on the specimen, and the identification of all fungi isolated. Fungal hyphae can fragment during some processing procedures, so the fragments do not accurately reflect the organism burden in the specimen. This is often the case in ground tissue samples. Thus, a single colony can, in a particular clinical situation, have as much significance as multiple colonies. Similarly, when multiple plates are inoculated with specimen but only one plate gives rise to a colony, the significance of that one colony is not lessened. Multiple factors, such as the specimen sampling error and growth requirements, can influence the isolation of a fungus.

B. Dermatological specimens

Dermatophytes and other filamentous fungi may be significant if grown from nail specimens that were positive by direct microscopy or if from a patient who is immunosuppressed or immunocompromised or has some other underlying problem. In these instances, the clinician ought to be aware that the presence of a mould, such as *Acremonium* or *Fusarium*, could be suspicious, and repeated specimens should be taken and evaluated. The isolation of *Scytalidium dimidiatum* from such susceptible patients could be important, as these fungi do not respond well to azole antifungals.

Evaluation of the fungal load recovered from scalp samples taken using soft toothbrushes or small, circular, soft hairbrushes is potentially useful when screening families with children where scalp ringworm is suspected. Children with infection tend to yield significantly greater counts of dermatophytes when the brushes are directly inoculated into the growth medium.

C. Respiratory and sterile body site specimens

Any fungus grown from a sterile site is potentially significant. The type of patient, specimen, result of direct examination, antigen tests (if appropriate), and fungus grown need to be considered, and the possibility of contamination during collection, transport, processing, or incubation must be excluded. If the fungus is of dubious importance, repeat specimens should be requested when possible.

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

In an era of increasing resistance of yeast species to antifungal agents and a widening range of species capable of causing diseases previously the domain of *Candida albicans*, there is almost no situation in which identification to species level is not warranted. This is especially true given the growth in the number of immunocompromised patients in our society, which has provided more opportunities for yeast infections to occur and to complicate and prolong the recovery period. Molecular methods to identify yeasts are under development, but no commercially available method which identifies a broad range of species has been introduced. In this procedure, methods which take advantage of physiological characteristics of various yeast species are presented. Molecular methods are discussed in general terms.

Carbon and nitrogen source differences are the primary characteristics used to discriminate yeast species, along with cell morphology and sexual reproductive structures when applicable. A variety of semiautomated and automated devices are available to perform carbon and nitrogen assimilation and carbohydrate fermentation tests. However, not all of these provide 100% agreement with the traditional method of Wickerham and Burton (37). In particular, less commonly isolated species tend to show poorer agreement. This problem can be offset by testing a large number of isolates of the unusual species for inclusion in any database provided by the manufacturer of commercial yeast identification systems. Other commercial systems take advantage of preformed enzymes alone or in conjunction with carbon

and nitrogen source assimilation and fermentation. When preformed enzymes are the only basis of the identification system, final results can be obtained in <8 h for many commonly encountered yeasts. The issue of database potency is also a consideration with these enzymatically based systems.

Sexual reproductive structures (e.g., asci and ascospores) may be formed by some yeasts on specialized media. As a result of the evidence of sexual reproduction, yeasts with species epithets in the form-phyllum Deuteromycota were invalid and the organisms were reassigned to one of the other phyla (typically Ascomycota) and taxonomically identified with a new genus-species binomial (teleomorph). While it is technically correct to call such an organism by this new binomial, the invalid asexual (anamorph) taxon is commonly used by physicians and microbiologists. It is unlikely that the anamorph name will disappear from use in the near future, and therefore, we have provided a listing of the anamorph-teleomorph binomials for the most commonly isolated yeasts in the clinical laboratory (Table 8.8-1).

The methods discussed below are designed to provide identification information for most of the commonly encountered pathogenic yeasts (Tables 8.8-2, 8.8-3, 8.8-4, and 8.8-5). The following several points concern yeast identification.

A. Figure 8.5-1 in procedure 8.5 provides an approach based on colony and microscopic characteristics. The initial screening tests are very useful and may suffice for the extent of identification

required for a particular specimen and quantity of organisms.

- B. A common practice for some specimens is to report a yeast isolate as either “*Candida albicans*” or “not *Candida albicans*” based on a germ tube test. While the germ tube test is an excellent screening test, the identification is presumptive because *Candida dubliniensis* can also form germ tubes and *Candida tropicalis* can produce pseudohyphae that closely resemble germ tubes except for the location of the septum, which can be difficult to see without high magnification. Clinical situations in which this report may be sufficient include the initial occurrence of either oropharyngeal or vaginal candidiasis, sputum isolates when deemed clinically significant, and isolates from onychomycosis.
- C. A variety of relatively inexpensive commercial systems that provide reliable identification of commonly encountered yeasts are available. These include API 20C, IDS RapID Yeast Plus, Vitek Yeast Biochemical Card, Fongiscreen, API Candida, Auxacolor, Microring YT, Fungichrom *I*, Fungifast *I twin*, Uni-Yeast Tek, ID 32C, and the Rapid Yeast Identification Panel (10).

Procedures for supplemental tests that may be required and the organisms for which the supplemental tests are most useful are provided in item II below and in procedure 8.5.

With all commercial systems, strict adherence to the manufacturer’s directions is required. Errors, such as overfilling cu-

pules (API 20C) and variations from recommended inoculum concentrations, will cause spurious results.

In general, the following tests should be performed as part of the initial identi-

fication routine of a yeast along with the commercial system: urease, morphology agar, and glucose assimilation (check for pellicle).

Tables 8.8–4 and 8.8–5 provide some of the characteristics of various pathogenic yeasts.

II. TESTS USEFUL FOR YEAST IDENTIFICATION FROM PRIMARY OR SECONDARY CULTURES

Supplemental tests can sometimes provide the single result that identifies an organism. Colony color is one indication (*see* procedure 8.5), and in combination with microscopic appearance, an identification can nearly be obtained (*see* Fig 8.5–2 above). It is recommended that morphology agar or cornmeal agar–2% Tween 80 be set up simultaneously with any commercial identification system. Yeast morphology on standard primary media and on morphology agar may, at times, be all that is needed to obtain an identification (21). Cycloheximide sensitivity testing (Appendix 8.8–1) and ascospore formation are reserved for problematic identifications (1). Refer to procedure 8.10 for sensitivity results and to Hazen (15) for ascospore and ascus characteristics of ascomycetous yeasts (e.g., *Saccharomyces cerevisiae*).

The supplemental tests take advantage of characteristics that are restricted to a limited set of organisms (Table 8.8–3). When these characteristics are present, in

Table 8.8–2 General considerations of two commercial yeast identification systems

System	Incubation period (h)	Principle	QC organisms	Comments
API 20C	72	Assimilation	<i>Cryptococcus laurentii</i> (ATCC 18803) <i>B. capitatus</i> (ATCC 10663)	New formulation requires strict adherence to inoculum preparation.

Lactose assimilation	<i>C. kefyi</i> , <i>Trichosporon</i> spp., some non- <i>C. neoformans</i> species
Morphology agar	Various species (part of subculture routine)
Glucose fermentation ^c	Most <i>Candida</i> spp. (+); <i>Cryptococcus</i> species (–); ascomycetous yeasts (generally +); basidiomycetous yeasts (generally –)
Cellobiose fermentation ^c	<i>C. guilliermondii</i> (+); <i>H. anomala</i> (variable)
Maltose fermentation ^c	<i>C. albicans</i> (+); <i>C. tropicalis</i> (+); other <i>Candida</i> spp. (–)

^a Note that some tests are components of commercial systems. They are listed because they are key tests.

^b +, positive; –, negative.

^c Fermentation tests require that the yeast first be grown on a sugar-free medium, such as malt extract agar or yeast morphology agar.

II. TESTS USEFUL FOR YEAST IDENTIFICATION FROM PRIMARY OR SECONDARY CULTURES (continued)

the absence of other indicative information, you should consider with some caution that the test organism is part of the limited set. Other tests that should be considered are the screening tests described in procedure 8.6.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Media

1. Nitrate assimilation test; yeast carbon agar, Wickerham card, KNO₃-saturated disks (see Appendix 8.8–1)
2. Sporulation (ascospore production); ascospore agar deeps, V-8 juice agar deeps, TB Kinyoun stain kit (see Appendix 8.8–1)
3. Carbohydrate fermentation test for yeast identification; yeast fermentation with control, glucose, cellobiose, maltose, sucrose, distilled water, and Vaspar (see Appendix 8.8–1)

■ **NOTE:** The requirement for Vaspar is questionable. It is included here because it does provide a barrier to oxygen penetration into the fermentation broths.

4. Canavanine-glycine-bromthymol blue (CGB) agar; for media and method of preparation, see Appendix 8.8–1.

B. General supplies

Petri dishes, microscope slides, coverslips, inoculating loops, Pasteur pipettes, water bath, microscope, and McFarland standards

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

Include QC information on reagent container and in QC records.

A. Media

Use within the expiration date.

B. Organisms

The following organisms should be used for the test indicated at the same time and in the same manner as the test being performed on the clinical isolate.

1. Nitrate assimilation test

Cryptococcus albidus ATCC 10231 is positive for nitrate utilization and positive for peptone growth, and *C. albicans* ATCC 60193 is negative for nitrate utilization but positive for peptone growth.

Table 8.8–4 Culture and biochemical characteristics of yeasts frequently isolated from clinical specimens^a

^d Also called an infection peg, which penetrates host tissue (hair).

IV. QUALITY CONTROL (continued)

2. Sporulation (ascospore production)

S. cerevisiae ATCC 24903 produces ascospores on ascospore agar.

3. Carbohydrate fermentation test for yeast identification

Performed at each receipt of medium and when testing a clinical isolate. We test only glucose and cellobiose fermentations, as they are helpful for organisms (e.g., *Candida lusitanae*) which have equivocal results with commercial assimilation kits. For glucose assimilation, the QC organisms are *C. lusitanae* ATCC 66032 (positive) and *C. albicans* ATCC 10231 (negative). For cellobiose fermentation, the QC organisms are *C. albicans* ATCC 10231 (positive) and *Blastoschizomyces capitatus* ATCC 10663 (negative). Other species which are useful for QC of other carbohydrate fermentation broths include *Candida glabrata* ATCC 2001 (trehalose positive) and *Candida kefyr* ATCC 8553 (lactose, sucrose, and galactose positive). *C. albicans* ATCC 10231 can be used for maltose fermentation.

V. PROCEDURES

Observe standard precautions.

A. Carbon assimilation test for yeast identification to species level

Carbon assimilation, in practical terms, is the ability to use a sole carbon substrate for growth; thus, an organism that assimilates a substrate will show growth or increased turbidity. There are several commercial kits which provide standardized carbon assimilation tests. Each kit is combined with a typically extensive database by which to identify an isolate based on the organism's assimilation profile. Examples of such assimilation test systems are the API 20C test (bioMérieux), the Vitek Yeast Biochemical Card (bioMérieux), and the YT MicroPlate (Biolog, Hayward, Calif.). Table 8.9–2 provides the QC organisms for the API 20C test. Assimilation tests can also be performed using nonautomated methods. These methods are described by Larone (21).

B. Nitrate assimilation test for yeast identification to species level

Yeast carbon agar with the addition of various nitrogen sources tests the ability of yeasts to assimilate nitrogen. Potassium nitrate and peptone are used as the nitrogen test sources. The peptone serves as a positive growth control. The nitrate reductase test *does not* substitute for the nitrate assimilation test.

V. PROCEDURES (continued)

Procedure

1. Melt two tubes of yeast carbon base medium per isolate or control.
2. In a separate tube of sterile distilled water, make a suspension of the yeast isolate to be identified in which the density is not greater than 1+ with a Wickerham card (line seen clearly but with rough edges).
3. When the tubes of yeast carbon base medium have melted and cooled to 50°C, so as not to kill the yeast, add 0.1 ml of the yeast suspension to each tube of medium.
4. Mix thoroughly but gently, taking care to avoid air bubbles, and pour into the sterile petri dish.
5. When agar has hardened, place a KNO₃ disk and a peptone disk on opposite sides of the plate at least 1 cm from the edge.
6. Incubate the plate with the inoculated surface up at 30°C for 48 to 96 h.

C. Sporulation (ascospore production)

One of the characteristics used to identify most fungi is the method of sporulation and the arrangement and morphology of the spores produced. In some fungi, sexual reproduction produces spores in an ascocarp. This contains small sacs, or asci, which contain ascospores. The medium used to demonstrate the production of ascospores in yeast depends on which species of yeast is suspected, i.e., *Saccharomyces*, *Schizosaccharomyces*, and *Candida norvegensis* produce ascospores on acetate (ascospore) agar, but all other yeasts produce ascospores more readily on V-8 juice agar.

Procedure

1. For those yeasts that produce ascospores on ascospore agar
 - a. Melt the ascospore agar deep in a boiling water bath and cool to 45 to 50°C.
 - b. Mix and pour into a sterile 15- by 100-mm petri dish. Allow the agar to solidify.
 - c. Inoculate the medium with the yeast to be identified.
 - d. Incubate at 25 to 30°C for 3 to 10 days.
 - e. After 3 days of incubation, perform a wet prep to check for ascospores.
 - f. If ascospores are seen or suspected, prepare a suspension of the yeast in a drop of water on a microscope slide.
 - g. Let the smear dry, heat fix it, and stain it by Kinyoun's acid-fast staining method (see procedure 7.2).
 - h. Examine microscopically for acid-fast (red) ascospores.
 - i. If no ascospores are seen, reincubate and reexamine daily for seven more days. If the control (*S. cerevisiae*) is positive and the test is negative at the end of 7 days, the result is considered negative.
2. For those yeasts that produce ascospores on V-8 juice agar
 - a. Melt the V-8 juice agar deep in a boiling water bath and cool to 45 to 50°C.
 - b. Mix and pour into a sterile 15- by 100-mm petri dish. Allow the agar to solidify.
 - c. Follow the procedure above for yeasts that produce ascospores on ascospore agar.

D. Carbohydrate fermentation test for yeast identification

Fermentation reactions are rarely used to identify yeasts because of the incubation period required and because assimilation reactions can identify most species isolated in the clinical laboratory. However, fermentation tests have their value when other tests cannot resolve an identification. A positive fermentation reaction is indicated by the presence of gas (bubbles) in the inverted Durham tube, *not* by a change in the bromthymol blue indicator.

V. PROCEDURES (continued)

It is imperative that these cultures be handled in a biosafety hood.

Procedure

1. Prepare a diluted suspension of a pure, 24- to 48-h-old yeast culture in distilled water equal to a no. 1 McFarland standard. Select control organisms that demonstrate a positive and negative test for each carbohydrate tested.
2. Add a single drop of this suspension to each tube of yeast fermentation broth.
3. Add a layer of molten Vaspar directly onto the top of the broth.
4. Incubate at 25 to 30°C and shake daily. Higher temperatures lead to breakdown of disaccharides.
5. Read the tubes every 2 to 3 days for the first week and then weekly up to 24 days.

E. CGB agar for differentiation of the three varieties of *Cryptococcus neoformans* (var. *grubii* [serotype A], var. *neoformans* [serotype D], and var. *gattii* [serotypes B and C])

CGB agar contains canavanine, which inhibits the growth of serotypes A and D and provides presumptive differentiation of the varieties of *C. neoformans*. In addition, serotypes B and C are able to assimilate glycine as a carbon source and will turn the medium blue (20). When growth of serotypes A and D does occur, it is typically weak, and there is no change in the medium color. This medium has relatively high sensitivity and specificity (30). The need to differentiate the varieties for the purpose of medical management is debatable. Knowledge of the varieties causing cases of cryptococcosis in a geographic area may be useful epidemiologically. If the specific serotype of a *C. neoformans* isolate is critical, then serological (e.g., Crypto Check Kit [Iatron Laboratories]) or molecular methods are recommended.

Procedure

1. Streak yeast inoculum onto medium. Use a heavy inoculum.
2. Incubate at 25 to 30°C.
3. At 5 days, evaluate plate growth. A positive test result is a color change to blue and indicates the yeast is the variety *gattii*.

F. Other methods for yeast identification

There are a variety of commercial systems for rapid (<8 h) and nonrapid identification of yeasts. Some of these systems are automated. The systems are reviewed by Freydiere et al. (10) and by Wolk and Roberts (39) and will not be described here.

POSTANALYTICAL CONSIDERATIONS

VI. REPORTING AND INTERPRETATION

A. Nitrate assimilation test for yeast speciation

1. Positive growth control (Peptone-inoculated portion)
 - a. All yeasts utilize peptone as a source of nitrogen—if this portion of the plate has *no* growth after 48 to 72 h, the test is invalid.
 - b. If growth is present, proceed to examine the KNO₃ area.
2. Positive test result
 - a. Growth control positive
 - b. Growth also present on KNO₃ portion of plate
3. Negative test result
 - a. Growth control positive
 - b. No growth on KNO₃ portion of plate

B. Sporulation (ascospore production)

1. Positive result: acid-fast (red) ascospores are seen among the counterstained yeast cells.
2. Negative result: no ascospores are seen.

VI. REPORTING AND INTERPRETATION *(continued)*

C. Carbohydrate fermentation tests

Positive fermentation is indicated by turbidity and accumulation of gas (CO₂) in the Durham tube or underneath the Vaspar seal. The bromthymol blue indicator will turn yellow due to carbohydrate assimilation. (All fermented carbohydrates will be assimilated, but not all assimilated carbohydrates will be fermented.) Fermentation reactions for some *Candida* spp. are given in Table 8.8–6.

VII. LIMITATIONS

Carbohydrate fermentation tests—a false-positive reaction may occur due to endogenous carbohydrates present in the yeast cells if a heavy inoculum is used.

VIII. MOLECULAR METHODS FOR THE IDENTIFICATION OF YEASTS

At present, yeasts are not routinely identified using nucleic acid technology; however, a number of different methods have been developed for use in research, in the development of diagnostic methods, and for epidemiological investigations. The literature contains frequent references to sequencing technology and its utility for species identification. Indeed, sequencing rRNA genes has differentiated closely related organisms, such as *Candida dubliniensis*, *C. albicans*, and *Candida stellatoidea* (33) and the *Malassezia* spp. (13). However, the equipment required for sequencing is not widely available to routine microbiology laboratories, so a variety of genetic recognition methods have been developed that utilize generally available equipment. These methods include restriction enzyme analysis (REA), pulsed-field gel electrophoresis (PFGE), probes, and applications of PCR. As there are no routine procedures to follow, descriptions of some of the available techniques and their applications are provided below.

REA or restriction fragment length polymorphism has been used for species and strain recognition, with the results dependent on the restriction enzyme used. The method requires extraction of DNA, followed by digestion with a suitable restriction enzyme and electrophoresis to separate the DNA fragments. The fragment band pattern is then compared for similarity to reference strains or other isolates of the same species. The enzymes *EcoRI* (24) and *HinfI* (11) have been used for a variety of *Candida* spp., and species-specific patterns have been described. These enzymes have been used for strain typing, but the discrimination of strains differs for each species; isolates of *C. albicans* are easily discriminated, but isolates of *Candida*

Table 8.8–6 Fermentation reactions for some *Candida* spp.^a

Species	Fermentation reaction ^b			
	Glucose	Maltose	Cellobiose	Sucrose
<i>C. albicans</i>	+	+	–	–
<i>C. dubliniensis</i>	+	+	–	–
<i>C. guilliermondii</i>	+	–	–	+ (w)
<i>C. krusei</i>	+	–	o	–
<i>C. lusitaniae</i>	+	–	+	V
<i>C. parapsilosis</i>	+	–	–	–
<i>C. tropicalis</i>	+	+	–	+ (v)

^a Note that *C. guilliermondii* and *C. parapsilosis* produce distinctively different morphologies on morphology media. *C. albicans* and *C. dubliniensis* are physiologically very similar. The difficulty in distinguishing these organisms is that no single differential test (e.g., growth at 45°C, color formation on CHROMagar, or assimilation profile) is definitive. However, several (at least three) differential tests in combination provide sufficient information to identify an organism as one or the other species. Otherwise, molecular techniques should be employed to distinguish the species.

^b –, negative; +, positive; o, not tested routinely; v, rare negatives; V, strain variation; w, weak.

VIII. MOLECULAR METHODS FOR THE IDENTIFICATION OF YEASTS (continued)

parapsilosis show few differences. The DNA pattern from restriction digests can be transferred to membranes by Southern blotting and hybridized to DNA probes. Probes have been designed that are species specific and do not hybridize to DNA from unrelated species: for example, 27A (28) and Ca3 (29) for *C. albicans*, Ct3 for *C. tropicalis* (19), Cg6 and Cg12 for *C. glabrata* (23), and Cp3-13 for *C. parapsilosis* (9). Variations within the hybridization patterns of such species-specific probes have been used to differentiate strains and in some cases have been used to demonstrate minor genetic changes within a single strain over a period of time, a process referred to as microevolution.

PFGE is a technique used to separate large fragments of DNA and whole yeast chromosomes which do not resolve using conventional gel electrophoresis. The method of extraction is unlike other DNA methods, as yeast cells are exposed to cell wall-digestive enzymes and lysed while immobilized inside agarose blocks. This ensures that chromosomes remain intact and are not fragmented by mechanical processes, such as pipetting or vortexing. The electrophoretic chromosome profiles, or karyotypes, can be used for identification, especially for species that exhibit little or no variation in the karyotype pattern between isolates. The seven species of *Malassezia* have unique karyotypes and demonstrate virtually no strain variation (2, 17) (Table 8.8–7), whereas there is sufficient variation to distinguish between isolates of other species, such as *C. albicans* and *C. glabrata* (6, 7).

PCR is becoming a powerful tool for species identification, as it requires less time than the other methods and can be performed on samples containing very small amounts of DNA. PCR amplifies specific sections of DNA, which are determined by the choice of primers, and the amplified products are examined using gel electrophoresis. Primers have been designed that recognize sequences common to all fungi, such as the internal transcribed spacer (ITS) and nuclear small (NS) sequences in the ribosomal DNA regions (36). Amplification using these primers produces DNA that can be used for identification by comparing the size of the amplicon and by its restriction digestion patterns (38). Another approach has used the M13 minisatellite sequence as a primer, which produced characteristic band patterns for each species and has even been used to identify anamorph and teleomorph pairs (22). Random amplification of polymorphic DNA using single oligomer primers and low annealing temperatures has generated fingerprints character-

Table 8.8–7 Key characteristics to differentiate *Malassezia* spp.

Species	Growth on Sabouraud dextrose agar ^a	Catalase	Assimilation of Tween ^b :		
			20	40	80
<i>M. pachydermatis</i>	+	–/w ^c	–	+	+
<i>M. restricta</i>	–	–	–	–	–
<i>M. sympodialis</i>	–	+	– ^d	+	+
<i>M. furfur</i>	–	+	+	+	+
<i>M. slooffiae</i>	–	+	+	+	–/w
<i>M. globosa</i> ^e	–	+	–	–	–
<i>M. obtusa</i> ^e	–	+	–	–	–

^a All species other than *M. pachydermatis* require lipid supplementation for growth. +, positive; –, negative.

^b This test is performed as described in references 12 and 13.

^c w, weak. Performed by placing a drop of H₂O₂ (10%) either directly on the plate culture or onto the smear of the culture on a glass slide (13, 14).

^d Growth of *M. sympodialis* is inhibited by high concentrations of Tween 20. At lower concentrations, the organism exhibits Tween 20 assimilation (13, 14).

^e *M. globosa* and *M. obtusa* can be distinguished by their morphologies. *M. globosa* is globose, while *M. obtusa* produces long, cylindrical cells.

VIII. MOLECULAR METHODS FOR THE IDENTIFICATION OF YEASTS (continued)

istic of species (34) and has facilitated strain typing of many organisms. However, reproducibility problems, particularly for strain typing, make interlaboratory comparisons of fingerprint patterns difficult (32). Species-specific primers have been developed for yeast identification and typing (4) and have been used in combination with universal primers for the detection of yeast DNA in mixed cultures (25) and from clinical specimens (3). DNA amplified using universal primers has been hybridized with species-specific probes to detect *Candida* spp. in blood samples (8, 31, 35) and has detected *C. albicans* in ocular samples (18). Yeasts have been detected in infected blood and CSF samples using primers for the ERG11 gene and hybridization to species-specific probes (27). Amplification of the ITS2 region, combined with precise determination of amplicon length and sequence polymorphism, distinguished 34 species of yeasts, some of which differed by <2 bp in length (5).

Many of these methods are not yet widely used, but as sequence databases are constructed and made available, automated sequencing and array technology will develop to provide rapid identification of numerous yeast species. The ability to provide prompt and accurate identification of an infecting organism directly from clinical material has obvious implications for early diagnosis and choice of the most appropriate therapy.

SUPPLEMENTAL READING

Remel. 1993. Technical information, ascospore agar. TI no. 9046-A. Remel, Lenexa, Kans.

APPENDIX 8.8-1

Medium Preparation and Sources

A. Morphology agar

1. Available commercially as a dehydrated powder from Remel (catalog no. 459962).
2. An alternative to morphology agar is to use cornmeal—Tween 80 with or without trypan blue (available as prepared plates from Remel [catalog no. 01328 and 01330, respectively]).
3. If not available commercially, cornmeal-Tween 80 can be prepared by the following recipe.

cornmeal	40.0 g
agar	20.0 g
Tween 80 (polysorbate 80)	10 ml
distilled water	1 liter

Mix cornmeal with 500 ml of water and heat for 1 h at 65°C. Filter through cheesecloth to clarify solution and add sufficient water to bring volume back to original. Adjust to pH 6.6 to 6.8. Dissolve agar in 500 ml of water by heating and add to cornmeal solution. Add Tween 80 and autoclave (121°C; 15 min). Dispense into petri dishes.

B. Nitrate assimilation test for yeast identification to species level

1. Yeast carbon agar
 - a. Purchased commercially from Remel (catalog no. 09-984)
 - b. Stored at 2 to 8°C
2. Disks impregnated with saturated KNO₃ or peptone solutions
3. Wickerham card—this can be made by drawing three parallel black lines 0.75 mm thick and 5 mm apart.
4. If yeast carbon agar is not available commercially, use the recipe provided by Atlas (1).

C. Sporulation (ascospore production)

1. Ascospore (also called Acetate Ascospore) agar deeps
 - a. Purchased from Remel (catalog no. 09-046)
 - b. Stored at 2 to 8°C
 - c. If not available commercially, use the following recipe.

potassium acetate	5 g
yeast extract	1.25 g
glucose	0.5 g
agar	15.0 g
distilled water	500 ml

Dissolve by boiling for 1 min and dispense into tubes. Autoclave (121°C; 15 min) and allow tubes to cool in slanted position.

2. V-8 juice agar deeps
 - a. Purchased from Smith River Biologicals (catalog no. 24V8)
 - b. Stored at 2 to 8°C
 - c. If not available commercially, use the following recipe.

V-8 juice	500 ml
dry baker's yeast	10.0 g
agar	20.0 g
distilled water	500 ml

Dissolve agar by boiling it in water. Mix juice and dry yeast; adjust to pH 6.8 with 20% KOH and then add to dissolved agar solution and mix well. Dispense into tubes. Autoclave (121°C; 15 min), and allow tubes to cool in slanted position.

3. TB Kinyoun stain kit
 - a. Contents of kit
 - (1) TB Kinyoun stain carbolfuchsin
 - (2) TB Kinyoun stain decolorizer
 - (3) TB Kinyoun stain brilliant green
 - b. Purchased from BBL (catalog no. 12318)
 - c. Stored at room temperature

APPENDIX 8.8-1 (continued)

D. Carbohydrate fermentation test for yeast identification

1. Yeast fermentation broth
Purchased commercially from Remel (with control, 06-5402; dextrose, 06-5314; cellobiose, 06-5310; maltose, 06-5330; sucrose, 06-5462). Alternative source is PML Microbiologicals (control, T-79-00; glucose, T-79-02; maltose, T-79-08; cellobiose, not available; sucrose, T-79-10).
Stored at 2 to 8°C
2. Distilled water
 - a. Stored at 2 to 8°C
 - b. Expiration date is 3 months from preparation.
3. No. 1 McFarland standard
 - a. Purchased from Remel (catalog no. 20-351)
 - b. Stored at room temperature
4. Vaspar (1 part white petrolatum and 2 parts paraffin tissue embedding medium)
 - a. Outdate is 1 year after preparation.
 - b. Stored at room temperature

E. Canavanine-glycine-bromthymol blue CGB agar for differentiation of the three varieties of *Cryptococcus neoformans* (var. *grubii* [serotype A], var. *neoformans* [serotype D], and var. *gattii* [serotypes B and C])

1. Agar

agar	20 g
------------	------
2. Solution A

glycine	10 g
KH ₂ PO ₄	1 g
MgSO ₄	1 g
thiamine-HCl	1 mg
L-canavanine sulfate	30 mg
distilled water	100 ml

Adjust to pH 5.6 and filter sterilize.

3. Solution B

sodium bromthymol blue	0.4 g
distilled water	100 ml

Mix 880 ml of distilled water, 20 ml of solution B, and 20 g of agar. Autoclave (121°C; 15 min), and cool to 50°C. Add 100 ml of solution A. Mix thoroughly and dispense into petri dishes (15 to 20 ml/plate).

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

“Mould” is an informal term signifying a fungus growing mostly or entirely in the form of diffuse filaments and usually producing an asexual reproductive state or a sexual state that is not a large, complex fruiting body. Most such fungi are recognized as asexual states or asexual species (the former have known sexual states, while the latter do not) related to various fungi in the phyla Ascomycota and Basidiomycota. In addition, members of the phylum Zygomycota generally grow as moulds.

Current conventions for naming moulds depend on which group they come from. Members of the Zygomycota, in which the asexual state is dominant, possess only a single name per biological species. Members of the Ascomycota and Basidiomycota, however, may or may not produce complex sexual states that, in pre-molecular times, were the best sources of information for systematic classification. Therefore, many species had one nonsystematic “form” or “anamorph” name for the asexual state as it was commonly seen in the laboratory and another, fully systematic “teleomorph” or “holomorph” name for the sexual state, if it could be produced in the laboratory or found in the field. Sometimes these names were unknowingly coined independently and were

not connected until years later. In addition, a few species had more than one anamorph name for radically different growth forms that were difficult to connect as being part of the same species—this convention is known as the “synanamorph name.” As molecular biology proceeds, the anamorph and synanamorph names could in theory be eliminated. They are, however, almost universally the best-known and most widely used names and also connect to common disease names, such as coccidioidomycosis, histoplasmosis, and aspergillosis. Nomenclatural stability is preferred whenever possible by everyone working with fungi, and therefore the anamorph names have been retained.

Although molecular and biochemical characters more and more facilitate identification of some moulds, it remains difficult in the “real world” to compete with morphological identification. It may require knowledge, but it is generally inexpensive and rapid. The more the laboratorian knows, the more these advantages can be maximized. Characteristics learned from cultures can sometimes even be recognized in direct specimen microscopy or histopathology (e.g., *Scedosporium* conidia in sinus wall scrapings), making possible the medical laboratory ideal of a 2-min preliminary identification directing

optimal therapy, with more time-consuming techniques directed toward confirmation.

Morphological classification schemes for moulds of ascomycetous and basidiomycetous affinities emphasize conidial ontogeny, that is, the process by which asexual propagules form. Conidial ontogeny provides a grounding in very stable characters that can then allow consideration of more variable characters, such as colony color and conidial septation. In some fungi in which conidia are similar among different species or are lacking or slow to form, supplementary characteristics, such as temperature tolerance, cycloheximide resistance, conversion in vitro to a host-adapted particulate state (e.g., yeast, spherule, or fission yeast), nutritional requirements, and enzymatic activities, may be used. In a few cases, immunological or nucleic acid-based confirmatory techniques are needed.

This procedure will first survey the types of characteristics that are examined in the different fungal groups. Then, using the terminology from this survey where necessary, procedures will be outlined. Some extra terminology usually applied only to dermatophytes will be mentioned in a separate item.

II. MOULD MICROMORPHOLOGY

Techniques for making microscopic mounts and observing mould structures are dealt with in procedure 8.7. The information below applies to the structures seen.

A. General mould micromorphological characteristics

A few general structural names are applied to morphologies seen across a wide range of moulds (Table 8.9–1); a few terms are seen mainly in mycological specialist literature and need not be learned unless such literature is approached.

B. Mould micromorphologies found in specific groups

1. Zygomycota

Most Zygomycota seen in the clinical laboratory are members of the order Mucorales. In culture, these fungi are rapidly growing, with woolly, brownish-gray colonies often over 1 cm deep. Less common Zygomycota that can be isolated from serious infections include members of the order Entomophthorales. These produce filaments that, while initially coenocytic, become septate much more rapidly than those of the Mucorales. Importantly, therapy of entomophthoromycoses may be very different from that of mucormycoses and other fungal diseases, making rapid identification valuable.

The morphological characteristics of these two orders are described and examples are given in Table 8.9–2 and Fig. 8.9–A1 and 8.9–A2 in Appendix 8.9–1

2. Ascomycota

Ascomycota make up most of the mould fungi of the medical laboratory, including all the dimorphic fungi, the dermatophytes, and the common opportunistic moulds producing normally septate filaments in tissue. Their colonies include all colors, growth rates, and textures. One distinctive charac-

Table 8.9–1 Definitions of terms used to describe morphological structures

Morphological characteristic	Definition
Ameroconidia	Single-celled conidia
Chlamydospore (resting cell)	Differentiated, swollen cells that remain attached to the mycelium on which they were formed; not disseminated (Note: occurrence of “spore” in “chlamydospore” is an anachronistic holdover that cannot be rationalized with modern structural terminology, but “chlamydospore” is still in use.)
Conidia (singular, conidium)	Propagules formed asexually by breaking off of cells or morphologically differentiated branches
Dictyoconidia (or muriform conidia)	Conidia divided in more than one plane by septa and thus appearing to be composed of squarish or polygonal cells
Didymoconidia	Conidia with a single cross wall dividing them into two cells
Hyphae (singular, hypha)	Fungal filaments
Mycelium	An aggregation or mass of hyphae (Note: singular word)
Phragmoconidia	Conidia with two or more parallel septa in a linear series
Sclerotia (singular, sclerotium)	Large multicelled resting structures formed on colony surface as round, rarely tubular, masses of compacted cells
Septa (singular, septum)	Cross walls dividing hyphae
Spores	Sexually formed propagules or propagules formed by free cell formation

Table 8.9–2 Phenotypic characteristics useful for identification of Zygomycota

Characteristic	Definition	Identification aid
Aseptate coenocytic filaments; >4 µm wide; often undulate	No cross walls; one extended, multinucleate, tubular cell; large diameter; often wavy outline	Mucoralean zygomycetes visible by direct microscopy of specimen and culture. Note that adventitious septa may be present.
Adventitious septa	With age, parts of coenocytic filaments die and are cut off from living portions by cross walls, the adventitious septa.	These septa are highly irregular in spacing and may be found in older hyphae connected to tracts of younger, aseptate hyphae.
Sporangiophores (Fig. 8.9–A1)	Tall upright branches that end in a sporangium	Useful to distinguish fungi such as <i>Rhizopus</i> and <i>Absidia</i> as members of the Mucorales in culture.
Sporangium	Sac-like inflated apex of a sporangiophore in which a mass of sporangiospores is produced	Seen in <i>Rhizopus</i> , <i>Mucor</i> , <i>Absidia</i>
Sporangiospores	One-celled spores found inside a sporangium	
Columella	Apex of sporangiophore forms an empty, swollen structure that supports the sporangium.	
Collarette	The collarette is the remnant of the sporangial wall attached to the columella; seen when spore mass is removed.	
Apophysis (Fig. 8.9–A1)	The sporangiophore has a funnel-shaped apex supporting the columella, beneath the collarette.	<i>Absidia</i> has typical funnel- or trumpet-bell-shaped apophysis. The apophysis of <i>Apophomyces elegans</i> is vase shaped.
Rhizoids (Fig. 8.9–A2)	Tuft of root-like structures that act as counterbalance to clusters of sporangiophores	<i>Rhizopus</i> —sporangiophores unbranched in tufts joined at base with rigid, thick-walled, often brown rhizoids located opposite (i.e., nodal) sporangial tufts. <i>Rhizomucor</i> —multiply branched sporangiophores; rudimentary rhizoids <i>Absidia</i> —some rhizoids produced when long aerial hyphae touch agar surface; not formed near sporangiophores; often not seen in medically important <i>A. corymbifera</i> .
Vesicle	Empty bulbous structure at apex of sporangiophore gives rise to one-celled sporangiospores on individual short pegs.	<i>Cunninghamella</i> —swollen vesicle If spores knocked off, vesicle appears spiny due to stubs of spore pegs.
Merosporangia	Vesicles that produce cylindrical finger-like sacs containing spores in a linear arrangement	<i>Syncephalastrum racemosum</i> merosporangia have 3 to 18 spores.
Primary spores	Large (~40-µm diameter) spores formed on short stalks and mechanically discharged by the sudden popping out of a papilla	Seen in <i>Conidiobolus</i> (Zygomycota, order Entomophthorales) (Note: other Entomophthorales may not have these structures.)
Papilla	Small mammary shape at base of the primary <i>Conidiobolus</i> spore	
Secondary microspore	Discharged primary <i>Conidiobolus</i> spores may produce a crown-like apical zone of short pegs bearing secondary microspores at their tips.	
Zygosporangia	As seen in <i>Basidiobolus</i> , thick-walled spores found in subsurface mycelium. These are sexual spores with beak-like structure composed of two cells fused side by side.	Different types of zygosporangia are formed by other zygomycetes, but except in <i>Basidiobolus</i> , these structures are seldom seen in the clinical laboratory.

II. MOULD MICROMORPHOLOGY

(continued)

teristic, melanization, resulting in strongly olive-gray to black colonies, is found in at least some members of three major groups, the Pyrenomycetes, Discomycetes, and Loculoascomycetes. Simply structured asexual stages of such melanized fungi were previously referred to as the form family Dematiaceae (hence the description of pigmented moulds as dematiaceous). Simply structured asexual states lacking such dark pigmentation were placed in the form family Moniliaceae. Asexual states with complex, flask- or

II. MOULD MICROMORPHOLOGY (continued)

blister-shaped fruiting structures were referred to as the class Coelomycetes. Finally, asexual states with no reproduction in culture were called Mycelia sterilia. The well known names Dematiaceae, Moniliaceae, Coelomycetes, and Mycelia sterilia have been dropped from formal use but remain in informal use. At the family level and above, asexual states are now said to belong to the holomorphic groups to which they have shown genetic affinity, e.g., *Aspergillus* is considered to be a eurotiaceous fungus (related to family Eurotiaceae), not a member of the Moniliaceae.

Both asexual and sexual states may be seen in ascomycetous fungi, but asexual states are more common and are usually quicker to form. The basis of conidial ontogeny (i.e., mode of production), rather than other characteristics, such as color and shape, is used for identification (Table 8.9-3 and Fig. 8.9-A3 to 8.9-A12 in Appendix 8.9-1).

3. Basidiomycota

Most clinically significant Basidiomycota are yeasts, not moulds. Members of the basidiomycetous yeast genus *Trichosporon* may be wrinkled-velvety in texture and look like arthroconidium-producing moulds, but they can ordinarily be found to also produce at least a few hyaline budding cells, identifying them (somewhat arbitrarily) as yeasts. Most other basidiomycetes of the clinical laboratory are seen as fast-growing, cottony moulds that are among the most common contaminants of certain types of specimens, especially respiratory secretions. They are very susceptible to cycloheximide but will grow on media like plain blood agar intended to isolate cycloheximide-sensitive systemic pathogens, such as the basidiomycetous yeast *Cryptococcus neoformans*. About half the isolates seen produce copious arthroconidia (usually simple, but sometimes alternate), while the other half remain sterile (nonreproductive). In nature, these isolates would ordinarily mate with others of the same species and produce a conspicuous sexual fruiting body (basidiome), such as a mushroom or wood decay conk (defined as the visible fruiting body of a bracket fungus). Those with arthroconidia are morphologically recognizable, especially when their cycloheximide intolerance has been ascertained. The others may be confirmed as probable basidiomycetes by their good growth on agar amended with 10 µg of benomyl/ml (20).

On rare occasions, basidiomycetous moulds cause infections. The most commonly significant organism is the split-gill mushroom *Schizophyllum commune*, which regularly causes chronic mycotic sinusitis and rarely other infections. It may occur as an unmated, haploid form with ordinary septate filaments and sterile, cottony cultures, but more commonly it occurs as a mated, dikaryotic form (that is, containing pairs of nuclei with one member of each pair derived from each of the two mating parents) whose hyphae, at each septum, bear a characteristic side loop called a clamp connection (Fig. 8.9-A13 in Appendix 8.9-1) looping laterally from the end of one adjacent cell to the beginning of the next. These connecting loops, derived from the complex cell division typical of dikaryotic hyphae, can be seen in histopathology and in sterile cultures, allowing instant identification of the organism as a basidiomycete. After 14 or more days in culture, most dikaryotic *S. commune* isolates form mushrooms in vitro, and in some cases the continuation of the sexual cycle may be followed. The mushroom gills give rise to a layer of club-shaped sexual cells called basidia (Fig. 8.9-A14 in Appendix 8.9-1), and nuclear fusion and meiosis take place in each one. Then, the four nuclear products of this reduction-division are incorporated into basidiospores attached by small outgrowths at the apex of each basidium. Each basidiospore is then forcibly shot into the air.

Table 8.9-3 Description of terms for conidial ontogeny and reproductive structures of the Ascomycota

Characteristic	Definition	Identification aid
Thallic	Simplest mode of conidiation. Filament differentiates so that it separates into individual cells or produces specialized short side branches that break away.	
Blastic	Conidiation begins at a focal site. An initially thin-walled, rounded, or tubular daughter cell begins to extend by a budding-like process out of a mother cell. It then differentiates into its characteristic form as it matures and is cut off by a septum so that it can break away.	
Arthroconidia	Example of thallic conidiation (<i>see</i> next two entries).	
Simple arthroconidia (Fig. 8.9-A3)	Produced when every cell of a fragmenting filament becomes a separate conidium	E.g., <i>Geotrichum</i> , <i>Scytalidium</i>
Alternate arthroconidia (Fig. 8.9-A4)	Nutrient-filled, healthy conidia are linked on either side by dead, empty disjunct cells that autodigest and break up.	E.g., <i>Coccidioides immitis</i> , <i>Malbranchea</i>
Aleurioconidia	Second form of thallic conidiation; specialized side branches break off.	
Micro(aleurio)conidia (Fig. 8.9-A5, right)	Small, single-celled side branches with bulbous tips break off.	E.g., dermatophytes, mould phase of <i>Histoplasma capsulatum</i>
Macro(aleurio)conidia (Fig. 8.9-A5, left)	Large, sometimes multicelled, more strongly inflated and differentiated side branches that break off	E.g., dermatophytes, mould phase of <i>H. capsulatum</i>
Spherule	Unique form of thallic conidiation; swollen, large spherical structure that divides internally into endoconidia, which fragment apart at maturity	Found in particulate host phase of <i>C. immitis</i>
Sclerotic fission cells	Rounded single cells split by arthroconidium-like fission into two daughter cells	E.g., <i>Fonsecaea pedrosoi</i> and related agents of chromoblastomycosis
Blastoconidia; yeast budding (Fig. 8.9-A6)	Simplest form of blastic conidiation; yeast buds usually single celled; blastoconidia from filaments may be larger and more specialized.	Black yeasts, e.g., <i>Exophiala</i> ; yeast states of dimorphic fungi, e.g., <i>H. capsulatum</i> <i>Cladosporium</i> and <i>Cladophialophora</i> produce bud-like conidia that initially fail to separate from each other, giving rise to upright conidial chains.
Conidiophore	Specialized fertile filament	
Sympodial proliferation	Conidiophore produces a budded conidium, elongates, and produces another conidium, etc. Each elongation is called a proliferation. In sympodial structures, proliferation often occurs at a Y-shaped angle to the conidium just produced.	
Rosette (Fig. 8.9-A7)	The proliferations of sympodial conidiophores are short, and when conidia remain attached, the whole structure resembles a flower.	E.g., <i>Sporothrix schenckii</i>
Rhachis	Longer extensions between conidial proliferations produce a zigzag structure.	E.g., <i>Beauveria bassiana</i>
Poroconidia	Conidia formed from a conidiophore, usually a rhachis, that shows a conspicuous, small, dark, ring-shaped scar at each place where a conidium formed and broke away	E.g., <i>Curvularia</i> , <i>Alternaria</i>
Collarette	Collar-like remnant of cell wall around the tip of a conidiophore producing phialo- or annelloconidia	
Enteroblastic	Successive conidia bud out from within the collarette as extensions of the inner cell wall.	
Phialide (Fig. 8.9-A8)	Simplest type of conidiogenous cell that produces enteroblastic conidia	Bottle-shaped phialides— <i>Phialophora</i> , <i>Aspergillus</i> . Needle-shaped phialides— <i>Acremonium</i>
Uniseriate (Fig. 8.9-A9)	In <i>Aspergillus</i> , phialides attached to a swollen vesicle located at apex of conidiophore.	E.g., <i>A. fumigatus</i>
Biseriate (Fig. 8.9-A9)	<i>Aspergillus</i> vesicle forms short branches (metulae), which bear tufts of phialides.	E.g., <i>A. terreus</i>

Table 8.9–3 (continued)

Characteristic	Definition	Identification aid
Anellide (Fig. 8.9–A10)	Each time a conidium is produced, an additional collar-ette or swelling is formed on the apex of the phialide.	E.g., <i>Scopulariopsis</i> , <i>Scedosporium</i> , <i>Exophiala</i>
Synnema	Formed where several hyphae bundle together and produce a tall, heavily stalked composite conidiogenous structure	E.g., <i>Graphium</i> synanamorph of <i>Pseudallescheria boydii</i>
Sporodochium	Hyphal bundles resemble cushion-like structures bearing masses of conidia.	E.g., <i>Fusarium</i> spp.
Pycnidium (Fig. 8.9–A11)	Flask-like structure that has differentiated opening (ostiole) and that contains conidia produced on conidiogenous cells	
Ascomata (Fig. 8.9–A12)	Sexual structure of an ascomycetous fungus; in the type most common in medically important fungi, the cleistothecium, a hollow ball or flask-like structure, produces single-celled sacs (asci) in the interior. Each ascus produces a set number of ascospores, 4 or 8, or rarely, 16 or 32. The outer wall of the cleistothecium is called the peridium.	Ascal structure helps to differentiate ascomata from asexual pycnidia.
Homothallism	Condition in which a single isolate goes through a sexual cycle without mating; this is seen as formation of teleomorphs (sexual states) in single strains.	E.g., some <i>Aspergillus</i> spp. <i>P. boydii</i>
Heterothallism	Sexual cycle that results from mating of two strains of opposite mating types	E.g., some dermatophytes, <i>H. capsulatum</i>
Cleistothecium	Asci formed within a closed ball-shaped ascoma that must crack to release ascospores	E.g., <i>Emericella nidulans</i> , teleomorph of <i>Aspergillus nidulans</i>
Evanescent	Walls of asci dissolve shortly after ascospore formation.	E.g., <i>Pseudallescheria</i>
Perithecium	An ostiole develops at the apex of a short protuberant neck of the ascoma.	E.g., <i>Chaetomium</i>
Hülle cells	Ascomata surrounded by a layer of round cells with heavily thickened walls	E.g., <i>Emericella</i>
Setae	Stiff, sharp, elongated spines on the ascomata	E.g., <i>Arthroderma</i> has helical setae, or “spirals,” also found in conidium-producing tufts of <i>Trichophyton mentagrophytes</i> .

III. DIMORPHIC FUNGI

Dimorphic fungi are thermal or thermal-nutritional dimorphic systemic pathogens that convert from a mould phase in ordinary culture or the environment to a budding yeast phase in the host or under special growth conditions at 37°C. Examples include *Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Paracoccidioides brasiliensis*, and *Sporothrix schenckii*. Certain dimorphic fungi produce thallic rather than yeast-like particulate phases, e.g., *Coccidioides immitis*, which produces spherules, and *Penicillium marneffei*, which produces elongated arthroconidia that fragment into daughter arthroconidia.

Once an isolate is suspected of being a dimorphic pathogen, based on colony and microscopic morphologies, it is essential to confirm its identity. Conversion to the particulate phase in vitro can be demonstrated for *B. dermatitidis* on specialized media (see item VII.C.3 below) within 48 to 72 h, although a type from sub-Saharan Africa may take several weeks to convert. *H. capsulatum* and *P. brasiliensis* also require specialized media for conversion, although the latter can also convert on BHI-blood agar. The medium of choice for *P. marneffei* is Sabouraud dextrose agar, and for *S. schenckii* it is BHI agar with overlaid liquid 10% yeast extract. Conversion of *C. immitis* is not reliable as a diagnostic test, even on specialized media; therefore, alternative confirmatory tests are required.

III. DIMORPHIC FUNGI

(continued)

Nucleic acid probes and exoantigen tests are available for the identification of *B. dermatitidis*, *H. capsulatum*, and *C. immitis*, but not for *P. marneffeii* and *S. schenckii*. Exoantigen testing is an alternative for identification but always requires time for subcultures to grow. These molecular tests are subject to a proportion of false results; therefore, the strict use of controls is required to minimize erroneous reporting.

IV. MATERIALS

In order to segregate preanalytical, analytical, and postanalytical considerations, the present procedure is structured to divide individual processes into up to five separate items. These are materials, given in item IV; QC, given in item V; identification techniques, given in item VII (for most moulds) or VIII (for dermatophytes); reporting and interpretation, given in item IX; and media and reagents, given in Appendix 8.9–2. Generally, to obtain complete information on a process, the notes for the process must be followed through these items. Connecting links are written into the text to facilitate this.

A. Fungal sporulation media for best visualization of reproductive structures in moulds

Several types of media are available for sporulation or conidiation of a wide range of fungi (Table 8.9–4). Some commonly used types in clinical mycology are listed below. See Appendix 8.9–2 for sources and recipes.

B. General supplies

1. Incubators at 35, 37, 40, 42, 45, 50, and 55°C (for temperature testing as outlined in item VII.B for species listed in Table 8.9–5)
2. Pipettes (variable volume)
3. Needles and loops
4. Slides and coverslips
5. Petri dishes
6. Glass tubes for media

C. Nucleic acid probe

1. AccuProbe kit
2. Luminometer

3. Sonicator
4. Heating block
5. Water bath
6. Vortex
7. Glass rods

See items V.B and VII.C.2 for QC and procedure and supplier information, respectively.

D. Conversion of dimorphic fungi

For specialized growth media needed, see sources and recipes in Appendix 8.9–2, as well as the interconnected items on QC (V.D) and procedure (VII.C.3).

E. Exoantigen test

Antiserum, with test antibody and control antigens, is available as kits, and the immunodiffusion agar plates are available commercially (see Appendix 8.9–2 for sources and recipes). Antigens are extracted using merthiolate and are concentrated with an Amicon Minicon macrosolute B-15 concentrator. More details, including supplier information, are given in the procedure for this method outlined in item VII.D below. A moist chamber or plastic bag is needed for the immunodiffusion plates.

F. Dermatophyte identification

Media include Sabouraud dermatophyte decontamination broth, *Trichophyton* agars, Christensen's urea agar and broth, bromocresol purple (BCP) milk glucose agar, 10% yeast extract broth, and cornmeal glucose agar. See Appendix 8.9–2 for sources and recipes and item VIII below for procedures.

Table 8.9–4 Common media used for moulds

Medium	Fungus
Potato glucose agar	Most fungi
Leonian's agar	Most fungi, especially ascomycetous moulds, basidiomycetes, <i>Microsporium canis</i>
Potato flake agar	Most fungi; especially useful for dermatophytes
Cereal agar	Dermatophytes, to reduce pleomorphic degeneration
Tap water agar	<i>Alternaria</i> , <i>Bipolaris</i> , <i>Exserohilum</i> (order Pleosporales), or similar isolates with fast-growing, nonsporulating, dark mycelia

Table 8.9–5 Temperature tests commonly used in identification of clinically important moulds

Mould	Temp (°C) (characteristic) ^a	Status
Zygomycota		
<i>Absidia corymbifera</i>	37 (+)	Opportunistic
Other <i>Absidia</i> spp.	37 (–)	Nonpathogenic
<i>Cunninghamella bertholletiae</i>	45 (+)	Opportunistic
<i>Cunninghamella elegans</i>	37 (–)	Nonpathogenic
<i>Mortierella wolffii</i>	45 (+)	Opportunistic
Other <i>Mortierella</i> spp.	45 (–)	<i>M. polycephala</i> rarely opportunistic; others nonpathogenic
<i>Mucor circinelloides</i>	37 (+/w/–)	Opportunistic when thermotolerant
<i>Mucor ramosissimus</i>	37 (–)	Reported as opportunistic (maximum growth temp, 36°C)
Most other <i>Mucor</i> spp.	37 (–)	Nonpathogenic
<i>Rhizomucor miehei</i>	55 (+)	Rarely opportunistic
<i>Rhizomucor pusillus</i>	50 (+); 55 (+/w/–)	Opportunistic
<i>Rhizomucor microsporus</i> var. <i>microsporus</i>	45 (+); 50 (–)	Opportunistic
<i>Rhizomucor microsporus</i> var. <i>rhizopodiformis</i>	45 (+); 50 (+/w); 55 (–)	Opportunistic
<i>Rhizopus oryzae</i>	37 (+); 40 (+); 45 (w/–); 50 (–)	Opportunistic
<i>Rhizopus stolonifer</i>	37 (–)	Nonpathogenic
Ascomycota		
Eurotiales		
<i>Aspergillus fumigatus</i>	42 (+); 45 (+ [rarely –])	Opportunistic
<i>A. flavus</i>	45 (+)	Opportunistic
<i>A. terreus</i>	45 (+)	Opportunistic
<i>A. nidulans</i>	45 (+)	Opportunistic
<i>A. versicolor</i>	37 (+); 45 (–)	Normally nonpathogenic; opportunistic in nails
<i>A. sydowii</i>	37 (+); 45 (–)	Normally nonpathogenic; opportunistic in nails
<i>Paecilomyces variotii</i>	40 (+); 50 (+ or –)	Opportunistic
<i>Penicillium chrysogenum</i>	37 (+); 40 (–)	Rarely opportunistic
<i>Penicillium citrinum</i>	37 (+); 40 (–)	Rarely opportunistic
<i>Penicillium decumbens</i>	37 (+); 40 (–)	Rarely opportunistic
Most other <i>Penicillium</i> spp. in subgenera <i>Penicillium</i> , <i>Furcatum</i> , <i>Aspergilloides</i>	37 (–)	Nonpathogenic
<i>P. marneffei</i>	37 (+) (converts to fission cells on SAB)	Pathogenic
<i>P. purpurogenum</i>	37 (+) (mycelium only); 45 (–)	Rarely opportunistic
Other <i>Penicillium</i> spp. in subgenus <i>Biverticillium</i> (including red-pigmented species and <i>Talaromyces</i> anamorphs)	37 (+ or –); 45 (+ or –); 55 (+ or –)	Rarely opportunistic when thermotolerant (e.g., <i>P. piceum</i> , <i>P. verruculosum</i>)
Onygenales		
<i>Trichophyton gloriae</i>	37 (+)	Nonpathogenic; rare
<i>T. mentagrophytes</i>	37 (+)	Pathogenic
<i>T. rubrum</i>	37 (+)	Pathogenic
<i>T. terrestre</i>	37 (–)	Nonpathogenic; common
<i>T. tonsurans</i>	37 (+)	Pathogenic
<i>Chrysosporium georgiae</i>	37 (+ or –)	Nonpathogenic; uncommon
<i>Chrysosporium</i> state of <i>Arthroderma cuniculi</i>	37 (–)	Nonpathogenic; uncommon
Mycosphaerellaceae		
<i>Cladosporium cladosporioides</i>	35 (–)	Rarely reported as opportunistic; even case isolates do not grow at 37°C.
<i>Cladosporium herbarum</i>	35 (–)	Nonpathogenic; occasional case reports dubious

Table 8.9-5 Temperature tests commonly used in identification of clinically important moulds (*continued*)

Mould	Temp (°C) (characteristic) ^a	Status
Herpotrichiellaceae		
<i>Cladophialophora arxii</i>	40 (+)	Opportunistic (rare)
<i>Cladophialophora bantiana</i>	40 (+)	Opportunistic
<i>Cladophialophora boppii</i>	37 (+); 40 (–)	Opportunistic (rare)
<i>Cladophialophora carrionii</i>	37 (+); 40 (–)	Opportunistic
<i>Cladophialophora devriesii</i>	37 (+); 40 (–)	Opportunistic (rare)
<i>Cladophialophora emmonsii</i>	37 (+); 40 (+ or –)	Opportunistic
<i>Exophiala (Wangiella) dermatitidis</i>	40 (+)	Opportunistic
<i>Exophiala jeanselmei</i>	37 (+); 40 (–)	Opportunistic
<i>Exophiala mesophila</i>	35 (–)	Nonpathogenic
<i>Exophiala moniliae</i>	30 (–) (former type strain)	Reported as opportunistic, but probably misidentified
<i>Exophiala spinifera</i>	37 (+); 40 (–)	Opportunistic

^a +, positive; –, negative; w, weak; SAB, Sabouraud agar.

ANALYTICAL CONSIDERATIONS

V. QUALITY CONTROL

■ **NOTE:** QC strains are listed for the tests below. Strains recommended by manufacturers of commercial products have been tested specifically and verified as reliable. On the other hand, “possible QC strains” listed for the remaining tests are known to be typical representatives of the species in question, but in most cases their performance in the specific test mentioned has not to our knowledge been validated in the published literature. Exceptions for some very limited applications may be found in NCCLS document M22-A2 (14). Expected results for a number of additional strains are listed by Sewell (17), who also states that “any strain that yields identical results is acceptable” for QC. In general, however, the strains listed here should be used with caution until validation studies have been done to ascertain the reliability of their QC application and the durability of this status under various conditions. It must be understood that dermatophyte and dimorphic fungal colonies stored as living cultures, whether refrigerated or kept at room temperature, may degenerate slowly or rapidly over time. It is best to make subcultures of QC strains immediately upon receipt and to store these subcultures in a –20 to –80°C freezer or, where possible, to make lyophils or liquid nitrogen storage preparations. New subcultures can then be made from the frozen or lyophilized material on a regular basis or at least when the living strain appears to have degenerated, that is, to have lost its original morphological or pigment features. The actual functional shelf lives of metabolically active cultures are not known for any of the strains cited below. There are as yet many unsolved problems in applying QC techniques to mycological testing. At present, pending formal studies of individual QC strains, a fresh isolate shown in local preliminary tests to give good performance may be substituted for the strains listed below, except for strains recommended by manufacturers. This is because undegenerated fresh isolates may be more reliably typical in such tests than any stored isolate.

A. Media

1. Always use commercial media within their expiration dates.
2. Ensure that the media are performing as expected by testing each batch with an isolate of known morphology.
 - a. Potato glucose agar (PGA)—St. Germain and Summerbell (19) suggest verifying yellow pigment production in a typical *Microsporium canis* isolate. Heavy production of macroconidia should also be seen. Possible QC

Include QC information on reagent container and in QC records.

V. QUALITY CONTROL

(continued)

strains: CBS (Centraalbureau voor Schimmelcultures, Utrecht, The Netherlands) 496.86, ATCC (American Type Culture Collection, Manassas, Va.) 36299, and UAMH (University of Alberta Microfungus Collection and Herbarium, Edmonton, Canada) 4174. For specific storage considerations involving the QC strain, see Appendix 8.9–2. There is no negative control for this medium.

- b. Leonian's agar—use a typical *M. canis* isolate, as for PGA.

☑ **NOTE:** Dermatophyte pigments are not expected to develop well on this medium.

- c. Potato flake agar (for the commercial formulation, see Appendix 8.9–2; for the procedure, see item VIII.C.4 below)

(1) Ensure that the indicator color is yellow.

(2) A typical red-pigmented *Trichophyton rubrum* isolate acts as a positive control, turning the indicator to blue-green in 7 days at 25 to 32°C. Visible red colony on reverse side after 7 to 10 days. Possible *T. rubrum* QC strains: ATCC 28188 and CBS 392.58.

B. Biochemical test

Cycloheximide resistance (see item VII.A below for procedure)—for a negative control, use *Candida glabrata* (CBS 138 = ATCC 2001 = IFO [Institute for Fermentation, Osaka, Japan] 0622 [same strain in all collections]), *Candida krusei* ATCC 14243, or *Aspergillus niger* ATCC 16404, which will not grow in the presence of 0.5 g of cycloheximide/liter, and use *Candida albicans* (ATCC 10231 = CBS 6431 = IFO 1594 [same strain in all collections]) as the resistant positive control.

C. Nucleic acid probe (see item VII.C.2 below for procedure)

1. Positive control organism—known strain of the test species. Recommended cultures: ATCC 60916 or UAMH 3604 (*B. dermatitidis*), ATCC 38904 or UAMH 3536 (*H. capsulatum*), and ATCC 28868 (*C. immitis*). As of this writing, ATCC 38904 and ATCC 28868 are no longer available from the ATCC; indeed, all distribution of *C. immitis* has been discontinued in connection with bioterrorism concerns. Several *H. capsulatum* strains remain available. In the absence of a recommended QC strain, a typical, well-confirmed clinical isolate giving an equally strong positive signal may of necessity be substituted. Typical *C. immitis* isolates may still be obtained from other culture collections, such as CBS, but there may be restrictions on shipment to some jurisdictions. See the comments in item VII.C.2 below on ongoing maintenance of QC strains in good metabolic condition to permit rapid, controlled testing.
2. Negative control—dimorphic fungus closely related to the test strain. Use *H. capsulatum* when *C. immitis* or *B. dermatitidis* is tested, and use *B. dermatitidis* when *H. capsulatum* is tested. Recommended cultures are as given above.

D. Conversion of dimorphic fungi (see item VII.C.3 below for the procedure and Appendix 8.9–2 for medium recipes and sources)

1. *B. dermatitidis*—use a readily converting North American or North African isolate; look for detached yeast cells budding with a broad base within 72 h at 37°C. Possible QC strains: ATCC 60916, CBS 673.78, and UAMH 3604.
2. *H. capsulatum*
 - a. Medium (Kurung-Yegian)—should be opaque, smooth, yellow with final pH of ~6.6.
 - b. Use a strain that converts to yeast phase within 5 to 15 days at 37°C. Possible QC strains: CBS 214.53, ATCC 8136, and UAMH 3536.
3. *P. marneffei*—reference strain should convert to a heaped, pasty, cream-colored colony composed of short branches rapidly fragmenting into arthro-

V. QUALITY CONTROL

(continued)

conidia, with colony composed mostly of free arthroconidia in early growth and entirely at maturity (7 days postconversion). Possible QC strains: ATCC 18224 = CBS 334.59 (same strain) or ATCC 24100 = UAMH 4181. If a negative control is required, *Penicillium purpurogenum* (possible QC strain: CBS 364.48 = ATCC 9777 [same strain]) will produce flattened, restricted colonies of hyphae, often with swellings and other irregularities and generally with relatively dark colony color and reverse colony pigments.

E. Identification of dermatophytes (see item VIII below for procedures and Appendix 8.9–2 for media and sources)

1. Christensen's urea agar—*T. rubrum*, negative result on days 7 and 10 at 25°C. Possible QC strain: ATCC 28188. *Trichophyton mentagrophytes*, discernible positive result by day 7, full positive reaction by day 10. Possible QC strains: ATCC 9533, CBS 318.56, and UAMH 5888.
2. BCP agar—positive control for pH change: *T. mentagrophytes* (alkalinity, purple color at 7 to 10 days at 25°C); negative control, *T. rubrum* (no indicator color change until after 14 days). Possible QC strains: ATCC 9533, CBS 318.56, and UAMH 5888 (*T. mentagrophytes*); ATCC 28188, CBS 392.58, and UAMH 8547 (*T. rubrum*).
3. Cornmeal glucose agar—typical *T. rubrum* strains should develop wine-red reverse pigmentation; *T. mentagrophytes* will be uncolored to reddish brown. QC strains as in item 2 above.
4. Polished-rice medium—*Microsporum audouinii* reference isolate shows feeble growth and may or may not produce some brown pigment (possible QC strains: CBS 108934 [African variant usually seen today] and ATCC 10216 [classic strain type]); *M. canis* reference isolate (possible QC strains: CBS 496.86, ATCC 36299, and UAMH 4174) shows vigorous growth and abundant yellow pigmentation.
5. Hair perforation test—positive control: *T. mentagrophytes* (possible QC strains: ATCC 9533, CBS 318.56, and UAMH 5888), or *M. canis*. Negative control: *T. rubrum* (possible QC strains: ATCC 28188, CBS 392.58, and UAMH 8547).

VI. PRELIMINARY IDENTIFICATION AND SUBSEQUENT CONFIRMATORY TESTS

Preliminary identification of isolates from primary culture is outlined in procedure 8.7. The colony appearance, microscopic morphology, temperature tolerance, cycloheximide sensitivity, and growth rate will provide clues to the genus of the isolate. This information should allow a suitable choice of culture medium for a slide culture to induce better production of characteristic microscopic morphology. In some instances, all of this information and the experience of the laboratorian will be sufficient for species identification. Where identification is uncertain or not possible, culture on the most suitable agar to induce conidiation and growth and a series of biochemical tests most appropriate for the suspected fungus (see below) should be performed.

VII. BIOCHEMICAL AND PHYSIOLOGICAL TECHNIQUES USED IN GENERAL MOULD IDENTIFICATION

Mould identification techniques differ to some extent among different types of laboratory mycology, and in some areas, using micromorphology alone may be inappropriate or too slow. In particular, many dermatophyte types have undergone evolutionary processes that tend to diminish both sexual and normal conidial reproduction. Some species essentially never produce conidia, apart from substrate arthroconidia formed in host tissue. Therefore, physiological or other characteristics are commonly used in the laboratory. Dimorphic fungi in their mould states all strongly resemble at least one nonpathogenic fungal species and thus need to be confirmed by specialized techniques. Confirmatory tests for dimorphic fungi, as

It is imperative that these cultures be handled in a biosafety hood.

VII. BIOCHEMICAL AND PHYSIOLOGICAL TECHNIQUES USED IN GENERAL MOULD IDENTIFICATION (continued)

well as physiological tests for dermatophyte identification, will be dealt with in specific items below.

Certain biochemical and physiological characteristics are used across a wide range of fungi. In particular, cycloheximide responses, widely applied in strategies of selective isolation (*see* procedures 8.6 and 8.7), are also useful to assist in identifying mould isolates. Temperature tolerance tests have also become applicable in many specific mould groups. These tests are outlined below.

QC procedures and isolates for many of the tests in this section are dealt with in items V.A to D above.

A. Cycloheximide responses

1. Procedure

Sensitivity may be inferred by examining selective cycloheximide-containing primary isolation media in contrast to cycloheximide-free isolation media used for the same specimen. It can better be determined, however, by sub-culturing colonies onto a cycloheximide medium (e.g., cycloheximide-supplemented Sabouraud's peptone glucose agar) and its cycloheximide-free equivalent control medium (e.g., plain Sabouraud's peptone glucose agar) and incubating them at a suitable temperature and for a duration appropriate to the control growth rate of the organism.

2. Results

Table 8.9-6 lists common or significant moulds showing a characteristic cycloheximide response. In general, many of the more virulent mould pathogens and opportunists are cycloheximide tolerant or semitolerant (i.e., with a restricted colony growth rate but not killed at 100 mg of cycloheximide liter⁻¹ and usually killed or strongly restricted at 500 mg liter⁻¹).

B. Temperature tolerance tests

1. Procedure

a. Temperature tolerance tests can generally be done on any cycloheximide-free medium commonly used for medically important fungi, e.g., plain Sabouraud agar or PGA.

b. Inoculated plates should be placed in incubators at 35, 37, 40, 42, 45, 50, and 55°C and left until growth is visible on the plate at the lowest temperature setting. Alternatively, a lower number of test temperatures may be selected based on relevance to the fungal group being tested (Table 8.9-5).

■ **NOTE:** As they require a range of incubators, these tests may be more convenient in larger laboratory operations, especially where various general and mycobacteriology incubators can be shared for occasional fungal incubations. Smaller laboratories wishing to do a temperature test but lacking the appropriate incubator may inoculate the fungus in question into a relatively narrow tube and immerse it to near the cap in an adjustable water bath stabilized at the temperature in question.

2. Results

Table 8.9-5 shows the common temperature responses examined.

C. Species confirmation of dimorphic moulds

1. Presumptive recognition of mould phases.

Examine the isolate, noting the colony appearance, microscopic morphology, and conidial ontogeny. The salient characteristics of mould phases of dimorphic fungi are given in Table 8.9-7.

2. Confirmation of dimorphic moulds using nucleic acid probes.

DNA probes for confirmation of *C. immitis*, *H. capsulatum*, and *B. dermatitidis* are marketed as kits under the name AccuProbe (Gen-Probe Inc., San Diego, Calif.). The method uses a fluorescent label and requires a lumino-

Table 8.9–6 Cycloheximide responses of common or critical clinical laboratory moulds (including abundant contaminants)

Mould group	Example(s)	Cycloheximide response	Status
Zygomycota			
Mucorales	<i>Rhizopus</i> , <i>Absidia</i> , <i>Mucor</i>	Semitolerant ^a	Opportunistic or nonpathogenic
Ascomycota			
Endomycetes	<i>Geotrichum</i>	Tolerant	Normally nonpathogenic ^b
Eurotiales	<i>Aspergillus</i> , <i>Penicillium</i> , <i>P. variotii</i>	Semitolerant	Opportunistic or nonpathogenic (<i>P. marneffeii</i> is pathogenic)
Onygenales	Dermatophytes, e.g., <i>Trichophyton</i> , <i>Microsporum</i>	Tolerant	Pathogenic
	<i>Coccidioides</i> , <i>Blastomyces</i> , <i>Histoplasma</i> , <i>Paracoccidioides</i> , <i>Emmonsia</i>	Tolerant	Pathogenic
	<i>Chrysosporium</i> , <i>Malbranchea</i>	Tolerant	Normally nonpathogenic
	<i>Onychocola</i>	Tolerant	Pathogenic
Ophiostomatales	<i>S. schenckii</i>	Tolerant	Pathogenic
	Other <i>Sporothrix</i> spp.	Tolerant	Normally nonpathogenic
Microascales	<i>Scopulariopsis</i> , <i>Pseudallescheria</i>	Semitolerant	Opportunistic
	<i>Scedosporium prolificans</i>	Susceptible	Opportunistic
Hypocreales	<i>Acremonium</i> , <i>P. lilacinus</i>	Semitolerant	Opportunistic or nonpathogenic
	<i>Fusarium</i>	Semitolerant or susceptible	Opportunistic or nonpathogenic
Sordariales	<i>Chaetomium</i>	Semitolerant	Normally nonpathogenic
	<i>Phaeoacremonium</i> , <i>Phialemonium</i>	Semitolerant	Opportunistic or normally nonpathogenic
	<i>Arthrinium</i> , <i>Nigrospora</i> , <i>Neurospora</i>	Susceptible	Nonpathogenic
Leotiales	<i>Ochroconis gallopava</i>	Susceptible	Opportunistic
	<i>Ochroconis constricta</i>	Tolerant	Nonpathogenic
Loculoascomyetes			
Dothioraceae	<i>Aureobasidium</i>	Semitolerant or susceptible	Normally nonpathogenic
	<i>Hortaea</i> , <i>Natrassia</i> (<i>Scytalidium dimidiatum</i>)	Susceptible	Pathogenic
Herpotrichiellaceae	<i>Fonsecaea</i> , <i>Exophiala</i> , <i>Cladophialophora</i> , <i>Phialophora verrucosa</i>	Tolerant	Opportunistic
Pleosporales	<i>Alternaria</i> , <i>Curvularia</i> , <i>Bipolaris</i> , <i>Exserohilum</i>	Usually semitolerant	Opportunistic or normally nonpathogenic
	<i>Epicoccum</i>	Susceptible	Normally nonpathogenic
Mycosphaerellaceae	<i>Cladosporium</i>	Susceptible or semitolerant	Normally nonpathogenic
Basidiomycota	<i>Schizophyllum</i> , <i>Hormoglyphiella</i>	Susceptible	<i>Schizophyllum</i> opportunistic; others normally or always nonpathogenic

^a Semitolerant, restricted in colony growth rate but not killed at 100 mg of cycloheximide liter⁻¹; usually killed or strongly restricted at 500 mg liter⁻¹.

^b Normally nonpathogenic, usually insignificant when isolated but rare opportunistic infection is possible.

VII. BIOCHEMICAL AND PHYSIOLOGICAL TECHNIQUES USED IN GENERAL MOULD IDENTIFICATION (continued)

meter to assess the results. It is thus most commonly used by reference laboratories, laboratories in areas of endemicity, or laboratories where similar kits are also used in the mycobacteriology laboratory.

The probe method has the advantage that it can be used on all suspected cultures of the organism, even when they are small (e.g., in early outgrowth on primary isolation plates) or contaminated with bacteria or other fungi. The alternative methods require a culture at least 48 h old, often 7 days old or more, and contamination may cause delay.

The probe test is relatively costly, and in the cases of *B. dermatitidis* and *C. immitis*, consideration may be given to the use of alternative methods in cases where appropriate treatment has already begun on the basis of well-

Table 8.9–7 Distinguishing features for preliminary identification of mould phases of dimorphic systemic pathogens

Species	Mould phase characteristics	Mimics
<i>Blastomyces dermatitidis</i>	Subglobose aleurioconidia, smooth or rarely finely roughened, mostly 2–7 µm in diam, sometimes on swollen stalks, commonly formed on dusty, pale to sandy colonies; however waxy, whitish, poorly conidial colonies are also common.	Closest, <i>Emmonsia</i> spp.; also, various <i>Chrysosporium</i> spp., <i>T. mentagrophytes</i> , microconidial <i>Histoplasma</i> ^a
<i>Coccidioides immitis</i>	Chains of alternate arthroconidia, which are barrel shaped or cylindrical and separated by empty disjunctive cells, are formed on dusty, often thin colonies with a raised margin, tending to creep far up glass tube walls and sides of plastic petri plates.	Closest, <i>Malbranchea</i> state of <i>Uncinocarpus reesei</i> ; also, other <i>Malbranchea</i> spp.
<i>Histoplasma capsulatum</i>	Globose macroaleurioconidia with tuberculate (finger-like) roughening, 8–16 µm in diam; subglobose, rough-walled microaleurioconidia 2–5 µm in diam often also formed; colonies are sandy brown or paler and powdery.	Closest, <i>Chrysosporium</i> states of <i>Renispora flavissima</i> and <i>Arthroderma tuberculatum</i> and <i>Sepedonium</i> spp. <i>R. flavissima</i> and <i>Sepedonium chrysospermum</i> have lemon yellow to golden colonies; <i>Sepedonium</i> usually has a phialidic synanamorph. <i>A. tuberculatum</i> has mainly ovoid, not globose, conidia, but similar conidia may also be found in some <i>H. capsulatum</i> isolates. ^a
<i>Paracoccidioides brasiliensis</i>	Slow-growing colonies with uncommon aleurioconidia and/or arthroconidia	Closest, an uncharacterized soil organism with similar conversion in vitro but avirulent and lacking gp43 antigen (5); also, <i>Chrysosporium</i> spp.
<i>Penicillium marneffei</i>	Colony typically with bright-red reverse and soluble pigment around the colony; surface dull brown or reddish and velvety, with sparse, dull-green conidia formed on biverticillate penicilli (penicilli with two successive ranks of whorled branches, the upper rank consisting of long, sharply pointed phialides); conidia smooth, ellipsoidal, 2.5–4.0 by 2.0–3.0 µm	Closest, several other <i>Penicillium</i> subgenus <i>Biverticillium</i> species with red reverse, e.g., <i>P. purpurogenum</i> , <i>P. minioluteum</i> , <i>P. funiculosum</i>
<i>Sporothrix schenckii</i>	Flat, slow-growing, whitish then partly deep brown to black; sometimes near black from the start; primary conidia formed in sympodial rosettes on spiny tooth-like denticles, hyaline, obovoidal (egg shaped, attached at the thin end), 3–6 by 2–3 µm; secondary conidia deep brown, often subglobose, sometimes triangular, attached individually on denticles on sides of hyphae, especially substrate (in the agar) hyphae, often densely packed and surrounding the hyphae in sleeve-like formation, at the same time turning colony dark	Closest, uncharacterized <i>Sporothrix</i> spp. sharing peat moss and decaying vegetation habitat; also, <i>Sporothrix</i> state of <i>Ophiostoma stenoceras</i> ; most mimics lack secondary conidia. According to Dixon et al. (4), mimics possessing these structures can be distinguished by lack of 37°C growth in vitro; however, the present author has had isolates from confirmed sporotrichosis growing poorly or not at all at 37°C. <i>O. stenoceras</i> forms black, long-necked perithecia after 3–4 wk in culture on PGA or Leonian's agar.

^a See Sigler (18) for detailed descriptions of important mimic fungi.

VII. BIOCHEMICAL AND PHYSIOLOGICAL TECHNIQUES USED IN GENERAL MOULD IDENTIFICATION (continued)

demonstrated, characteristic direct microscopy (histopathology or direct hydroxide mount) plus isolation of a micromorphologically typical culture. The probability of a nonpathogenic mimic species (e.g., various *Malbranchea* spp. in the case of *C. immitis*; various *Chrysosporium*, *Emmonsia*, and *Trichophyton* spp. in the case of *B. dermatitidis*; and various cycloheximide-susceptible basidiomycetes in both cases) being isolated from such a microscopically diagnostic lesion is minimal, and such a coincidental isolation, if it occurred, would not by any means indicate that the interpretation of structures seen in vivo was incorrect. In the case of *H. capsulatum*, which is much less distinctive in tissue and has known in vivo mimics (e.g., *C. glabrata* cells in macrophages), the probe is best utilized in each case if available. For all three organisms, the probe may be advantageously used immediately whenever a suspected culture grows from a lesion for which direct microscopy was negative or whenever direct microscopy was done elsewhere (i.e., in another institution) with an unknown or questionable result.

VII. BIOCHEMICAL AND PHYSIOLOGICAL TECHNIQUES USED IN GENERAL MOULD IDENTIFICATION (*continued*)

The probe test is based on the detection of rRNA, which is present in high quantity in cells. A specific DNA probe labeled with an acridinium ester fluorophore by the manufacturer hybridizes with the species-specific cellular RNA of test isolates; a subsequent luminometer reading then detects the double-stranded hybrids between the test isolate RNA and the probe DNA. Detailed procedures are found in the package inserts that accompany the kits. The information in this procedure should not be substituted for the package insert, as specifications may change if technical improvements are introduced.

Running the AccuProbe tests reliably depends on comparing the test results with results from a simultaneously tested known-positive control strain of the test species (potential control strains are discussed above in item V.C), as well as a negative control strain of another species (protocols with less frequently used controls can be designed for laboratories with a high volume of these tests). Generally, a closely related dimorphic fungus is run as a negative control, e.g., *H. capsulatum* when *C. immitis* or *B. dermatitidis* is tested and *B. dermatitidis* when *H. capsulatum* is tested. If a probe is to be run the same day a new isolate is recognized as a potential dimorphic species, such a stored stock subculture of the same species will suffice as a positive control provided its signal level when the test is completed proves to be above the cutoff value indicated by the manufacturer. In our experience, the probe readings for stored stock cultures are slow to decline, and such cultures may be stored at 25°C in a usable condition for at least 2 months. In the extremely unlikely event of a below-range positive control reading, a new test of the unknown strain against fresh subcultures of the positive and negative controls may be needed, but the failure of the original test is otherwise harmless, in that it cannot give rise to a false test interpretation.

In any case where the laboratory intends to inoculate a subculture of the test isolate for probing after 48 or more hours, the positive and negative control isolates needed should also be subcultured at the same time. A subculture of the test isolate should be inoculated in all cases, since false-positive results may occasionally be caused by very different fungi not resembling the dimorphic fungi in question. For example, fungal melanin may chemiluminesce and cause dark, melanized fungi to give false-negative probe readings for *H. capsulatum* (25). Recently, Iwen et al. (8) reported repeated false-positive results in the *B. dermatitidis* probe for *Gymnascella hyalinospora*, a distantly related and morphologically distinct fungus. *P. brasiliensis* may also cross-react with the *Blastomyces* probe (15). Other limitations of this method are described elsewhere in this handbook.

The basic protocol for the AccuProbe test for mycelial material grown on plates is as follows.

a. Materials

- (1) Test isolate and positive and negative control cultures
- (2) Types of material utilized: DNA probe tubes containing labeled probe, lysis tubes with glass beads, lysis reagent (reagent I), hybridization buffer (reagent II), selection reagent (reagent III), and detection reagents connected to luminometer pumps

b. Set up procedure

- (1) Turn sonicator (Gen-Probe) on 15 min in advance to degas the water.
- (2) Turn on 95°C heating block; prepare 60°C water bath; turn on and prepare luminometer (Gen-Probe) and ensure luminometer detection reagents are in sufficient supply.

VII. BIOCHEMICAL AND PHYSIOLOGICAL TECHNIQUES USED IN GENERAL MOULD IDENTIFICATION (continued)

- c. RNA isolation procedure
 - (1) Label sufficient lysis tubes for test isolate and both control isolates.
 - (2) Add 100 µl each of reagents I and II [see item a.(2) above] to each labeled lysis tube.
 - (3) In the biological safety cabinet, use a loop to take ~2 mm² of mycelium and transfer it to the appropriately labeled lysis tube.
 - (4) Grind the material for 20 to 30 s with a previously ethanol-flamed and cooled glass rod in order to disrupt the mycelium.
■ **NOTE:** This step was added in our laboratory; it is not in the manufacturer's instructions.
 - (5) Briefly vortex each tube and then place in sonicator rack. Sonicate for 15 min at 40 kHz.
 - (6) After sonication, place tubes in a 95°C water bath for 10 min. The resulting solution should be strongly enriched in isolated RNA from the test strains.
- d. Procedure for hybridization of DNA probe to RNA isolated from cultures
 - (1) Label sufficient probe tubes (material type a.(2) in above list) for the number of cultures tested. Add 100 µl of the lysed culture solutions obtained in step 2 (item c above). Vortex briefly.
 - (2) Incubate tubes at 60°C for exactly 15 min. It is important to be vigilant about the time. This is the step in which labeled DNA specifically binds to the RNA in solution. Incubation for too short a time could cause the value of a true-positive result to be lower than it should be in subsequent reading, while incubation for too long may allow nonspecific binding to occur.
 - (3) Add 300 µl of selection reagent [reagent III in item a.(2) above] to each tube and vortex briefly. This reagent hydrolyzes the acridinium ester fluorescent label on any DNA probe that has not bound to compatible RNA from a test isolate, thus minimizing most nonspecific background signal.
 - (4) Incubate tubes at 60°C for exactly 5 min.
 - (5) Remove tubes from the 60°C water bath and leave them at room temperature for 5 min. Remove the caps and read the results in the luminometer within 1 h.
 - (6) Compare the final values of the luminometer readings to acceptable cutoff values for positive results as given by the manufacturer. The positive control and positive test isolate readings should be above 1,500 photometric light units (PLU) in the Gen-Probe ACCULDR (formerly PAL)-type luminometer or 50,000 relative light units (RLU) in the Gen-Probe Leader-type luminometer, while the negative controls should be below 600 PLU or 20,000 RLU in the two meter types.

More detailed instructions and a greater range of procedural options are contained in the manufacturer's insert. The above, however, briefly represents the procedure our laboratory found most convenient to use routinely.

3. Conversion of dimorphic fungi to their particulate phases

The various morphologies seen in converted cultures are briefly summarized in Table 8.9–8. QC, including QC isolates for most species, is discussed in item V.D above, and details of media are given in Appendix 8.9–2.

a. *B. dermatitidis*

Since diagnostic conversion of *B. dermatitidis* occurs on special media within 48 to 72 h (the traditional BHI agar is usually significantly slower and is not recommended), conversion is appropriate for all laboratories

Table 8.9–8 Particulate phases of dimorphic fungi as seen in in vitro conversion and their differentiating characteristics

Species	Particulate phase in vitro	Organism(s) to distinguish
<i>B. dermatitidis</i>	Yeast, budding on a broad base; heavy (“double”) walled, typically 9–15 µm with bud attachment	<i>Cryptococcus neoformans</i> , with narrow bud attachment, growing mixed with a subcultured test mould in conversion test at 37°C, so that the mixture of yeast and mould gives a false appearance of being a dimorphic fungus
<i>C. immitis</i>	Spherule, 10–80-µm diam, with many 2–5-µm-diam endoconidia	<i>Prototheca</i> spp., smaller, with <10 endospores at maturity
<i>H. capsulatum</i>	Yeast, budding on narrow base, 2–4 µm	<i>C. glabrata</i> and other small yeasts; distinction is by reconvertng to the mould phase at 25°C.
<i>P. brasiliensis</i>	Yeast, 30–60 µm, typically with multiple buds (cells with single buds also found)	<i>B. dermatitidis</i> in young stages, where only single buds are seen, especially outside endemic zone; <i>C. neoformans</i> overgrowing subcultured mould
<i>P. marneffei</i>	Fission yeast (self-replicating arthroconidia)	Overgrowth of another subcultured mould by <i>Trichosporon</i> spp. Do dilution plate from 37°C culture to 25°C culture if in doubt.
<i>S. schenckii</i>	Yeast, 3–10 by 1–3 µm, with initially long obclavate (cigar-shaped) buds; sympodially formed pairs of such buds (“rabbit ears”) also typically seen	<i>C. glabrata</i> and other small yeasts overgrowing subcultured mould; look for rabbit ears and cigar-shaped buds; if in doubt, dilute and subculture to Sabouraud agar at 25°C.

VII. BIOCHEMICAL AND PHYSIOLOGICAL TECHNIQUES USED IN GENERAL MOULD IDENTIFICATION (continued)

with sufficient volume of *B. dermatitidis* to justify retaining special media and in all cases where a subculture needs to be made prior to confirmation study for any reason or where the etiology of the disease has already been presumptively ascertained on the basis of diagnostic direct microscopy or histopathology. See further test strategy notes in item VII.C.2 above.

- (1) Purify culture of contamination, especially by *Candida* spp., as contaminants can cause failure to convert.
- (2) Inoculate isolate onto either Blasto D medium (17) (see Appendix 8.9–2) or cottonseed agar (11) and incubate it at 37°C for 72 h, or for several weeks if an African variant is suspected.
- (3) Examine for production of detached yeast cells budding from a broad base.

■ **NOTE:** Chloramphenicol is inhibitory to the yeast phase of *B. dermatitidis* in vitro. If antibiotic is required in the medium, use tobramycin (100 µg/ml). To decontaminate cultures, use cycloheximide for susceptible yeasts and special media containing egg albumin (3) for cycloheximide-tolerant yeasts. See Appendix 8.9–2 for a recipe for yeast-inhibiting blood agar.

b. *C. immitis*

Although some strains of *C. immitis* can be converted to the spherule phase in vitro on Converse medium in a 20% CO₂ atmosphere, this is not sufficiently reliable to use as a diagnostic test. In developing nations, where exoantigen and probe kits may not be available, animal inoculation (typically guinea pig testis) may be necessary. This topic is beyond the

VII. BIOCHEMICAL AND PHYSIOLOGICAL TECHNIQUES USED IN GENERAL MOULD IDENTIFICATION (continued)

scope of this procedure. Historically published methods may not be currently ethically approved, and anyone intending to implement these techniques must seek or devise an ethically approved procedure that meets the criteria of the investigator's institution, region, and nation.

c. *H. capsulatum*

Conversion of *H. capsulatum* to its yeast phase in vitro is time-consuming and highly vulnerable to bacterial and yeast contamination. It should be avoided wherever exoantigen or probe tests can be made available. See further test strategy notes in item VII.C.2 above. Various media may be used for conversion, including BHI-blood agar with cysteine or glutamine, blood-glucose cysteine agar, and Kurung-Yegian medium. The simple but effective Kurung-Yegian medium recipe (19) is given in Appendix 8.9–2 for possible use in areas where advanced technologies are difficult to obtain. This agar-free medium is very inexpensive. Blood-glucose-cysteine agar, which may also be used for *P. brasiliensis* and *S. schenckii* conversion, is given as an alternative.

- (1) Inoculate suspected *H. capsulatum* at 8 to 10 places on slant and incubate at 37°C.
- (2) At 5-day intervals (or more frequently), examine a previously undisturbed inoculum point. The amount of converted yeast may be limited at first, and insufficient material may be left in previously picked inoculum points to show timely conversion.
- (3) If conversion fails within 10 days, transfer some material from previous slant to a new slant, but leave some material on older slant and continue incubating both.
- (4) If copious yeast appears 2 to 5 days after initial inoculation, subculture to Sabouraud agar to investigate possible yeast contamination. In case of doubt about the status of budding cells, show reconversion to mould phase on Sabouraud agar at 25°C.

d. *P. brasiliensis*

No commercially available exoantigen or DNA probe test is yet available for *P. brasiliensis*. Diagnosis is often strongly supported by direct microscopy and serology, so culture confirmation may vary in importance from case to case. Conversion occurs slowly on BHI-blood agar (11) (see section 3 of this handbook), blood-glucose-cysteine agar (see Appendix 8.9–2), or Kelley agar (see McGinnis [11] for the recipe) at 35 to 37°C. An exoantigen test performs well in confirmatory study (15) but is not commercially available. Formal confirmation at the research level is normally performed by demonstrating the characteristic 43-kDa glycoprotein gp43 in sodium dodecyl sulfate-polyacrylamide gel electrophoresis. This is done because poorly characterized nonpathogenic mimics converting in vitro in a manner suggestive of *P. brasiliensis* have been isolated from soil, and these mimics lack gp43 (5). A possible QC strain for *P. brasiliensis* is CBS 372.73 = ATCC 32069 (same strain) or UAMH 8037.

e. *P. marneffei*

Since there are several *Penicillium* subgenus *Biverticillium* species producing red colony reverse pigment, and since *P. marneffei* may be difficult to distinguish in histopathology from *H. capsulatum*, confirmation by conversion to the particulate phase may be important in diagnosis.

- (1) Inoculate isolate onto Sabouraud agar (without cycloheximide) and incubate at 37°C.

VII. BIOCHEMICAL AND PHYSIOLOGICAL TECHNIQUES USED IN GENERAL MOULD IDENTIFICATION (continued)

- (2) Conversion should be visible microscopically within 4 to 10 days. QC strains are given in item V.D.3 above.

☑ **NOTE:** Formulations for Sabouraud agar vary; I have used the recipe in Appendix 8.9–2 successfully on repeated occasions for *P. marneffei*.

f. *S. schenckii*

Since *S. schenckii* is often sparsely present in infected tissue and appears as a nondescript budding yeast-like organism, it may be missed or misidentified in direct microscopy or histopathology. Therefore, culture and the confirmation of identity are often critical in diagnosis.

Conversion is not formally necessary but should be practiced by all laboratories not thoroughly expert in morphological identification of this organism. *S. schenckii* can be distinguished from other *Sporothrix* species by its formation of sheaths of dark secondary conidia around substrate hyphae (4, 10). Dixon et al. (4) reported rare avirulent isolates that could be distinguished from *S. schenckii* by failure to grow at 37°C in vitro. However, I have occasionally worked with isolates that grew poorly or not at all at this temperature (despite growing well at 35°C), suggesting that further investigation of this characteristic is needed. Despite the distinctive micromorphology of the *S. schenckii* mould phase, confirmation by conversion to the yeast phase is normally done routinely as a precaution (i.e., to ensure that other types of structures formed by unrelated fungi have not been confused with secondary conidia), even though some of the uncharacterized mimics may also undergo partial or complete conversion under the same conditions.

- (1) Inoculate isolate onto a slant of BHI and overlay with 2 drops of a sterile 10% aqueous solution of yeast extract. Moisture favors conversion in this species.
- (2) Incubate at both 35 and 37°C to avoid temperature intolerances. Potential QC strains are ATCC 14284 and UAMH 3613.

D. Exoantigen testing (see Appendix 8.9–2)

Exoantigen testing is based on a specific reaction between two components: (i) purified antibodies obtained from animals injected with known species-specific fungal antigens and (ii) antigens extracted from cultured cells of the same species. This reaction is visible in an immunodiffusion test in which solutions of extracted antigens and antibodies are placed into adjacent wells cut into a plate of special agar medium. The antigen and antibody solutions diffuse through the agar at a predictable rate (at a preselected temperature), and where they meet, they precipitate to form a visible whitish band of material, generically called precipitin. If antigens from an incompatible fungus are used, they usually do not precipitate with the antibodies at all, and so no precipitin line is formed. In a few closely related species, somewhat different antigens may still possess enough similarity to the original antigens to cross-react with the antibodies. However, the precipitin line formed will lie at a different distance from the wells than that formed by the fully compatible antibody-antigen precipitation. This is detected by using known control antigens with each test and placing them in wells adjacent to those inoculated with the antigens from the test isolate.

1. Procedure

Manufacturers' instructions for any kits or devices should be considered to supersede the methods given here unless sufficient controlled comparison trials have been done to ensure that the methodologies are functionally interchangeable.

It is imperative that these cultures be handled in a biosafety hood.

VII. BIOCHEMICAL AND PHYSIOLOGICAL TECHNIQUES USED IN GENERAL MOULD IDENTIFICATION (continued)

It is imperative that these cultures be handled in a biosafety hood.

a. Extracting and concentrating antigens

■ **NOTE:** All procedures in this item should be carried out in a class II biological safety cabinet. Bear in mind that even though the extraction solution tends to kill the fungus, the impact of adding it to the culture will cause an ascent of aerosols, especially with *Coccidioides*. Also, the insides of the growth tubes, even after the extraction procedure, will contain many conidia not contacted by the extracting medium. Some procedures call for performance of a sterility test by inoculating extract onto Sabouraud glucose agar; however, the time required for minute amounts of viable inoculum to produce a visible colony is uncertain, and the procedure is not recommended here.

- (1) Use a ≥ 6 -day-old culture grown in a tube of Sabouraud glucose agar (a 20- by 150-mm tube with 10 ml of agar is recommended by McGinnis and Pasarell [12]). A colony diameter of at least 30 (along the slant) by 15 (across the slant) mm is preferred.
- (2) Use a pipette to cover the culture with 8 to 10 ml of a 1:5,000 aqueous solution of Merthiolate (thimerosal; Sigma-Aldrich, St. Louis, Mo.). Breaking the mycelium up by scraping it with an inoculum spatula may be advantageous, especially with *Histoplasma* (*Coccidioides* material is generally manipulated as little as possible). Allow antigen extraction to proceed for at least 24 h at room temperature (not less than 22.5°C).
- (3) After this 24-h period, swirl the extract gently to mix it and then pipette 5 ml into an Amicon Minicon macrosolute B-15 concentrator (Millipore, Bedford, Mass.).
- (4) Concentrate extracts from suspected *Coccidioides* cultures 25-fold (levels of concentration are marked on the concentrator). I have found it advantageous to extract a second culture or to use the other half of an original 10 ml of extract in order to also prepare a 5-fold concentration of *Coccidioides* antigen, as the normally recommended 25-fold concentration may be overly concentrated for clear reading. Extracts from suspected *Histoplasma* or *Blastomyces* isolates should be concentrated 50-fold. Nonsporulating or atypical organisms that might be either *Coccidioides* or one of the other test organisms should be prepared so that sufficient extract is available to perform both 25- and 50-fold concentrations.

b. Performance of immunodiffusion

- (1) Thaw any frozen antiserum or control antigen reagents and mix gently. Such reagents may be obtained as components of commercially available kits, e.g., the Exo-Antigen identification system (Immunomycologics, Norman, Okla.).
- (2) Obtain a plate of immunodiffusion agar marked out with immunodiffusion grids. These can be obtained from commercial sources (e.g., Meridian Diagnostics, Cincinnati, Ohio) or made in-house (see Appendix 8.9-2). Pipette the reference antiserum so that it fills the center well of the immunodiffusion pattern but does not overflow from the sides of the well. After filling the well, allow the serum to diffuse for 1 h at room temperature.
- (3) After the serum has diffused, place control antigen in the two end wells of the hexagonal grid. Place antigen of the unknown isolate in three to four of the remaining wells. One may be filled with blank Merthiolate reagent if desired as a negative control. Extracts of two different isolates should not be placed immediately side by side in adjacent wells, as a strong positive reaction in one of the two may

VII. BIOCHEMICAL AND PHYSIOLOGICAL TECHNIQUES USED IN GENERAL MOULD IDENTIFICATION (continued)

- prevent accurate reading of the other, potentially giving a weak false-positive reading.
- (4) Place the immunodiffusion plate in a moist chamber or in a plastic bag (without jostling or slanting) and allow the antigen and antibody to diffuse together and react for 24 h at 25°C.
 - (5) Read the plates by using an immunodiffusion plate reader or by otherwise using diffusing backlighting. If reactions are still not clear, McGinnis and Pasarell (12) suggest washing the agar surface, covering it with distilled water, and reexamining it.

c. Results

The test is considered positive if the unknown isolate forms lines of identity with reference control antigens of a dimorphic fungus. When the antigen from the test isolate matches that of the positive control, a perfect hexagonal corner ("line of identity") is formed where the two precipitin lines from each pair of adjacent wells meet exactly and fuse end to end. In the event of a cross-reaction from another species, the precipitin line formed does not meet with the control line in a regular, closed corner, but instead meets so that one of the two lines overlaps the other or so that both lines cross over each other. With *Histoplasma*, since the H and M antigens do not form simultaneously in equal quantities in growing cultures, a certain line of identity with either of the two control antigens is sufficient to confirm the identification.

VIII. DERMATOPHYTE IDENTIFICATION

Identification of dermatophytes to the species level is important: (i) to rule out confusion with nonpathogenic fungi both outside and within the genera *Trichophyton* and *Microsporum*, (ii) to allow control of dermatophytes acquired from animals by correctly indicating species with particular normal animal host ranges, (iii) to allow correct treatment in diseases such as tinea capitis, where drug dosage levels or treatment times may require species-specific adjustment, and (iv) to allow epidemiologic connection with other affected persons and contagious, asymptomatic carriers in the family or in schools and other institutions, especially with *Trichophyton tonsurans*, *M. audouinii*, *Trichophyton violaceum*, and *Trichophyton soudanense*.

Dermatophytes are the only fungi specialized to cause contagious human and animal disease. Two fundamental features related to continuous pathogenicity strongly influence identification: (i) lack of recent evolutionary selection for normal types of fungal reproduction has caused many species to produce few or no conidia, and (ii) release from selection for ordinary fungal morphology has led to a conspicuous rise in macromorphological and micromorphological variability, meaning that a relatively high proportion of atypical to aberrant isolates are seen (23).

At the same time, however, it remains true that most of the isolates seen for a given species are typical, and many dermatophytes can easily be identified from primary growth medium. Below, a method to decontaminate cultures is presented; then, the useful characteristics in dermatophyte identification will be outlined, and a scheme will be put together for their best usage. This scheme is based on that outlined by Summerbell and Kane (24).

A. Decontamination of dermatophyte cultures contaminated with antibiotic-polyresistant bacteria

Association with antibiotic-polyresistant skin bacteria is common for *T. rubrum* and is occasionally seen with other dermatophytes. *T. rubrum* has been reported to produce penicillin and to select a lactam-resistant bacterial microbiota; also, it competes with highly polyresistant pseudomonads in nails, and these bacteria may be coisolated with it. Moreover, because some contaminating bacteria may

VIII. DERMATOPHYTE IDENTIFICATION (continued)

adhere to aerial filaments in culture and not be fully exposed to antibiotics in growth media, even some partially antibiotic-susceptible bacteria may be carried over into subcultures. All these bacteria cause false-positive and false-negative reactions in physiological tests. The detection of cryptic contamination on BCP milk glucose agar is mentioned in item VIII.C.3. Decontamination of such bacterially contaminated cultures requires the primitive microbiological technique outlined below. Note that the series of medium tubes required is described in Appendix 8.9–2, and this must be consulted before reading the procedure below.

1. Culture and reisolation

Take inoculum from the margin of the contaminated colony or area of least contamination and inoculate each of the four tubes (*see* Appendix 8.9–2). Incubate at 25°C and examine in 7 days.

2. Growth in tube 0 will frequently be turbid because of the presence of bacteria. Examine tubes 1 to 3 to detect both fungal growth and similar bacterial turbidities. Agitate slightly if necessary to visualize the latter. Mark all turbid tubes as contaminated.

3. Among the clear tubes, look for sufficient distinct new fungal growth to allow reisolation. Use only growth from within the medium, not from the surface. If clear new growth is insufficient on day 7 to allow reisolation from any tube, place tubes back into the incubator and reexamine on day 10 or 14 or until day 21, when growth can be recorded as negative. When growth is detected, reisolate the dermatophyte by subculturing from the tube with the highest acid concentration permitting purified growth

B. Dermatophyte micromorphological characteristics

Dermatophyte micromorphological structures are listed in Table 8.9–9 and illustrated in Fig. 8.9–A15 through 8.9–A24 in Appendix 8.9–1.

The special morphological features of various dermatophytes are listed, along with special medium tests, in Table 8.9–10. Note that *Trichophyton interdigitale* (a long-disused name newly revived by Gräser et al. [6] to include all zoophilic, as well as anthropophilic, *T. mentagrophytes*-like isolates in a phylogenetic cluster related to the teleomorph *Arthroderma vanbreuseghemii*) is not distinguished from *T. mentagrophytes* in the table. *T. interdigitale* as phylogenetically defined can only be identified by using molecular techniques or, in zoophilic isolates, by mating them, and this distinction currently has no medical significance. *T. mentagrophytes* as conventionally defined was already long known to be an aggregate of more than one biological species, and the name is used here in that collective sense. The names *Microsporum gypseum* and *Trichophyton terrestre* are also used as conventional aggregate names comprehending four and three known biological species, respectively.

C. Physiological and other special medium tests for identifying dermatophytes

Dermatophytes may be recognized by morphology alone without needing to resort to physiological testing. Among those which remain unidentified after initial morphological characterization, some may be suspected of being particular species based on the morphological characteristics seen, and special tests to aid these presumptive identifications are given below. For others, where the species identification may be uncertain, a minimal set of physiological test media is recommended: vitamin-free Casamino Acids agar (*Trichophyton* agar no. 1) to screen for vitamin and growth factor requirements, Christensen's urea broth or agar, BCP milk glucose agar, and Sabouraud agar as a growth control (*see* Appendix 8.9–2 for medium recipes).

Always examine the isolate for colony and microscopic morphology. Since some species can be very similar, it can be useful to consider the results of direct specimen microscopy and any patient details, such as travel or association with animals, before deciding which growth factor test to perform.

Table 8.9–9 Dermatophyte micromorphological structures

Characteristic	Definition	Identification aid
Aerial arthroconidia	Hyphal branches forming conidia may also break up, forming single cells.	
Substrate arthroconidia	Chains of strongly swollen cells that break to form separate round cells—seen on the host or in fresh isolates	
Terminal chlamydospores	Chlamydospores produced near the ends of hyphae; variations include symmetrical and asymmetrical laterally distended chains.	<i>M. audouinii</i> , <i>T. verrucosum</i> , <i>T. violaceum</i> (Fig. 8.9–A15 to A17)
Pedicels (Fig. 8.9–A18)	“Matchstick” stalks connecting microconidia to hyphae	<i>T. tonsurans</i> and <i>M. persicolor</i>
En thyrese; sessile	Distribution of microconidia along a relatively unbranched hypha	<i>M. gypseum</i> complex
Racemose; en grappe	Microconidia on hyphae with densely rebranching pattern resembling branching in a bunch of grapes; formation is grape-like.	<i>M. racemosum</i>
Distoseptate (Fig. 8.9–A19)	Macroconidia that lack distinct cross walls and have cytoplasm broken into cellular compartments	<i>T. ajelloi</i> , <i>M. cookei</i> , <i>M. vanbreuseghemii</i>
Setae (Fig. 8.9–A20)	Also called spirals (see ascoma morphology [Table 8.9–3])	<i>T. mentagrophytes</i> , <i>M. persicolor</i>
Reflexive branching (Fig. 8.9–A21)	Radial thickenings on colony surface contain hyphae growing both forward and backward in respect to the direction of colony extension.	<i>T. soudanense</i>
Favic chandeliers (Fig. 8.9–A22)	Hyphae with terminal branching in an antler-like pattern with strongly swollen tips; sometimes called nail-head hyphae	<i>T. schoenleinii</i>
Balloon forms	Greatly swollen microconidial structures	<i>T. tonsurans</i>
Filiform	Abortive, spindly side branches arising from chains of slightly swollen cells; also called caterpillar form	<i>T. tonsurans</i>
Pectinate branching (Fig. 8.9–A23)	Short, rounded side branches in a comblike pattern on one side of the hypha	<i>M. audouinii</i> , <i>T. rubrum</i>
Diverticula (Fig. 8.9–A24)	Solitary, very wide, nonextending side branches; also called projections	<i>T. rubrum</i>
Nodular bodies	Tightly coiled, knotted-looking thickened hyphal structures in the submerged mycelium	<i>T. mentagrophytes</i> nodular variant (<i>T. krajdinii</i>)
Perforating organ	Robust, sharply pointed long cone, with a restricted waist near the point of origin; produced to perforate hair	<i>T. mentagrophytes</i> complex, <i>M. canis</i> complex, and soil isolates

VIII. DERMATOPHYTE IDENTIFICATION (continued)

1. Growth factor tests for identifying dermatophytes

- a. Most dermatophytes do not require any external supply of vitamins or other special growth factors, but some *Trichophyton* spp. require one or more of the following: thiamine, inositol, nicotinic acid, and L-histidine. To perform all possible vitamin tests on an unknown isolate requires seven media, referred to as *Trichophyton* agars (the conventional phrase “*Trichophyton* agar no.” is abbreviated as “T” below).

- (1) T1, vitamin-free Casamino Acids agar (possible QC isolates: one each of the QC isolates suggested for media T2, T4, and T5 plus one isolate listed in item V.E.1)

Table 8.9–10 Phenotypic identification characteristics of common and occasionally seen dermatophytes, as well as rare species potentially used in QC trials

Dermatophyte	Growth ^c	Macromorphology	Micromorphology	Growth factor requirement	BCP milk glucose (pH results for 7–10 days)	Urease (7 days; broth)	Hair perforation ^f	Other comments
<i>E. floccosum</i> ^a	Mod. rapid	Flat, slightly granular at first, soon developing white puffs of degeneration; sandy to olive-brown; reverse pale to yellowish	Macroconidia abundant, club shaped with broadly rounded apex; usually with <6 cells; no microconidia formed; many chlamydospores in primary isolates	None	Alkaline	Pos	Neg	
<i>M. audouinii</i> ^b	Mod. rapid	Flat to velvety, thin; pale-salmon to pale-brownish reverse	Rare, deformed macroconidia, often with beak, constricted midregion, and at least trace granulation; drop-shaped microconidia and aerial arthroconidia may be present; pectinate branching, terminal chlamydospores often seen	None on <i>Trichophyton</i> agars (see “Other comments”)	No pH change or alkaline	Neg	Neg	Poor growth and no or brownish pigment on polished-rice medium; usually connected with patient or insect in or recently from Africa; only children typically infected
<i>M. canis</i> ^a	Rapid	Flat to velvety, thin, with yellow (rarely pale) reverse	Macroconidia thick walled, roughened, and beaked; microconidia drop shaped	None	No pH change; macroconidia often abundant	Pos	Pos	Good growth and yellow pigment on polished-rice medium; human infection usually from cat or dog
<i>M. cookei</i> ^b	Mod. rapid	Granular to velvety; reverse wine red	Macroconidia rough, thick walled, with cellular compartments rather than true cross walls; microconidia drop shaped	None	No pH change	Pos	Pos	Nonpathogenic
<i>Microsporum ferugineum</i> ^f	Slow	Flat; reverse yellow, rusty, or pale	No conidia; coarse, straight “bamboo” hyphae may be present.	None	No pH change	Neg	Neg	Yellow colony on Lowenstein-Jensen medium (compare <i>T. soudanense</i>)

(continued)

Table 8.9–10 Phenotypic identification characteristics of common and occasionally seen dermatophytes, as well as rare species potentially used in QC trials (*continued*)

Dermatophyte	Growth ^e	Macromorphology	Micromorphology	Growth factor requirement	BCP milk glucose (pH results for 7–10 days)	Urease (7 days; broth) ^f	Hair perforation ^f	Other comments
<i>M. gallinae</i> ^c	Mod. rapid	Flat to velvety; red pigment diffuses into agar	Macroconidia smooth to slightly rough, often bent and with thickest cells near the apex	None	No data	Neg	Neg	Rare; human infection usually from chicken
<i>M. gypseum</i> ^a	Rapid	Granular; sandy in color; reverse usually pale to brownish	Macroconidia abundant, thin walled, fusoid (tapered at both ends), roughened; microconidia drop shaped, mostly formed “en thyrsé” (a feature only noted if <i>M. racemosum</i> is queried)	None	No pH change	Pos	Pos	Human infection usually from soil contact
<i>M. nanum</i> ^b	Mod. rapid	Powdery; sandy in color; reverse often reddish brown	Macroconidia rough, usually only 1–3 cells long, egg shaped to ellipsoidal	None	No data	Pos	Pos	Human infection usually from pig
<i>M. persicolor</i> ^b	Rapid	Powdery; sandy in color; reverse pale to yellowish, sometimes with rosy tones	Macroconidia fusoid (tapered on both ends); often absent or smooth walled on Sabouraud agar but usually common and rough walled on Sabouraud agar with added salt (3 or 5% NaCl); microconidia formed on pedicels (must be checked within 5 days)	None	No pH change	Pos	Pos	Usually poor growth at 37°C in vitro; rose to wine-red reverse on sugar-free media, e.g., glucose-free Sabouraud agar; human infection usually from soil (fomites from voles)
<i>M. praecox</i> ^b	Rapid	Powdery; sandy in color; reverse yellow	As for <i>M. gypseum</i>	None	No pH change	Pos	Neg	Uncommon
<i>M. racemosum</i> ^c	Rapid	Powdery; sandy in color; reverse red	Macroconidia as for <i>M. gypseum</i> ; microconidia mostly formed “en grappe”	None	No pH change	Pos	Pos	Rare

<i>M. vanbreuseghemii</i> ^a	Rapid	Powdery; pinkish or buff; pale to yellow reverse	Macroconidia rough, thick walled, cylindrical; often >8 cells long, with cellular compartments rather than true cross walls	None	No data	Pos	Pos	Rare
<i>T. ajelloi</i> ^b	Mod. rapid	Powdery, rich tan in color; reverse pale, brownish, or with purple-black pigment	Macroconidia smooth, thick walled, cylindrical; often >7 cells long, with cellular compartments rather than true cross walls	None	No data	Pos	Pos	Nonpathogenic
<i>T. concentricum</i> ^c	Slow	Folded, honey-brown colony	No conidia	50% of isolates show slight stimulation by thiamine (compare <i>Trichophyton</i> agars 1 and 4)	No data	Pos or Neg	Neg	Only from indigenous Asian, Australasian/Melanesian, or indigenous Central and South American people with distinct tinea imbricata infection
<i>T. equinum</i> ^b	Mod. rapid	Flat to velvety colony with yellow to red-brown reverse	Macroconidia uncommon; cylindrical to club shaped, smooth; microconidia abundant, on small pedicels (examine before 5 days)	Most isolates absolutely require nicotinic acid (compare <i>Trichophyton</i> agars 1 and 5); rare Australian <i>T. equinum</i> var. <i>autotrophicum</i> does not.	Alkaline	Pos	Usually Neg, sometimes Pos	Human infection usually from horse
<i>T. megnini</i> ^b	Mod. rapid	Cottony, with white down sometimes suffused with rosy pigment; reverse red to red-brown	Macroconidia seldom seen, pencil shaped; microconidia drop shaped	Requires L-histidine (compare <i>Trichophyton</i> agars 6 and 7)	Alkaline	Pos or weak Pos	Neg	Endemic in Portugal and nearby areas

(continued)

Table 8.9-10 Phenotypic identification characteristics of common and occasionally seen dermatophytes, as well as rare species potentially used in QC trials (continued)

Dermatophyte	Growth ^e	Macromorphology	Micromorphology	Growth factor requirement	BCP milk glucose (pH results for 7–10 days)	Urease (7 days; broth) ^f	Hair perforation ^f	Other comments
<i>T. mentagrophytes</i> (zoophilic) ^a	Rapid	Granular to powdery; yellow-cream to buff surface; pale to red-brown reverse	Macroconidia uncommon; club shaped, smooth; microconidia nearly spherical, abundant, mostly produced en grappe in dense tufts; spiral appendages present	None	Alkaline (rarely weak)	Pos	Pos	Human infection usually from rodent or rabbit
<i>T. mentagrophytes</i> var. <i>erinacei</i> ^b	Rapid	Granular to powdery; yellow-cream to buff surface; yellow reverse	Macroconidia uncommon, club shaped, smooth; microconidia nearly spherical, abundant, mostly produced en grappe in dense tufts; spiral appendages present	None	Alkaline	Neg	Pos	Human infection usually from hedgehog or its fomites; therefore, mostly restricted to regions with wild hedgehogs or to pet hedgehog owners
<i>T. mentagrophytes</i> (anthropophilic) ^{1,4d}	Rapid	Powdery to cottony; yellow-cream to buff or white surface; pale to red-brown reverse	Macroconidia uncommon, club shaped, smooth; microconidia nearly spherical or drop shaped, abundant, produced mainly en grappe when round and en thyse when drop shaped; spiral appendages present but rare in very cottony isolates	None	Alkaline	Pos	Pos	
<i>T. mentagrophytes</i> (nodular variant = <i>T. kraidenii</i>) ^b	Mod. slow	Cottony; cream to white surface; intense yellow reverse	Macroconidia rare; microconidia usually drop shaped, sometimes also round; coiled, yellow “nodular bodies” and yellow pigment granules present in submerged mycelium; spiral appendages seldom seen	None	Alkaline	Pos	Pos	Although usually very different in morphology, this variant so far is not genetically distinguished from other anthropophilic anamorphs related to <i>A. vanbreuseghemii</i> .

<i>T. rubrum</i> ^a	Mod. slow	Cottony to velvety; white to reddish surface; typically wine-red reverse, but yellow variants occasional; red color poorly formed in presence of common bacterial contamination	Macroconidia seldom seen, pencil shaped; microconidia drop shaped, abundant, scanty, or not formed; lateral hyphal projections often present	None	No pH change (alkalinity after 14 days)	Neg (rarely weak)	Neg	Although usually very different in morphology, this variant so far is minimally genetically distinguished from typical <i>T. rubrum</i> . It is usually from upper-body infection (tinea corporis; tinea cruris).
<i>T. rubrum</i> (Afro-asiatic variant = <i>T. raubitschekii</i>) ^b	Mod. slow	Powdery to low velvety; cream to deep red; reverse wine red	Macroconidia abundant, club shaped, sometimes with "rat tail" extension; microconidia drop shaped to round; many chlamydo-spores in primary isolates	None	No pH change (alkalinity after 14 days)	Pos	Neg	Very rare; associated with climatically recognizable "favus" lesions; now extirpated except in rural central Asia, rural Africa
<i>T. schoenleinii</i>	Slow	Convoluted, slightly velvety whitish colony	No conidia seen; "favic chandeliers" or "nailhead hyphae" present	None	Alkaline	Variable	Neg	Endemic to India and Africa; similar to zoophilic <i>T. mentagrophytes</i> but macroconidial number and shape are atypical; reference distinction is by mating or molecular study.
<i>Trichophyton simii</i> ^b	Rapid	Granular to powdery; yellow-cream to buff surface; pale to red-brown reverse	Macroconidia abundant, often with some cells swollen as chlamydo-spores; microconidia drop shaped	None	Alkaline	Pos	Pos	Endemic to India and Africa; similar to zoophilic <i>T. mentagrophytes</i> but macroconidial number and shape are atypical; reference distinction is by mating or molecular study.

(continued)

Table 8.9–10 Phenotypic identification characteristics of common and occasionally seen dermatophytes, as well as rare species potentially used in QC trials (*continued*)

Dermatophyte	Growth ^c	Macromorphology	Micromorphology	Growth factor requirement	BCP milk glucose (pH results for 7–10 days)	Urease (7 days; broth) ^f	Hair perforation/ ^g	Other comments
<i>T. soudanense</i> ^b	Mod. slow	Flat, bright-yellow to (less commonly) wine-red colony with radial striations and starlike margin; uncommonly cottony; reverse yellow to wine red	Macroconidia not seen; microconidia drop shaped, scarce, or absent; reflexive hyphal branches in radial striations	Usually no growth on <i>Trichophyton</i> agar no. 1; a few isolates grow well. Stimulation on other <i>Trichophyton</i> agars usually not seen, but stimulation on no. 5 may occur rarely.	Alkaline, with small zone of clearing	Usually Neg, occasionally Pos	Neg	Endemic to sub-Saharan Africa but widely disseminated in cosmopolitan parts of Europe and Americas; dark colony on Lowenstein-Jensen medium (compare <i>M. ferrugineum</i>)
<i>T. terrestre</i> ^b	Mod. rapid	Powdery white to cream or pinkish surface; pale or rarely yellow to red reverse	Macroconidia numerous, mostly small (5 or fewer cells) intergrading with large club-shaped microconidia in a continuous series, so that 3-, 2-, and 1-celled conidia are present	None	Alkaline	Pos	Pos	No growth at 37°C in vitro; non-pathogenic
<i>T. tonsurans</i> ^d	Mod. slow	Powdery to velvety surface; reverse chestnut red-brown and/or sulfur yellow, rarely pale	Macroconidia uncommon, small, pencil or club shaped; microconidia abundant, often on broad “matchstick” pedicels; “balloon forms” and “filiform branches” may be seen.	Strongly stimulated by thiamine (compare <i>Trichophyton</i> agars 1 and 4)	Alkaline, sometimes weak	Pos	Usually Neg, sometimes Pos	

<i>T. verrucosum</i> ^a	Slow	Convoluted, slightly velvety whitish or tan colony	Macroconidia seldom seen, with rat tail extension; microconidia round to drop shaped	Strongly stimulated by thiamine and in most cases also inositol (compare <i>Trichophyton</i> agars 1, 3, and 4)	Alkaline (may be weak) with broad zone of clearing	Neg	Neg	Human infection usually from cat-tle, growth stimulated at 37°C
<i>T. violaceum</i> ^b	Slow	Glabrous (bald-looking), smooth or convoluted colony; purple-red, sometimes with white sectors; rarely whitish	Macroconidia seldom seen; microconidia not formed or formed mostly on thiamine medium or on sporulation media	Stimulated by thiamine (compare <i>Trichophyton</i> agars 1 and 4)	No pH change or weak alkaline with small to broad zone of clearing (always broad after 14 days)	Pos or weak	Neg	Endemic to north Africa and Middle East but widely disseminated in cosmopolitan parts of Europe, Americas, and South Africa

^a Common.

^b Uncommon, but likely to be seen in large laboratories in the Americas and Europe.

^c Unlikely ever to be seen except in proficiency test or region of endemicity.

^d Technical taxonomic note. This ecological category includes anthropophilic but not zoophilic forms both of *T. interdigitale* sensu Gräser et al. (6) and of *T. mentagrophytes* anamorphs phylogenetically clustered with *Arthroderma benhamiae*. These forms were previously collectively called by the nomenclaturally invalid name "*T. mentagrophytes* var. *interdigitale*" by some workers. Although this name was conceived as encompassing all anthropophilic *T. mentagrophytes*-like isolates, this heterogeneous group cannot be placed under any single name except *T. mentagrophytes* sensu lato (species aggregate concept of *T. mentagrophytes* as used in the present work). Recent phylogenetic work has not been clear on this point, because the existence of rat and chinchilla strains, as well as anthropophilic strains, within the concept of *T. interdigitale* sensu Gräser et al. was not explicitly mentioned.

^e Mod., moderately.

^f Pos, positive; Neg, negative.

VIII. DERMATOPHYTE IDENTIFICATION (continued)

- (2) T2, T1 plus inositol; used for showing partial stimulation in ~80% of *Trichophyton verrucosum* isolates (possible QC isolate, UAMH 5666)
 - (3) T3, T1 plus thiamine plus inositol; used for showing stimulation in *T. verrucosum*
 - (4) T4, T1 plus thiamine; the most useful medium, used for showing stimulation in *T. tonsurans* and *T. violaceum* and slight stimulation in *T. verrucosum*, as well as ~50% of *Trichophyton concentricum* isolates (possible QC isolate: *T. tonsurans* ATCC 14002, CBS 118.65, or UAMH 8552)
 - (5) T5, T1 plus nicotinic acid; used for showing absolute requirement for nicotinic acid by *Trichophyton equinum* var. *equinum* (possible QC isolate: *T. equinum* ATCC 26365 = CBS 856.71 [same strain; listed as *T. tonsurans* in CBS database due to controversial proposal for taxonomic merger of *T. equinum* and *T. tonsurans*])
 - (6) T6, amino acid-free ammonium nitrate agar
 - (7) T7, T6 plus L-histidine; used for showing stimulation in *Trichophyton megninii* (possible QC isolate: *T. megninii* ATCC 12106 or CBS 500.48 [the latter is listed as *T. rubrum* in CBS database due to controversial proposal for taxonomic merger of *T. megninii* and *T. rubrum*])
- b. If the isolate has a preliminary identification, use the *Trichophyton* agars that will prove or disprove the identification.
 - c. Inoculation and reading
Inoculate a small piece of fungus, being careful not to transfer any growth medium and to use cooled sterilized inoculation needles.
 NOTE: Only the nicotinic acid requirement of *T. equinum* is an absolute requirement leading to no growth on the vitamin-free T1. Other dermatophytes show weak growth on the media negative for the growth factor they “require” but abundant growth on the appropriate growth factor-supplemented medium.
 - d. Cultures should be incubated at 25°C for 7 days for moderate- to fast-growing isolates and for 10 to 14 days for slow-growing isolates. Cultures suspected of being *T. verrucosum*, *Trichophyton schoenleinii*, or *T. concentricum* may be incubated at 37°C to exploit the accelerated growth rate of *T. verrucosum* at that temperature.
 - e. Record results in a range from + (trace growth) to 4+ (control level growth). Species with thiamine, inositol, or L-histidine requirements ordinarily show ~2+ growth on growth factor-free medium. New readers unfamiliar with this system should compare the growth of appropriate QC strains (as listed above under item VIII.C.1) on growth factor-free medium and the appropriate control medium in order to gain an appreciation of the differences between nutrient-deprived and normal growth.
2. Urease test for identifying dermatophytes
Several dermatophyte species specialized for pathogenesis have lost the urease enzyme activity that is found in all soil-associated dermatophyte species. This difference is detected by means of the Christensen urea test. In practice, this test is most commonly used to distinguish the urease-negative *T. rubrum* from similar isolates in the *T. mentagrophytes* complex. This test is also useful to recognize occasional clinical contaminants that are cycloheximide tolerant, white, protractedly nonsporulating nondermatophytic moulds and some nonpathogenic *Chrysosporium* spp., such as *Chrysosporium georgiae*, that may resemble atypical *T. mentagrophytes* or *T. rubrum*.
The complete list of urease-negative and -positive species is given in Table 8.9–10. QC strains are given in item V.E.1 above.

VIII. DERMATOPHYTE IDENTIFICATION (continued)

Inoculation and reading are performed as follows.

- a. Use only pure cultures, as contaminants can give false results. Simultaneous inoculation onto BCP agar will demonstrate the presence of contaminants (24).
 - b. Use a small amount of inoculum to inoculate the tubes so that acid or basic compounds are not transferred from prior medium. Incubate at 25°C for 14 days, reading positive results when visible (examine on day 7) and negative results on day 14.
 - c. Positive results consist of a change of the phenol red indicator to red-purple; negative results are seen as an unchanging yellow-orange color as found in the freshly prepared medium. A yellow, acid reaction indicates bacterial or yeast contamination.
3. BCP milk glucose test for identifying dermatophytes

Dermatophytes all raise the pH of most complex media, such as Sabouraud agar, by breaking down proteins to produce alkaline compounds. In many species, however, this action either is not seen or is strongly delayed when milk casein is used as a protein base and glucose is added as a carbon source. *T. rubrum* and most *Microsporum* spp. in particular show this repression of ammonifying proteolysis on milk glucose medium, as detected by the indicator BCP. On the other hand, *T. mentagrophytes*, *Epidermophyton floccosum*, *T. tonsurans*, and most soilborne *Trichophyton* species (e.g., *Trichophyton ajelloi*) rapidly ammonify milk glucose medium, producing a color change in the pH indicator.

In addition, most rapidly growing dermatophytes produce enzymes that break down opaque milk proteins to produce clear medium, but the action of these proteases usually does not extend beyond the colony margin. However, the slow-growing *T. verrucosum* and *T. violaceum*, and to a lesser extent the moderately slowly growing *T. soudanense*, have milk-clearing enzymes that diffuse outward more rapidly than the colony itself grows, producing a distinctive ring of clearing on milk media.

BCP milk glucose agar is antibiotic free, as it favors heavy growth of bacteria, exposing their presence. It also indicates organic acid production by many contaminating bacteria and yeasts, with an indicator change to yellow. This then allows one to correctly interpret correlated false-positive (or acid) urease tests.

Finally, BCP milk glucose medium strongly favors production of macroconidia by *M. canis* isolates that remain nonsporulating on Sabouraud glucose agar, and it elicits strong production in *T. soudanense* of radial striae in which abundant reflexive branches may be found. QC strains for this test are given in item V.E.2 above.

Inoculation and reading are performed as follows.

- a. BCP milk glucose agar should be inoculated near the middle of the slant with a small inoculum to make it easier for the differences in the growth rates of different species to be seen.
- b. Record growth rates at 7 days, after comparing them with the control Sabouraud tube. Rates should be recorded as slow (meaning slow growing but essentially the same as on Sabouraud), restricted (meaning slow growth significantly slower than that seen on Sabouraud), or profuse (rapid growth as seen on Sabouraud).
- c. Record medium pH at 7 and 10 days. The potential readings are as follows: unchanged (sky blue), indicating a negative reaction; alkaline (blue-purple to purple), indicating a positive reaction; and acid (yellow), indicating contamination.
- d. Record distinct clearing of milk solids around the colony periphery on day 7. Ignore clearing beneath the colony.

VIII. DERMATOPHYTE IDENTIFICATION (continued)

■ **NOTE:** Many *Trichophyton* cultures kept >14 days will produce extensive clearing, and some bacterial contaminants may also produce clearing. Also, degenerated cultures of all dermatophytes, if they have been improperly stored in local or professional culture collections, will tend to have much stronger clearing reactions than fresh isolates. QC, therefore, must not be performed with such isolates.

e. Check the micromorphology of: (i) cultures suspected to be *M. canis* but not sporulating on Sabouraud glucose, (ii) cultures suggestive of *T. soudanense* with radial striae, and (iii) any very atypical cultures. BCP milk glucose may stimulate formation of macroconidia in unusual isolates, such as degenerated *E. floccosum*, in situations where other media do not.

4. Cornmeal glucose agar (cornmeal dextrose agar)

Cornmeal glucose agar (2) is one of several media used to elicit wine red pigment in *T. rubrum* and characteristic micromorphology in numerous dermatophytes. Others include Casamino Acids erythritol albumin agar (24), which has the advantage of nutritionally inhibiting yeast and bacterial contamination; modified Borelli's lactrimel agar (9); and potato flake agar. These media are to some extent interchangeable in this function, although the optimal incubation times may vary and the exact micromorphologies elicited may differ.

Stimulation of the pigment production of atypical *T. rubrum* isolates can facilitate their identification, while *T. violaceum*, *T. soudanense*, *T. megninii*, and *C. georgiae*, which also produce red pigments, can be distinguished by morphology or characteristics developed on other media.

■ **NOTE:** Red-pigmented *T. terrestre* isolates are either rare or nonexistent, despite statements in the literature.

QC strains for this test are given in item V.E.3 above.

Inoculation and reading—inoculate an ~1-mm² piece centrally, incubate it at 25°C, and examine it on days 7, 10, and 14.

5. Polished-rice test for *Microsporum* spp.

The most common *Microsporum* spp. are *M. canis* and *M. gypseum*. Both can usually be identified by characteristic micromorphology on primary isolation medium, although *M. canis* produces a certain proportion of atypical isolates requiring subculture to the minimal set of physiological test media suggested earlier. The polished-rice test is mainly used to confirm suspected *M. audouinii*, an anthropophilic dermatophyte almost always seen in scalp ringworm in children. *M. audouinii* is quite variable but resembles many weakly pigmented, poorly conidial *M. canis* isolates and can best be distinguished from them on autoclaved polished rice. It has an uncharacterized growth factor deficiency that causes it to grow only weakly on this medium, sometimes with concomitant production of some brownish soluble pigment. *M. canis*, on the other hand, grows vigorously and usually produces lemon yellow pigmentation. Other dermatophytes also grow vigorously. QC strains for this test are given in item V.E.4 above.

Inoculation and reading—inoculate the surface of the rice with the test fungus, placing four pieces evenly around the bottle adjacent to the wall. This maximizes the reader's ability to see pigment formation and compensates in part for the tendency of *M. audouinii* to die out in culture. Simultaneously inoculate Sabouraud glucose growth control for the suspected *M. audouinii*.

6. Hair perforation test

Dermatophytes that are ecologically associated with soil and with animals denning in the soil are specialized to rapidly perforate and digest loose-lying shed hairs. A specialized "hair perforation organ" is produced to physically and enzymatically pierce them. Dermatophytes that have an ecological as-

VIII. DERMATOPHYTE IDENTIFICATION (continued)

sociation with animals not denning in the soil have strongly tended to lose this specialized hair-perforating ability. Typical animal hosts associated with at least some dermatophytes lacking hair perforation abilities are horses, cattle, fowl, and humans (23). The spectrum of dermatophytes growing on humans includes several specialized anthropophilic species, such as *T. rubrum* and *T. tonsurans*, that always or mostly lack hair perforation ability; some members of the *T. mentagrophytes* complex that have retained hair perforation ability; species such as *T. verrucosum* and *T. equinum*, acquired from non-soil-dwelling animals, that always or mostly lack hair perforation ability; and species from soil-dwelling or ancestrally soil-dwelling animals (rodents, rabbits, dogs, and cats) that always manifest hair perforation ability. The hair perforation test is mainly used to distinguish atypical *T. rubrum* from *T. mentagrophytes* but can also be used to distinguish *M. audouinii* from *M. canis*, the uncommon *Microsporum praecox* from *M. gypseum*, and so on (Table 8.9–10). QC strains are given in item V.E.5 above.

Preparation, inoculation, and reading are performed as follows.

- a. Collect hair from a prepubertal child, ideally under 18 months old; some texts recommend blond hair if available. Place in a test tube and autoclave for 15 min at 121°C.
- b. In a petri dish, add 25 ml of sterile distilled water and 2 or 3 drops (0.1 ml) of sterile 10% yeast extract solution, and add several (at least eight) pieces of sterile hair.
- c. Place several inoculum pieces of the test fungus into the suspension, preferably so that they contact some of the hairs. Incubate at room temperature. Set up positive and negative control tests on separate plates.
- d. Examine test fungus and controls on day 7 and at 7-day intervals thereafter until a definitive result is obtained. The cutoff for negative results is 4 weeks.
- e. Remove a few conspicuously fungally colonized hairs; mount them in KOH, NaOH, or lactophenol cotton blue mounting medium; and examine their whole lengths under low-power microscopy. Search for the conspicuous perpendicular pits indicative of hair perforation. Artifacts, such as fractures of the hair, burns from overheated forceps, and especially elongated trapped air bubbles, must be distinguished. If in doubt, confirm the presence of the fungal perforating organ in the perforation pit. Positive and negative controls should be checked at the same time.

In recent years, as commercially available yeast extract has become more highly purified and as the diversity of antifungal inhibitors in shampoos has increased, it has become more difficult to obtain reliable performance of positive controls in at least some laboratories. There are alternative phenotypic tests for almost all decisions that can be made using the hair perforation test, except for the reference confirmation of *M. praecox* and *T. equinum* var. *autotrophicum*, which otherwise may be confused with *M. gypseum* and *T. mentagrophytes*, respectively.

D. Practical dermatophyte identification scheme

Below is a relatively cautious identification scheme that will serve to identify >99% of dermatophytes seen in laboratories in cosmopolitan areas. It is assumed that if contamination is detected, decontamination will be carried out, except in cases where identification of the isolate can be fully confirmed by examining characteristics whose formation is not affected by contamination (e.g., spiral appendages). The scheme will not suffice for all QC test isolates because some species seldom or never seen except in these tests—particularly *Microsporum nanum*, *T. schoenleinii*, and *Microsporum gallinae*—have been omitted. For these, see Table 8.9–10. *T. equinum* var. *autotrophicum* has also been omitted due to its extreme rarity outside of Australia and New Zealand.

VIII. DERMATOPHYTE IDENTIFICATION (*continued*)

1. Examine primary Sabouraud medium or other selective isolation medium at 7 and 14 days.
 - a. Cottony or deeply velvety white colonies with wine-red reverse: confirm at least one typical drop-shaped microconidium and no spiral appendages or other atypical features; identify as *T. rubrum*.
 - b. Powdery to low-cottony cream to white colonies with pale to pale-brownish reverse: confirm abundant round or broadly drop-shaped microconidia (not formed on long “matchstick” pedicels) plus at least one well-formed spiral appendage; identify as *T. mentagrophytes*.
 - c. Powdery to low-cottony whitish, yellow, or mahogany red-brown colonies with red-brown to sulfur yellow reverse: confirm abundant optically dense, broadly drop-shaped microconidia, often formed on broad matchstick pedicels, sometimes intermixed with balloon forms or filiform “cat-erpillar” branching clusters. If from tinea capitis or from known heavily infested geographic area, identify as *T. tonsurans*.
 - d. Flat to velvety thin colony with yellow reverse: confirm at least one thick-walled, roughened, and beaked macroconidium; identify as *M. canis*.
 - e. Granular, sandy colony with pale reverse: confirm abundant rough, thin-walled, fusoid macroconidia; identify as *M. gypseum* (if reverse is bright yellow, reference test for *M. praecox* is called for [reconsider *M. canis* if there is some doubt about whether macroconidial walls are thick or thin]; if red, reference test for *Microsporum racemosum* is called for.)
 - f. Flat, olive-brown to olive-gray or dull yellowish-brown colony with pale or yellowish reverse: confirm abundant broadly club-shaped macroconidia and no microconidia (if only chlamydoconidia are present, subculture and reexamine in 7 days); identify as *E. floccosum*.
 - g. Isolates with features suggestive of geophilic, nonpathogenic dermatophytoids, e.g., rough, thick-walled macroconidia with cellular compartments and colony with red reverse (*Microsporum cookei*); copious macroconidia intergrading with long microconidia in a continuous range from one- to six-celled (occasionally more) conidia (confirm no growth at 37°C and identify as *T. terrestre*; if 37°C growth occurs and colony reverse is red, go to item 2.b.(5) below for suspected Afro-Asiatic *T. rubrum* or *Trichosporon raubitschekii*); isolates with long, smooth, thick-walled macroconidia with cellular compartments and usually purple colony reverse (*T. ajelloi*), confirm as in Table 8.9–10 where possible and otherwise do reference identification.
 - h. All other dermatophytes, including any suggestive of the first six species listed above but with any unusual appearance or features, subculture to minimal set of physiological test media suggested in the introductory paragraph of item VIII.C above. If any isolate is suggestive of a dermatophyte with a known growth factor requirement or standard auxiliary test (e.g., polished-rice test for *M. audouinii*) as outlined in Table 8.9–10, subculture to that test as well. Subculture very slow-growing, white to pale-tan isolates suggestive of *T. verrucosum* and very slow growing, deep-purple-red isolates suggestive of *T. violaceum* to BCP milk glucose agar incubated at 37°C, as well as to the minimal physiological set and *Trichophyton* agars T3 and T4.
2. Examine minimal set of physiological test media after 7 to 10 days at 25°C.
 - a. Isolates with distinct zones of peripheral clearing on BCP milk glucose and no signs of contamination
 - (1) BCP milk glucose from 25 or 37°C incubation shows distinct zone of clearing; colony small, pale red or purple-red; poor growth on T1. Confirm T4 stimulation and red-purple colony for *T. violaceum*; con-

VIII. DERMATOPHYTE IDENTIFICATION (continued)

firm strongest *Trichophyton* agar growth on T3 and whitish to pale-tan color for most *T. verrucosum* isolates, with equally strong growth on T4 in some isolates. Examine substrate mycelium from 37°C BCP milk glucose, and confirm chains of symmetrical chlamydospores for *T. verrucosum*. If asymmetric chlamydospores are seen instead and T4 growth is equal to T3 growth and especially if the patient may have history of travel to east Africa (surrogate: Arabic, Eritrean, Ethiopian, or Somali surname) and especially if isolate is from endo-thrix tinea capitis, check with physician, rule out recent contact with cattle, and confirm atypical pale *T. violaceum*.

- (2) BCP milk glucose shows small but consistent zone of clearing all around colony; pH alkaline; colony on this medium brownish, yellow, or red with radial striations; urea negative (rarely positive); no growth on T1: confirm reflexive branching in striations; typical *T. soudanense*.
 - (3) Other colonies with zones of clearing: check for bacterial contamination by streaking to blood agar at 37°C; if positive, purify and resubculture to minimal physiological medium set. If negative, reference examination is needed.
- b.** Isolates with no clearing and no pH change on BCP milk glucose and normal growth on T1
- (1) Urease negative; BCP milk glucose colony restricted, cottony, with peripheral wine-red pigment. Confirm at least one drop-shaped microconidium on T1 or sporulation medium (e.g., potato flake agar); *T. rubrum*.
 - (2) Urease positive; BCP milk glucose colony profuse, flat, often with yellow pigment. Confirm at least one thick-walled, roughened, and beaked macroconidium. Confirm that colony is not salmon colored or pale brownish with few and mostly distorted macroconidia and from a child; if it combines these features, do polished-rice test to rule out *M. audouinii*. Otherwise, identify as *M. canis*. If isolate tested to rule out *M. audouinii* produces vigorous growth on polished rice (yellow pigment will also usually, but not always, be formed), identify as *M. canis*. If isolate shows poor growth on polished rice (brownish pigment will also usually, but not always, be formed), identify as *M. audouinii*.
 - (3) Urease negative; BCP milk glucose colony profuse, flat. Sabouraud colony has salmon or pale-brownish pigment, conidiation sparse or absent on both Sabouraud and BCP milk glucose. Distorted, beaked, partially rough-walled macroconidia may be seen, as may microconidia, small aerial arthroconidia, pectinate branches, or terminal chlamydospores. Isolate is from child, usually from scalp. Do polished-rice test. If isolate shows poor growth (brownish pigment will also usually, but not always, be formed), identify as *M. audouinii*. Otherwise, reference identification is needed.
 - (4) Urease positive; BCP milk glucose colony profuse, powdery, reminiscent of *T. mentagrophytes*. Subculture to Sabouraud and incubate at 37°C; also subculture to Sabouraud plus 3% NaCl and Sabouraud plus 5% NaCl (just add the stated proportion of salt to regular Sabouraud recipe while making up in-house). Confirm poor 37°C growth and abundant formation of rough-walled macroconidia on at least one of the two salt media; *Microsporum persicolor*.
 - (5) Urease positive; BCP milk glucose colony restricted, velvety, with wine-red reverse pigment. Confirm copious macroconidia and micro-

VIII. DERMATOPHYTE IDENTIFICATION (continued)

conidia on Sabouraud, usually also on T1 (however, microconidia are more predominant on this medium); intense red colony reverse pigment on Sabouraud and on potato flake, cornmeal glucose, or lactrimel if used; Afro-Asiatic *T. rubrum*, considered by some authors to be separate species *T. raubitschekii*.

- c. Isolates with no clearing and no pH change on BCP milk glucose and reduced growth on T1

Urease positive; BCP milk glucose colony powdery; abundant optically dense, broadly drop-shaped microconidia on BCP milk glucose and Sabouraud, often formed on broad matchstick pedicels, sometimes intermixed with balloon forms or filiform “caterpillar” branching clusters. Confirm growth stimulation on T4; *T. tonsurans*.

- d. Isolates with no clearing but with pH change to alkaline (blue-violet to purple color) on BCP milk glucose and normal growth on T1

- (1) Urease positive; BCP milk glucose colony profuse with granular, powdery, velvety, or cottony surface texture; copious round or drop-shaped microconidia present; wine-red pigments not formed on any medium (chestnut red-brown pigments rarely formed); confirm at least one well-formed spiral appendage; *T. mentagrophytes*.

☑ **NOTE:** If copious macroconidia intergrading with long microconidia are present on Sabouraud glucose agar, a test for growth at 37°C should be done to rule out *T. terrestre*.

- (2) Urease positive; BCP milk glucose colony yellow-brown or cottony white with or without yellow margin; no microconidia present; confirm at least a small number of broadly clavate, short macroconidia; atypical *E. floccosum*.

- (3) Urease negative or positive; BCP milk glucose colony profuse, flat. Sabouraud colony has salmon or pale-brownish pigment; conidiation sparse or absent on both Sabouraud and BCP milk glucose. Distorted, beaked, partially rough-walled macroconidia may be seen, as may microconidia, small aerial arthroconidia, pectinate branches, or terminal chlamydo spores. Isolate is from child, usually from scalp. Do polished-rice test. If isolate shows poor growth (brownish pigment will also usually, but not always, be formed), identify as *M. audouinii*. Otherwise, reference identification is needed.

- (4) Urease positive or negative; BCP milk glucose colony profuse but only moderately rapidly growing (same rate as on Sabouraud; not restricted in respect to Sabouraud growth rate); colony with wine-red reverse on Sabouraud. Confirm absence of contamination by streaking a plate of blood agar and incubating it at 37°C; inoculate T6 and T7. If stimulation is seen on T7, indicating histidine requirement, call physician and confirm travel history to Portugal, west Mediterranean, or central Africa; *T. megninii*. Otherwise, reference identification is needed.

- (5) Urease positive; possibly weak at 7 days but strong at 10 days. BCP milk glucose colony profuse but only moderately rapidly growing (same rate as on Sabouraud; not restricted in respect to Sabouraud growth rate); colony with yellow to yellow-orange reverse on Sabouraud and yellow peripheral growth on BCP milk glucose. Confirm yellow, coiled nodular bodies in subsurface mycelium, at least some broadly drop-shaped or round microconidia; *T. mentagrophytes* “nodular variant,” sometimes considered a separate species, *Trichophyton krajdinii* (see comment in Table 8.9–10.) The occasionally seen name “*T. mentagrophytes* var. *nodulare*” is apocryphal (no such taxon was ever formally described) and cannot be used.

VIII. DERMATOPHYTE IDENTIFICATION (*continued*)

- (6) Urease negative; BCP milk glucose colony profuse, with granular surface texture; copious round or drop-shaped microconidia present; wine-red pigments not formed on any medium; colony reverse yellow; spiral appendages present. Confirm patient may have had contact with hedgehog or with soil in region inhabited by hedgehogs; *T. mentagrophytes* var. *erinacei*.
- e. Isolates with no clearing but with pH change to alkaline (blue-violet to purple color) on BCP milk glucose and reduced growth on T1
 - (1) Urease positive; BCP milk glucose colony powdery; abundant optically dense, broadly drop-shaped microconidia on BCP milk glucose and Sabouraud, often formed on broad matchstick pedicels, sometimes intermixed with balloon forms or filiform caterpillar branching clusters. Confirm growth stimulation on T4; *T. tonsurans*.
 - (2) Urease positive; BCP milk glucose colony velvety, with colorful (yellowish to red-brown) reverse; drop-shaped conidia present, sometimes on short pedicels; no growth at all on T1. Confirm normal growth on T5; *T. equinum* var. *equinum*.

POSTANALYTICAL CONSIDERATIONS**IX. REPORTING AND INTERPRETATION****A. General considerations**

Full reporting of mycological identifications may take time, and the problem of preliminary reporting, omnipresent in medical laboratory work, is particularly exacerbated. There are two nearly contradictory general principles that should be kept in mind: (i) anything that the laboratory knows about the case that the physician needs to know in order to treat the patient correctly should be reported and (ii) laboratories should, as much as possible, avoid sending out preliminary reports that they will later have to contradict. These two exigencies call for the development of maximally accurate preliminary reporting systems.

B. Dimorphic fungi

The laboratory is often well aware before the formal confirmation of identity that a fungus is highly unlikely to be anything other than a dimorphic pathogen. This is especially the case when characteristic structures have been seen in direct bodily specimen microscopy. In some cases, rapid reporting may be essential to save the patient's life.

1. Report suspected diagnosis with any caveat (e.g., suggestive of . . . ; confirmation to follow) by telephone. Keep a record of notification, including name of person receiving report.
2. Send a fax only if it will be received immediately by suitable personnel and receipt is confirmed.
3. If confirmation using DNA probes can be achieved the same day, within normal hours, delay notification until the result is obtained.

C. Opportunistic and subcutaneous fungi from normally sterile sites

1. Reporting the growth of "a mould" as soon as such growth is evident but before identification structures are formed is important where immunocompromised patients are concerned but is not normally necessary in cases of subcutaneous infection (e.g., mycetoma) of immunocompetent patients. In the latter type of case, where direct microscopy or histopathology indicates the presence of fungal structures, such preliminary culture reports are redundant. Unless there are contraindications, it is more useful to identify the causal agent at least to the genus level before sending out a preliminary report. Genus level identification of moulds, in general, has a high correlation with appropriate antifungal drug selection today and should be carried out

IX. REPORTING AND INTERPRETATION *(continued)*

as soon as possible. Preliminary reporting of a few broad categories with potential treatment significance may also be useful when recognized

☑ **NOTE:** Recommended treatments may change over time or in different geographic areas; they are noted here only to substantiate the potential value of these preliminary reports.

- a. “A zygomycetous fungus with aseptate hyphae; identification to follow” (treatable mainly with amphotericin B)
 - b. “A ‘black yeast’ fungus in the related genera *Exophiala*, *Wangiella*, *Phaeococcomyces*, or *Phaeoannellomyces*; identification to follow” (itraconazole and ketoconazole may be most commonly used)
 - c. “A dematiaceous fungus; identification to follow” (treatment options often as for black yeasts, i.e., itraconazole or ketoconazole)
2. Generic reports of the following organisms are especially important as preliminary reports because of their important treatment ramifications. They concern agents that may be involved in rapidly progressing opportunistic infection.
 - a. Zygomycetes: *Rhizopus*, *Rhizomucor*, *Absidia*, and *Cunninghamella*
 - b. Hyalohyphomycetes (hyaline filamentous moulds): *Aspergillus*, *Fusarium*, *Scedosporium*, *Acremonium*, *Paecilomyces*, and *Trichoderma*
 - c. Phaeohyphomycetes (melanized filamentous “dematiaceous” moulds): *Curvularia*, *Exserohilum*, *Bipolaris*, *Dactylaria* (*Ochroconis*), and *Scedosporium*

☑ **NOTE:** *Scedosporium* has been included with both the hyaline and melanized groups above because in preliminary examination it may appear either way, depending on the individual isolate and the growth medium.
 3. For *Fusarium* spp. not immediately forming macroconidia, distinction from related fungi, such as *Acremonium* and *Cylindrocarpon*, may be delayed. It may be useful to preliminarily report these fungi collectively as “an atypical Hypocrealean fungus, e.g., *Fusarium*, *Acremonium*, or a related genus; identification to follow.” Treatments of members of this group of fungi have many commonalities (e.g., poor susceptibility to amphotericin B is common). The fungal order name Hypocreales is not yet widely familiar in biomedicine but appears destined to become so soon as molecular biology reorganizes fungal taxonomy.
 4. In tropical and subtropical areas, including the U.S. Gulf Coast area, aseptate mycelial cultures that may be the oomycete *Pythium insidiosum* should also be preliminarily recognized as rapidly as possible (very rapidly growing nonsporulating aseptate mycelium, usually from subcutaneous biopsy; sporulation with swimming zoospores may be induced by placing a block of colonized agar in water).
 5. In addition, some species identifications are especially important for their urgent treatment ramifications and should be performed as soon as possible on fungi from normally sterile sites.
 - a. Zygomycetes: *Apophysomyces elegans*, and *Saksenaea vasiformis* (mainly agents of severe cutaneous, subcutaneous, and osteomyelitic zygomycosis sometimes necessitating limb amputation, especially if allowed to progress through diagnostic delay)
 - b. Hyalohyphomycetes: *Paecilomyces variotii* (polyene [e.g., amphotericin B] susceptible), *Paecilomyces lilacinus* (often polyene resistant), *Scedosporium apiospermum* (all agents of a wide variety of opportunistic mycoses)
 - c. Phaeohyphomycetes: *Scedosporium prolificans*, and *S. apiospermum* (difficult-to-treat agents of a wide variety of opportunistic phaeohyphomy-

IX. REPORTING AND INTERPRETATION (*continued*)

cotic manifestations, including disseminated infection; early identification may be critical in some cases)

D. Corneal scrapes or ocular aspirates

Growth of any mould whatsoever entails an immediate, telephoned preliminary report that a mould is growing. The same broad-category generic and species names given above as urgent when from normally sterile systemic sites are equally urgent for ocular outgrowths. The rapid recognition of *P. lilacinus*, which is usually resistant to the commonly used pimarinic-natamycin and topical amphotericin B, is especially important. It should be recognized that many species, such as *Penicillium citrinum*, that are generally thought of as common contaminants are well-known and serious pathogens of mechanically traumatized corneas and that no outgoing report should suggest without qualification that they are insignificant.

Use the following note with all identifications of non-dimorphic-mould fungi from eyes where information about etiologic verification (e.g., a note that fungal filaments were seen in corneal scrapings) has not been included in the laboratory requisition.

“This species is a normally nonpathogenic, common contaminant, but an indefinite number of such fungi are capable of causing mycotic keratitis subsequent to traumatic inoculation. If keratitis is suspected in this case, confirmation can be accomplished by demonstrating fungal filaments directly in corneal scrapings.”

Such a note is unnecessary when the report is directed to a recipient known to have expertise in ocular mycoses or when the isolate or specimen is stated to be from endophthalmitis or from an immunocompromised patient.

E. Nonsterile respiratory sites (except sinuses)

Screening that allows the most rapid recognition and preliminary or final reporting of dimorphic fungi from these sites is of urgent concern. This matter is dealt with in item IX.B above. It should be noted in addition, however, that any pale mould that grows out on cycloheximide-containing medium from a respiratory specimen should be under a high index of suspicion as a possible dimorphic fungus until microscopically demonstrated otherwise. Nonsporulating, whitish, cycloheximide-tolerant fungi remain suspect, and in known *Blastomyces*-endemic areas they should be subcultured to specialized (48- to 72-h) conversion medium, such as Blasto D medium, immediately. It is the laboratory director's judgment call, in consultation with the physician, as to when to do probe or exoantigen tests on such isolates and which species to test for. Even the normally heavily sporulating and easily preliminarily recognized *Coccidioides* is occasionally isolated as a form with strongly delayed and aberrant conidiation.

Equally important is the preliminary reporting of aspergilli, zygomycetes, and *Fusarium* and *Scedosporium* spp. from any patients who are or may be immunocompromised. These reports may be at the genus level or at the broad-category levels outlined above for fungi from normally sterile sites. Species level reporting should follow unless the isolate in question has been ruled out as a potential opportunist (e.g., shown to be a *Mucor* sp. not growing at body temperature or a *Fusarium* sp. not corresponding to any of the described opportunistic species in the genus and not suggested by case circumstances to be a novel opportunist).

The genus *Aspergillus* is complex in that it contains both aggressive opportunists and common, almost entirely nonpathogenic fungi. A preliminary genus level report may be necessary where species identification cannot be performed immediately, but it carries a relatively low level of medical resolution. The following species are potentially opportunistic and should be reported at the species level as soon as possible, not because the species name has particular

IX. REPORTING AND INTERPRETATION (*continued*)

treatment significance (except with *Aspergillus terreus*), but to show that the fungus has been confirmed as a potentially opportunistic *Aspergillus* sp.: *Aspergillus fumigatus*, *Aspergillus flavus*, *A. terreus*, *Aspergillus nidulans*, and *A. niger*. On the other hand, *Aspergillus ochraceus*, *Aspergillus versicolor*, *Aspergillus sydowii*, and members of the *Aspergillus glaucus* complex have very little opportunistic potential, even in severely immunocompromised patients. These species should also be reported at the species level, along with the comment “normally nonpathogenic.”

The very significant fungus that has commonly been misidentified in past medical literature as *A. glaucus* and *A. versicolor* (as well as *Aspergillus restrictus*, *Aspergillus conicus*, *Aspergillus penicillioides*, and *Penicillium spinulosum*) is the host-adapted form of *A. fumigatus*, which is isolated either as a nonsporulating fungus or as a fungus with few and aberrant conidiogenous structures. This fungus can be rapidly preliminarily recognized by outgrowth of whitish, often dense and radially folded colonies from respiratory sources. Usually, although not always, isolation plates show several similar colonies. Subculture such colonies immediately to sporulation medium (e.g., PGA or Leonian's), and place these subcultures at 45 and 37°C. In almost all cases, growth at 45°C will be detectable within 24 h. I have routinely used the following preliminary report. “A nonsporulating fungus able to grow at 45°C in vitro has been isolated. Although such isolations from respiratory samples may be insignificant, they often indicate the host-adapted ‘dysgonic’ variant of *Aspergillus fumigatus*. Full identification of this organism may be delayed. Further report to follow.”

Scedosporium spp. should be identified at the species level as soon as possible, because treatments may differ. Because *S. apiospermum* may or may not form its *Pseudallescheria boydii* teleomorph, report this species as “the *Scedosporium apiospermum* asexual state of *Pseudallescheria boydii*” even when only the asexual morph is seen. This report may appear cumbersome, but it gives the physician access to all relevant literature keywords. The mycology laboratory director's telephone number should be on the outgoing report in all mycology reporting in case clarification is needed. Be aware that the *Scedosporium* state of *Petriella setifera* may also be seen, and this fungus of very low virulence should not be reported as *S. apiospermum*. It is microscopically similar to the latter until the perithecial sexual state develops after 14 days, but it appears atypical macroscopically in young growth, presenting either as a heavily tufted (synnematos), flat colony or as a white colony with little conidiation. *S. apiospermum*, on the other hand, is rather constant as a heavily powdery or, more often, woolly mouse gray-brown colony, with some ropy synnemata or hyphal bundles but not with a consistent growth of short (1-mm), upright tufts on a flat background. When in doubt, report “*Scedosporium* species; atypical; full identification to follow.”

Respiratory specimens intermix potential pathogens with the entire incident outdoor and indoor air spora, and it is common to isolate organisms such as *P. variotii*, *Fusarium oxysporum*, *Beauveria bassiana*, and *Engyodontium album* that are potentially opportunistic but that are far more commonly isolated from respiratory specimens as insignificant organisms. For these fungi, the following clarifying note is used in all cases of such isolation. “This normally nonpathogenic, common contaminant may uncommonly cause opportunistic infection, usually in the severely immunocompromised patient.”

The reporting of nonpathogenic respiratory contaminants to physicians may give the false impression that a potential disease agent has been reported and that treatment should be considered. On the other hand, however, it remains possible that a species never before recognized as an opportunist may cause an

IX. REPORTING AND INTERPRETATION (continued)

opportunistic infection. Some of the fungi commonly growing from respiratory specimens, especially *Cladosporium* spp., are well known to have maximal growth temperatures well below body temperature and to have little or no realistic potential as opportunists. The quantity and diversity of such organisms growing out may make it very difficult for larger or busier laboratories to deal with them except by ruling out known opportunists, especially as ~10 to 20% of the insignificant fungi that grow out are persistently nonsporulating wood-decaying basidiomycetes or plant-associated ascomycetes that cannot be conventionally identified at the genus level in culture. It is convenient for mycologically sophisticated laboratories to recognize locally common insignificant fungi at the genus or broad-group level and simply not to report them. There are “gray area” fungi, such as *Penicillium chrysogenum*, *P. citrinum*, and *Alternaria alternata*, that grow from respiratory specimens on a daily basis but are also validly reported from a respiratory infection approximately once per decade worldwide. These fungi should be reported at least at the genus level if the patient is stated to be immunocompromised or if there is an extenuating circumstance signaling possible infection, in particular, filaments seen in direct microscopy or in biopsy histopathology that are not connected with a more likely opportunist. (Unfortunately, quantity of growth is not a reliable criterion, as prevalent airborne fungi may grow from respiratory specimens, including bronchoalveolar lavage fluid, in large numbers.)

F. Nasal and facial sinus scrapings

To avoid insignificant contaminants being isolated from nasal and facial sinus sites, an effort should be made to connect the species isolated with filaments seen in direct microscopy. Most genuine sinus colonizations are associated with heavy fungal colonization, yielding a typical direct microscopy presentation of a thickly interwoven, blanketing layer of fungal filaments. This heavy growth may not coat the entire sinus interior, but pockets containing such growth exist and are normally readily detected in typical surgically obtained specimens. These masses of filaments are frequently mostly or entirely dead, but if growth is obtained in culture at all, it is usually obtained as multiple consistent colonies. The following filamentous fungi are most commonly involved.

1. Zygomycetes: *Rhizopus* spp.
2. Hyalohyphomycetes: *A. flavus*, *A. fumigatus*, *A. nidulans*, *A. terreus*, *S. apiospermum*, and *Schizophyllum commune*
3. Phaeohyphomycetes: *A. alternata*, *Bipolaris* spp., *Curvularia* spp., *Exserohilum* spp., *S. apiospermum*, and *S. prolificans*

Other fungi well known as opportunists, such as *Scopulariopsis brevicaulis*, *P. lilacinus*, and *P. variotii*, may occasionally be significant, especially in immunocompromised patients.

Growth of *Rhizopus* can be correlated with aseptate filaments, aspergilli and *Scedosporium* spp. have septate filaments and sometimes produce typical conidia in situ (or ascospores in the case of *A. nidulans*), the basidiomycetous mushroom *Schizophyllum* usually has clamp connections visible in direct microscopy, and the filaments of *Bipolaris*, *Curvularia*, and *Exserohilum* are usually conspicuously melanized. *Alternaria* filaments may or may not appear melanized (also, heme derived from blood may make *Aspergillus* filaments in sinus scrapings appear slightly brownish, so that they may be nearly as colored as *Alternaria* filaments) but will stain as melanized in the common histopathological Fontana-Masson melanin stain.

A recent publication arguing that all fungi isolated from partially lysed nasal mucus may be involved in causing sinusitis (16) overlooks or ignores the established presence of dormant air-derived conidia frequently trapped in this mucus. Such fungal spores are usually unable to grow at sinus cavity temperature and

IX. REPORTING AND INTERPRETATION (continued)

thus are highly unlikely to be involved in disease production, except in cases where they can be confirmed as correlating with the presence of fungal elements in direct microscopy of scrapings. Confirming the insignificance of most cultures from nasal mucus is the finding in the same study (16) that similar fungi can be isolated from nasal-mucus lysates obtained from individuals without signs or symptoms of sinus infection. Thus, culture results from this technique should not be reported in a way that suggests causation of infection unless fungal establishment is confirmed by detecting vegetative structures (e.g., filaments, pseudohyphae, or budding yeast cells) in direct microscopy.

G. Ear canals

The isolation of insignificant contaminating inoculum from ear canals is common, and if possible, all isolations should therefore be correlated with direct microscopic evaluation before being reported. An exception should be made in apparent invasive infections of immunocompromised patients, where all fungi grown should be reported rapidly. Genuine otomycotic colonization of immunocompetent patients, when caused by moulds, features a very heavy investment of fungal filaments in the ear canal, and these filaments usually bear copious conidiogenous structures, especially when aspergilli are involved. The fungus isolated can normally, though not always, be correlated with that seen in direct microscopy by examining this in situ conidiation. The in situ conidiation leads to very heavy outgrowth on the primary isolation plate, so if information is not available on direct microscopy (e.g., where the fungus has been elucidated incidentally by a bacteriological swab study for culture only), the occurrence of confluent outgrowth of many dozens of colonies may be taken as suggestive of causality in otomycosis. Suspected agents of otomycosis may be preliminarily reported by genus name if species identification will take additional days, since otomycotic colonizations may be painful. The following species are most commonly involved: *A. niger*, *A. fumigatus*, *A. terreus*, *A. flavus*, *A. nidulans*, *S. apiospermum*, and *S. prolificans*. Occasionally, unusual fungi will be involved, and it should always be borne in mind that dimorphic fungi may be isolated from any body site.

H. Skin scrapings yielding nondermatophytes

For filamentous fungi other than dermatophytes obtained from dry dermatological skin scrapings (i.e., not from skin biopsies, punch biopsies, pus aspirates, wound swabs, burn eschar, etc.), only two organisms, *Scytalidium dimidiatum* (pycnidial synanamorph name, *Nattrassia mangiferae*; outdated name, *Hendersonula toruloidea*) and the possibly conspecific *Scytalidium hyalinum*, are likely to be etiologically significant. These two *Scytalidium* spp. may be reported directly as etiologic agents just as dermatophytes are *except in rare cases where all three of the following conditions apply*: (i) the fungus obtained is a "type 1" fast-growing, woolly *S. dimidiatum* isolate (13), (ii) no filaments were detected in direct microscopy of the skin specimen (reexamination of any residual skin scrapings is warranted if this was the initial finding prior to culture), and (iii) the laboratory is in a tropical or subtropical area where potential host plants of the wild-type type 1 *S. dimidiatum*, such as pecan or mango, occur. The two significant *Scytalidium* spp. are recognized by cycloheximide sensitivity in vitro (~5% of isolates are semitolerant as defined in item VII.A above) and by their production of branching chains containing both one-celled and two-celled arthroconidia that vary conspicuously in size. *S. dimidiatum* is dark gray, while *S. hyalinum* is white with a pale-yellowish colony reverse (21).

Scytalidium isolations from skin and nails may be reported as follows. "*Scytalidium* [insert species name]. This species frequently causes dermatophytosis-like infections of nails, soles, and palms. It is usually resistant to antifungal drugs in vivo, despite appearing susceptible in in vitro tests."

IX. REPORTING AND INTERPRETATION (continued)

On rare occasions, especially in immunocompromised patients, the cornified skin epidermis may be colonized by moulds other than dermatophytes and *Scytalidium*. Such cases can only be verified by consistent repeated isolation from successive samples taken at different time points *in combination with* demonstration of compatible fungal elements in direct microscopy or histopathology.

I. Toenails and fingernails yielding nondermatophytes

1. Filamentous fungi other than dermatophytes obtained from toenails and fingernails present by far the most ecologically complex area of mycological diagnosis. *S. dimidiatum* and *S. hyalinum* are simple: they should be reported under the same conditions given in item H above for dry skin scrapings.

Fungi other than *Scytalidium* spp. that have repeatedly been rigorously shown to cause onychomycosis in the absence of a concomitant dermatophyte are relatively few in number. The most commonly significant are listed in Table 8.9–11. All of these fungi may also be isolated purely as insignificant contaminants; in fact, in most cases, they are much more commonly seen as insignificant isolations than as significant isolations. In addition, there are a few gray-area fungi, such as *A. alternata* and *Chaetomium globosum*, that are abundant nail contaminants and that are only extremely rarely seen as etiologic agents. These fungi have been excluded from Table 8.9–11 and are discussed further below.

The fungi listed in Table 8.9–11 may grow in laboratory specimens under a bewildering variety of significance conditions. These conditions are listed below, marked with one to four asterisks for situations varying from uncommon (one asterisk) to common (four asterisks). All are regularly encountered in larger laboratories. The following describe fungi in Table 8.9–11 when grown in culture from nails, especially the hallux (large) toenail.

a. If grown out in cases with unusual, definitely nondermatophytic microscopic structures seen invading the nail tissues in direct microscopy or histopathology, they

- (1) May be sole agents of onychomycosis, growing alone and connected with distinctive structures in direct nail microscopy (e.g., *Scopulariopsis*-like lemon-shaped conidia or *Aspergillus* heads with conidia)**
- (2) May be agents of a mixed infection with a dermatophyte which failed to grow either because it was overgrown by the mould or because it was not viable or not present in the exact portion of nail that was sampled*
- (3) May be agents of a mixed infection with a dermatophyte that also grows out*

b. If grown out in cases with ordinary, possibly dermatophytic or possibly nondermatophytic filaments seen in direct microscopy and *with no dermatophyte growing*, they

- (1) May be sole agents of onychomycosis, growing alone and connected with the nondistinctive, septate filaments seen in direct microscopy**
- (2) May be contaminants growing alone on isolation media and seemingly (although falsely) connected with the nondistinctive, septate filaments that in fact (as revealed by later repeat cultures or by specific immunohistochemistry) are dead dermatophyte filaments (the connected dermatophyte infection has living elements elsewhere in the nail, but the portion sampled contained only dead filaments)***
- (3) May be contaminants that have overgrown a causal dermatophyte on isolation media***
- (4) May be agents of mixed onychomycosis co-occurring with a causal dermatophyte that by chance is not isolated from the initial filaments or that has been overgrown*

Table 8.9–11 Most common fungi other than dermatophytes and *Scytalidium* repeatedly and rigorously implicated as causal agents of onychomycosis

<i>Acremonium potronii</i>
<i>Acremonium strictum</i>
<i>Aphanoascus fulvescens</i>
<i>Aspergillus candidus</i>
<i>Aspergillus flavus</i>
<i>Aspergillus fumigatus</i>
<i>Aspergillus nidulans</i>
<i>Aspergillus niger</i>
<i>Aspergillus sydowii</i>
<i>Aspergillus terreus</i>
<i>Aspergillus versicolor</i>
<i>Fusarium oxysporum</i>
<i>Fusarium solani</i>
<i>Microascus cinereus</i>
<i>Onychocola canadensis</i>
<i>Scopulariopsis brevicaulis</i>

IX. REPORTING AND INTERPRETATION (continued)

- c. If grown out in cases with ordinary, possibly dermatophytic or possibly nondermatophytic filaments seen in direct microscopy and *with a dermatophyte growing*, they
 - (1) May be contaminants insignificantly co-occurring with a causal dermatophyte****
 - (2) May be agents of mixed onychomycosis significantly co-occurring with a causal dermatophyte*
- d. If grown out in cases with no filaments seen in direct microscopy and *with a dermatophyte growing*, they
 - (1) May be contaminants isolated along with a dermatophyte, and the filaments of the causal dermatophyte may be missed in direct microscopic analysis or histopathology**
 - (2) May be agents of mixed infection growing along with a dermatophyte, and the filaments of both the dermatophyte and the nondermatophyte may have been missed in direct microscopic analysis or histopathology*
- e. If grown out in cases with no filaments seen in direct microscopy and *with no dermatophyte growing*, they
 - (1) May be contaminants growing purely from sedimented conidia with no correlated filaments in the nail****
 - (2) May be sole agents of onychomycosis growing alone, but their filaments may be relatively sparse and may have been missed in direct microscopic analysis (especially a problem with *Acremonium* from superficial white onychomycosis)**

Additional details are given in Summerbell (22). Note that the well-demonstrated (1) reality that more than one nondermatophyte may co-occur etiologically in the same nail, in the presence or absence of a dermatophyte, has not been permutationally expatiated in the list in terms of the possible laboratory presentations that may ensue. Further permutations are generated when physicians mix materials from separate nails together in the same specimen packet, since individual nails may have separate nondermatophyte colonizers (unlike dermatophytes, these nondermatophytes cannot grow from nail to nail across contiguous skin; they also differ from dermatophytes in being unlikely to invade successive nails contagiously). For example, see Gupta et al. (7), where a patient with *A. terreus* established in one hallux nail and *Onychocola canadensis* in the other is documented. It is not surprising, therefore, that this complexity coincides with an area of diagnosis often proclaimed to be controversial, mainly because simplistic beliefs and solutions avoiding the above-mentioned complexity may be fervently adhered to despite abundant counterevidence.

- 2. After much experience and consultation with dermatologists and researchers, I developed the following system of reporting the fungi listed in Table 8.9–11 from nails.
 - a. If a fungus from Table 8.9–11 is grown in the presence of distinctive elements that explicitly confirm its nail invasion, the elements seen are characterized as nondermatophytic and are described in the direct microscopic report (e.g., “dark [melanized] fungal filaments seen”), and the fungus is identified by name and noted as consistent with the elements seen.
 - b. If a fungus from Table 8.9–11 is grown from a specimen for which direct microscopy shows nondistinctive fungal filaments, the species is identified and the following note is appended. “This common, normally non-pathogenic fungus, when isolated from filament-positive nail material, is usually a contaminant overgrowing nonviable dermatophyte inoculum.

IX. REPORTING AND INTERPRETATION (continued)

Uncommonly, it causes onychomycosis and can be confirmed as an etiologic agent by consistently repeated isolation in the absence of a dermatophyte. Rare mixed infections will show consistently repeated isolation in successive samples, along with at least one isolation of a dermatophyte.”

- c. If a fungus in Table 8.9–11 is grown from a specimen for which direct microscopy is negative, the species is identified, and the following note is attached (based on numerous incidents in which nondermatophytes first isolated in such cases later proved to be causal and to have localized filaments that were detectable after extensive searching). “In cases like the present one where direct microscopic examination shows no mycelium, this isolation would ordinarily be considered surface contamination. Since the above species does occasionally cause onychomycosis, however, in addition to being a common contaminant, this isolation is noted for your records.”
- d. If a fungus in Table 8.9–11 is grown along with a dermatophyte, it is reported beneath the dermatophyte report, and the following note is appended. “This common, normally nonpathogenic fungus, when isolated concurrently with a dermatophyte, is usually an insignificant contaminant. Uncommonly, it is involved in a mixed onychomycosis infection and can be confirmed as established in the nail by consistently repeated isolation in successive samples. Whether such fungi, if established in the nail, may be concomitantly eliminated by therapy directed against the dermatophyte is in many cases not reliably predicted by their antifungal susceptibilities in vitro.”
- e. If a species from Table 8.9–11 is received from another laboratory with a requisition stating that it is from a nail but with no indication of whether direct microscopy was positive or negative for fungal elements, the species is identified, and two successive notes are attached.
 - (1) If direct microscopy (hydroxide, calcofluor, or periodic acid-Schiff [PAS]) of the nail specimen is negative for fungal filaments, this isolate would conventionally be regarded as a contaminant. If direct microscopy is positive, the note in item (2) below applies.
 - (2) This common, normally nonpathogenic fungus, when isolated from filament-positive nail material, is usually a contaminant overgrowing nonviable dermatophyte inoculum. Uncommonly, it causes onychomycosis and can be confirmed as an etiologic agent by consistently repeated isolation in the absence of a dermatophyte. Rare mixed infections will show consistently repeated isolation in successive samples, along with at least one isolation of a dermatophyte.

The net effect of all these notes is to elicit repeat samples in situations where physicians judge that these samples are applicable, given accurate information about the opportunistic nature of the fungi isolated and their own knowledge about how patients are responding to therapy. Not all the species known to rarely cause opportunistic onychomycosis are listed in Table 8.9–11 (see Summerbell [21] for others), and additional species are still being added to the list of rigorously confirmed agents of onychomycosis.

■ *Spurious reports based on inadequately confirmed cases are also relatively common.*

Especially in the case of fungi such as *C. globosum* that are ubiquitous as nail contaminants but very rarely confirmed as agents of onychomycosis, reporting all possible agents of opportunistic onychomycosis as Table 8.9–11 fungi would be an immense and unjustifiable generator of inconsequential reports. Non-*Scytalidium* moulds other than Table 8.9–11 fungi are best only

IX. REPORTING AND INTERPRETATION (*continued*)

reported as possibly implicated in opportunistic onychomycosis, using the notes for Table 8.9–11 fungi above, if no dermatophyte is isolated *and* if direct microscopy shows fungal elements that are unusual and that appear very likely not to belong to a nongrowing dermatophyte. *Chaetomium* and *Alternaria*, for example, when actually infecting nails, may have distinctive brown (melanized) hyphae in situ. As another example, very rare onychomycoses caused by *Exophiala (Wangiella) dermatitidis* show abundant dark yeast cells and filaments in nail tissue (21).

Some laboratories report all nondermatophyte isolations from nails, whether or not the organisms have ever been confirmed as causal agents of onychomycosis or possess the physiological prerequisites of such pathogenesis. This is sometimes represented as letting the physician decide the significance of these names. I have experienced a steady stream of calls from physicians and their staff for treatment advice for imagined infections caused by completely nonpathogenic fungi, such as *Epicoccum nigrum* and *Pithomyces chartarum*, in nails, frequently accompanied by comments that nothing can be found about these fungi in any book. Physicians in general practice and many specialties do not have access to large components of the mycology information base. The calls mentioned surely represent only a small portion of the medical confusion caused by this irresponsible reporting practice, and the probability that at least some patients will be treated, at considerable expense, for these nonexistent infections is very high.

Several recent publications in dermatology journals have recommended histopathology with fungus-specific stains (e.g., PAS) as a sole method of diagnosing onychomycosis. It should be noted that this technique is only able to distinguish dermatophytic from nondermatophytic elements in the rare cases where the latter have highly distinctive features incompatible with a dermatophyte. This proposed technique is thus a recipe for misdiagnosing nondermatophytic onychomycosis as dermatophytosis and potentially for treating it with inappropriate drugs. Differential immunohistochemistry is theoretically able to solve this problem by distinguishing dermatophytic and nondermatophytic elements in nails with specific immunofluorescent antibody reactions, but to my knowledge this esoteric and laborious technique has only been utilized so far in a single research project (1). PCR is similar to culture in connection with nondermatophytic onychomycosis because it is unable to distinguish between etiologic elements and contaminating elements in a single specimen.

J. Wounds and ulcers sampled by swabs, and syringe-aspirated pus

For filamentous fungi other than potential dimorphic fungi obtained from wounds and ulcers of nonimmunocompromised patients sampled by bacteriological swabs or syringe aspirations of pus, several ecological situations need to be encompassed in reports. The most common cause of heavy fungal outgrowth from these samples is saprobic growth of moulds, especially *Fusarium* spp., on serous exudate on the surfaces of nonsterile open lesions. If a direct microscopic Gram smear or KOH mount is done, copious fungal filaments may be seen, but these are loose, not penetrating tissue. There are, however, some less likely possibilities.

1. A mycetoma in which grains were not observed either macroscopically or in direct microscopy but nonetheless were included in the sample and grew to yield the causal organism
2. An intact mycotic subcutaneous cyst sampled by syringe aspiration alone, or recently traumatically broken open and sampled by swab, with subsequent elucidation only of the material from loose filaments in the serous core of the cyst but not of the filaments penetrating the tissue of the cyst wall

IX. REPORTING AND INTERPRETATION (continued)

- An opportunistic disseminated or primary cutaneous opportunistic infection in a patient whose immunocompromised status is unknown or has not been disclosed

Normally, nonpathogenic species from such samples are identified and given the following clarifying note. "This normally nonpathogenic, common organism often heavily colonizes surfaces of wounds and ulcers as a seemingly harmless saprobe (saprophyte) growing on serous exudate. In the strongly immunocompromised patient (usually neutropenic), invasion may be possible. If infection of an immunocompetent patient is long-lasting and involves deep tissue, then the possibility of a mycetoma or mycotic cyst may be considered. These conditions are demonstrable by biopsy histopathology showing fungal elements organized into granular structures in dermal tissue (mycetoma) or diffusely invading the dermal cyst wall (mycotic cyst). If the lesion extends to bone, mycotic osteoarthritis or, in compound fractures, osteitis may also be considered."

As with all the clarifying notes given above, this one is subject to modification by the laboratory director in cases where part of its contents may not be appropriate or on all occasions where new scientific knowledge renders it partially obsolete or incomplete. Medical mycology literature must be diligently followed to ensure that all such information remains up to date.

Acknowledgments. Thanks to Lynne Sigler, Ursula Bunn, and Maria Witkowska for contributing vital information and to Helen Demshar for enabling laboratory diagnostic improvement.

APPENDIX 8.9–2

Media and Reagents, Sources, and Recipes

■ **NOTE:** QC of most of the materials summarized in this appendix is detailed in appropriate parts of items 8.9.V, 8.9.VII, and 8.9.VIII.

A. Potato glucose agar (PGA)

potato flour*	39 g
yeast extract	2.5 g
glucose	10 g
agar (Difco**)	15 g
distilled water	1,000 ml

Autoclave at 121°C for 15 min. Pour into tubes or plates.

*No known difference among many potential commercial sources available from grocery store or wholesaler; therefore, no supplier is specified.

**Difco: BD Biosciences, Sparks, Md. The manufacturer is mentioned because the quantity of agar necessary varies by manufacturer.

B. Leonian’s agar (Cain modification)

malt extract (Difco)	12.5 g
maltose	12.5 g
monopotassium phosphate (KH ₂ PO ₄)	2.5 g
yeast extract	2.0 g
magnesium sulfate · 7H ₂ O	1.25 g
Bacto-Peptone (Difco)	1.25 g
agar (Difco)	40 g
distilled water	2,000 ml

Autoclave at 121°C for 15 min. Pour into tubes or plates. The double-size (2,000-ml) batch is prepared to render the quantities of the minor ingredients convenient to work with.

■ **NOTE:** The complex biologicals malt extract and Bacto-Peptone could possibly be obtained from other manufacturers; no comparison data are available.

C. Potato flake agar

Potato flake agar in its cycloheximide-free, colorless form can be used generically to promote sporulation or conidiation in a wide variety of clinical fungi. It has become most widely used, however, for dermatophyte identification, and for this use it is supplemented with cycloheximide and a pH indicator. This specialized version is available commercially as Potato Flakes Agar (Hardy Diagnostics, Santa Maria, Calif.) or as Rapid Sporulation Medium (Bacti-Lab, Mountain View, Calif.). It may elicit more rapid formation of conidia in dermatophytes than can be obtained on Sabouraud agars. Also, according to Aly (1), its colored pH indicator does not obscure the red pigment of *Trichophyton rubrum*. This indicator allows dermatophyte growth to be tentatively confirmed. Dermatophytes produce alkaline byproducts during growth on proteinaceous materials; in this case, the result is a change of the bromthymol blue indicator (Difco) from yellow to blue-green. This is a relatively specific response, although uncommonly isolated non-pathogenic dermatophytoids like *Trichophyton terrestre* and onygenalean chrysosporia like the *Chrysosporium* state of *Arthroderma cuniculi* will produce the same effect (5). The recipe below is for the dermatophyte version of the medium; for the generic version, omit the cycloheximide in step 2 and all of step 3. The volume of distilled water in step 1 should be adjusted to 900 ml. For work with known pure cultures, step 2 can be omitted and the water in step 1 can be adjusted to 1,000 ml.

APPENDIX 8.9–2 (continued)

1. Step 1. To a 2-liter flask, add the following:

agar (Difco)	25 g
glucose (Difco)	10 g
Betty Crocker Potato Buds*	20 g
distilled water	850 ml

Heat and stir until boiling commences.

2. Step 2. To a 250-ml flask, add the following:

distilled water	100 ml
chloramphenicol**	0.5 mg
cycloheximide***	0.5 mg

Heat and stir just until particles dissolve.

3. Step 3. To 15 ml of 0.1 N NaOH
 - a. Add 0.5 g of bromthymol blue (BTB) and then make up to 100 ml with distilled water (stock solution).
 - b. Use 40 ml of BTB stock solution for each 1 liter of medium.
 - c. Prepare 0.8 N solution of HCl for pH adjustment.
4. Step 4. Mixing
 - a. Add 100 ml of antibiotic solution to agar solution just as boiling commences.
 - b. Add BTB solution as indicated in step 3b; stir.
 - c. Adjust pH to 5.8 with 0.8 N HCl.
 - d. Autoclave at 121°C for 15 min.
 - e. Pour into tubes or plates.

*General Mills, Minneapolis, Minn.; variants use only 15 g of Potato Buds; Instant Mashed Potato Puffs (General Mills) is given by Rinaldi (4) as an alternative.

**Parke Davis Pharmaceuticals, Detroit Mich. (division of Pfizer Inc., New York, N.Y.)

***Calbiochem: CN Biosciences, San Diego, Calif.; Merck KG AA, Darmstadt, Germany

D. Cereal agar

Mead Johnson Mixed Cereal Pabulum (for babies) (Mead Johnson Nutritionals, Evansville, Ind.)	25 g
agar	5 g
water	250 ml

Add water to dry ingredients and autoclave at 121°C for 20 min (15 lb/in²; 20 min). Pour into plates or tubes. The small volume is to ensure good heat penetration and prevent survival of spore-forming bacteria. If more is wanted, make multiple small batches, not large batches. Kane et al. (3) comment that mixed cereal is superior to baby oatmeal, although the latter has also been used in similar media.

E. Tap water agar

tap water	1,000 ml
agar	15 g

Autoclave at 121°C for 15 min. Pour into tubes or plates.

F. QC isolates—maintenance

For PGA, if the same isolate is used repeatedly, stocks should be carefully conserved, ideally as multiple subcultures at –20 to –80°C to ensure that pleomorphic degeneration does not distort results. No *Microsporium canis* subculture that has remained on growth medium at room temperature or above for >30 days should be considered reliable.

APPENDIX 8.9–2 (continued)

G. Dimorphic fungus identification—media for conversion of dimorphic fungi

1. Blasto D medium

glucose	7 g
Tween 80	0.2 ml
potassium sulfate (K ₂ SO ₄)	0.5 g
magnesium citrate	1.5 g
dipotassium phosphate (K ₂ HPO ₄)	5.0 g
asparagine	5.0 g
Casamino Acids	3.0 g
sodium chloride (NaCl)	0.85 g
agar	15 g
distilled water	1,000 ml

a. Step 1. Mix ingredients; adjust to pH 6.6; bring to a boil to dissolve completely; autoclave at 121° C for 15 min.

b. Step 2. Apportion into tubes and slant.

Antibiotic-supplemented versions are advantageous for dealing with bacterially contaminated cultures. Chloramphenicol, which is a commonly used antibiotic addition to media, is inhibitory to yeast phase *Blastomyces dermatitidis* in vitro, and another antibiotic, such as tobramycin (100 µg/ml), should be used.

2. For *Histoplasma capsulatum*

a. Kurung-Yegian medium

potato flour*	5 g
deionized water	500 ml
whole egg*	250 ml
egg yolk* (50% enrichment)	500 ml

*No known difference among many potential commercial sources available (grocery store or wholesaler); therefore, no supplier is specified.

(1) Step 1. Mix potato flour and water, adjust pH to 5.0, and then heat to dissolve. Autoclave at 121°C for 15 min and then cool to 50°C in a water bath.

(2) Step 2. Surface disinfect whole eggs by standing them in 70% ethanol for 15 to 30 min. Break open eggs with a sterile knife and prepare egg yolk enrichment by draining off sufficient egg white. Break open additional eggs and blend both egg fractions together thoroughly, in sterile blender if available. Add egg mixture to potato mixture from step 1 and mix. Apportion into tubes and slant. Allow to set for 25 min at 82°C in the autoclave (isothermal cycle).

b. Blood-glucose cysteine agar

tryptose blood agar base (Acumedia; Neogen, Lansing, Mich. [catalog no. 7282])	33 g
L-cysteine (hydrochlorate)	1 g
defibrinated sheep blood	.50 ml
penicillin (100,000 U/ml)	10 ml
distilled water	990 ml

Mix tryptose blood agar base, cysteine, and water and bring to a boil so that dissolution occurs. Autoclave at 121°C for 15 min. Cool to 50°C and add blood and penicillin. Apportion into tubes and slant.

3. For *Penicillium marneffei*

Sabouraud's agar (Sabouraud formulation, with original glucose level and animal protein)

distilled water	1,000 ml
glucose	40 g
Bacto-Peptone*	10 g
Difco agar*	15 g

Heat to near boiling to dissolve. Adjust pH with NaOH to 7.0. Autoclave at 121°C for 15 min. Apportion into tubes and slant.

*Difco: BD Biosciences, Sparks, Md.

APPENDIX 8.9–2 (continued)

H. Exoantigen test—immunodiffusion agar

sodium chloride	0.9 g
sodium citrate ($\text{Na}_3\text{C}_6\text{H}_5\text{O}_7 \cdot 2\text{H}_2\text{O}$)	0.4 g
phenol (aqueous, 90% [wt/wt])	0.25 ml
glycine	7.5 g
purified agar (Difco)	1.0 g
distilled water	to 100 ml

Mix sodium chloride and sodium citrate in 50 ml of distilled water in a 125-ml Erlenmeyer flask, dissolve, and then thoroughly mix in the phenol and glycine. Add agar, bring level of ingredients up to 100 ml with additional water, and autoclave for 10 min at 120°C. Final pH should be 6.3 to 6.4; adjust if necessary.

Preparing immunodiffusion plates

1. Aseptically pipette 6.5 ml of immunodiffusion agar (after autoclaving it and when it has cooled to 60 to 65°C) into each plastic petri dish (diameter, 100 mm). Allow to gel (30 min); this forms the basal layer of medium. Retain some agar at 60°C in a water bath so that an upper layer can be overlaid later.
2. After the basal layer is well gelled, add 3.5 ml of the retained 60°C medium on one side of each plate. Immediately lower and press a microimmunodiffusion template (Quality House, Cartersville, Ga.) into the hot agar so that air bubbles are not trapped. The template should be securely appressed to the basal layer. Again allow the medium to cool for at least 30 min to gel. After this point, the plates can be used immediately if needed.
3. After the upper medium layer has gelled, remove extra agar from the template with a 1-mm-wide spatula. This is most easily done if the plates have first been cooled in a refrigerator for 5 to 10 min. Plates may be stored for up to 4 weeks if retained in a moist chamber at 4°C. The expiration date should be recorded on the plate and in the laboratory's work records. It should be noted that commercially obtained identification plates (Meridian Diagnostics, Cincinnati, Ohio) will simply have precut wells forming an immunodiffusion grid and will already bear their expiration date on the plate or bag label.

Include QC information on reagent container and in QC records.

I. Growth factors for dermatophytes

1. *Trichophyton* agars

Trichophyton agars are commercially available (Difco-BD Biosciences). If the media are to be made in-house, the following recipes apply. Prepare vitamin-free Casamino Acids Agar.

Casamino Acids, vitamin-free	2.5 g
glucose	40 g
magnesium sulfate $\cdot 7\text{H}_2\text{O}$	0.1 g
monopotassium phosphate (KH_2PO_4)	1.8 g
agar	15 g
distilled water	to 1,000 ml

Autoclave at 10 lb/in² for 10 min (110°C). Adjust pH to 6.8. Add nutrient solutions as outlined below, pour into tubes, and slant.

For *Trichophyton* agar no. 2 (T2), add 20 ml of a sterile 250- $\mu\text{g}/\text{ml}$ aqueous stock solution of inositol to the vitamin-free medium while still molten and mix well prior to pouring. For T3, add inositol as for T2, as well as 20 ml of a sterile 10- $\mu\text{g}/\text{ml}$ aqueous stock solution of thiamine. For T4, add 20 ml of thiamine stock solution alone. For T5, add 20 ml of a sterile 10- $\mu\text{g}/\text{ml}$ aqueous stock solution of nicotinic acid. For T6, substitute 1.5 g of ammonium nitrate (NH_4NO_3) for the Casamino Acids in the basal formulation. For T7, add 20 ml of a 150- $\mu\text{g}/\text{ml}$ aqueous stock solution of L-histidine to T6. (To prepare γ - $\mu\text{g}/\text{ml}$ aqueous stock solution, add 0.1 γ mg of growth factor to 100 ml of distilled water. Sterilize by micropore filtering [0.22- μm pore size] or by gentle autoclaving at 10 lb/in² for 10 min. There is some controversy about whether such growth factors survive autoclaving well; QC tests that should be done on growth factor media in any case should detect any problems that may arise.)

All these media can be prepared in 100-ml volumes if small quantities are used. For the rarely used nicotinic acid test, the stock solution can simply be retained in the refrigerator, and 2 or 3 drops can be pipetted across the medium surface of a T1 slant in order to obtain a functional T5 test. This convenience is possible only for the nicotinic acid test because of its absolute (growth or no growth) nature.

APPENDIX 8.9-2 (continued)

2. Christensen's urea agar and broth

Christensen's urea broth or agar slants are commercially available from numerous manufacturers. A recipe for broth is given for in-house production. Due to the high cost of agar and quicker yield of test results in broth, broth is somewhat preferable to agar.

a. Step 1. Prepare sterile urea solution.

distilled water	100 ml
urea	.20 g
glucose	1 g

Dissolve and sterilize by micropore filtration.

b. Step 2. Prepare remaining ingredients.

Bacto Peptone	1 g
sodium chloride	5 g
anhydrous monopotassium phosphate (KH_2PO_4)	2 g
phenol red (0.25% stock in ethanol)	8 ml

Dissolve, adjust pH to 6.9, autoclave at 15 lb/in² for 15 min (121°C). Cool to circa 55 to 60°C and add urea solution. Readjust pH to 6.9 if indicator color shows any change. Dispense aseptically as 5-ml aliquots into, for example, 16- by 125-mm screw-cap tubes.

3. Brom cresol purple (BCP) agar

BCP milk glucose medium is available commercially from numerous sources (e.g., Hardy Diagnostics, Santa Maria, Calif., as Dermatophyte Milk Medium [Biomedica Unlimited, Toronto, Canada]; or as Dermatophyte Differentiation Agar [Quelab Laboratories, Montreal, Canada]). A recipe for in-house production is given below. Note that although the recipe has glucose separately autoclaved, this was originally instituted as a precaution and may not be entirely necessary. Laboratories could, if desired, experiment to determine if steps 2 and 3 below could be combined, using appropriate QC isolates to judge the results.

a. Step 1

Difco agar	7.5 g
distilled water	100 ml

Soak agar for 15 min; autoclave at 15 lb/in² for 15 min (121°C). Retain at 60°C in a water bath unless steps 2 and 3 can be done at the same time. These steps have a shorter autoclave time, so two autoclaves are required to do all three steps simultaneously.

b. Step 2

skim milk powder	.20 g
BCP (1.6% stock solution in ethanol)	0.5 ml
distilled water	250 ml

Dissolve and autoclave at 10 lb/in² for 8 min.

c. Step 3 (done at same time as step 2)

D-glucose	10 g
distilled water	500 ml

Dissolve and autoclave at 10 lb/in² for 8 min.

d. Step 4

Combine the autoclaved products of steps 1 to 3 and adjust pH to 6.6. Dispense aseptically and slant, e.g., 5-ml aliquots into 16- by 125-mm screw-cap tubes, with the longest slant allowed by the tube. Production QC: the medium should be sky blue in color.

4. Cornmeal glucose agar

Available commercially from Remel Inc. (Lenexa, Kans.)

a. Step 1

cornmeal	40 g
distilled water	1,000 ml

Make an infusion from cornmeal as follows. Mix cornmeal with water, heat for 1 h at 52°C or autoclave for 10 min at 121°C. Filter through cheesecloth and then through Whatman no. 2 filter paper. Bring up liquid to 1,000 ml with additional distilled water as necessary.

APPENDIX 8.9–2 (continued)

b. Step 2

glucose	20 g
agar	15 g

Add agar to infusion from step 1 and boil to dissolve. Add glucose. Bring liquid up to 1,000 ml with additional distilled water as necessary. Autoclave for 15 min at 121°C. Pour into tubes and slant. Final pH, 6.0.

Other agars that may be used to elicit the wine-red pigment of *Trichophyton rubrum* include Casamino Acids erythritol albumin (CEA) agar (6) (commercially available as Candida Inhibitory Agar [Biomedica Unlimited, Toronto, Canada]) and modified Borelli's lactrimel agar (2) (available from Excel Laboratory Products, Belmont, West Australia).

5. Polished-rice medium

polished (white) rice*	4.5 g
distilled water	14 ml

*No known difference among many potential commercial sources available from grocery store; therefore, no supplier is specified. However, ordinary long grain white rice is generally used in preference to products with potentially higher or lower nutrient levels, such as converted rice, parboiled rice, instant rice, jasmine rice, or sticky rice.

Add ingredients to a 1-oz. universal bottle or to a suitable Erlenmeyer flask. Autoclave for 15 min at 121°C.

6. Sabouraud dermatophyte decontamination broth

a. Step 1. Make Sabouraud broth with selective agents.

glucose	40 g
Bacto Peptone (Difco)	10 g
distilled water	1 liter
chloramphenicol (10-mg/ml stock)	10 ml
cycloheximide (in 2 ml of acetone)	0.1 g
gentamicin (10 mg/ml)	5.0 ml

Dissolve and adjust pH to 7. Autoclave for 15 min at 121°C. Dispense in 10-ml aliquots into tubes.

b. Step 2. Prepare a stock solution of 0.5 N HCl.

c. Step 3. Prepare an acidification series.

Take four tubes of broth from step 1. Label them 0, 1, 2, and 3. Dispense 1 drop of HCl stock solution into tube 1, 2 drops into tube 2, and 3 drops into tube 3. Batches of such tube series can be made up and stored in the 5°C refrigerator, with screw caps tightened, for at least 6 months.

QC isolates have not yet been designated for this technique; therefore, it is recommended to screen several isolates of *T. rubrum* and find one that grows well in tube 2 and shows at least some growth in tube 3. Ideally, a polyresistant bacterial isolate should be selected on the basis of showing visible inhibition in growth within the range of acid concentrations used. It should be monitored with newly made batches of decontamination broth series to be certain that it is constantly inhibited at the same point in the series.

J. Yeast-inhibiting blood agar

Yeast-inhibiting blood agar is used for selective isolation and partial purification of cultures of dimorphic and other cycloheximide-tolerant fungi. Egg white inhibits growth of all biotin-requiring yeasts, e.g., all common clinical *Candida* spp. except *C. krusei*.

1. Step 1. Prepare egg whites.

Sterilize 250-ml blender cylinder, and prepare eggs as follows.

- Clean eggs and then soak in 95% ethyl alcohol for 15 min.
- Clean hands with alcohol.
- Crack eggs with a sterile knife, and drain egg white into sterile blender cylinder. Discard egg yolk.
- Switch the blender on and then off almost immediately to make an even consistency of the egg whites. (Do not leave it on any longer, or too much froth will be formed. Too much oxygenation destroys activity.)
- Pour egg white into a sterile flask. Store any excess at 4°C.

APPENDIX 8.9-2 (continued)

2. Step 2. Prepare heart infusion agar.

distilled water	1,000 ml
heart infusion agar (Difco)	40 g

Autoclave at 15 lb/in² for 25 min.
3. Step 3. Cool heart infusion agar and add the following.

sterile defibrinated sheep blood	53 ml
chloramphenicol (1.6% stock solution)	3 ml
cycloheximide (2.0% stock solution)	25 ml
gentamicin (5% stock solution)	0.4 ml
prepared egg white	30 ml
4. QC strains are *Candida albicans* ATCC 10231 = CBS 6431 = IFO 1594 (same strain in all collections), negative (no or pinpoint growth), and *B. dermatitidis* ATCC 60916 = CBS 673.78, positive (normal growth).

PREANALYTICAL PROCEDURES**I. PRINCIPLE**

Until recently, antifungal susceptibility testing (AFST) has lagged behind its antibacterial counterpart. A number of important achievements helped propel the antifungal susceptibility field forward. These achievements include publication of the approved reference method for broth dilution AFST of yeast (Document M27-A2) (3); publication of interpretive breakpoints using this method (6); the recommended use of AFST during selection of therapy for patients with candidemia and

hematogenously disseminated candidiasis, as outlined by the recently published *Practice Guidelines for the Treatment of Candidiasis* (7); publication of a proposed reference method for broth dilution AFST of conidium-forming filamentous fungi (Document M38-A) (4); and efforts directed at developing AFST methods for dermatophytes (2, 5). The methods described in this procedure are based on NCCLS documents M27-A2 (approved) (3) and M38-A (proposed) (4).

The NCCLS AFST method for both yeast and moulds adopts a broth dilution MIC methodology which quantitatively measures the in vitro activity of an antifungal agent against a fungal isolate. Test tubes (or multiwell microdilution plates) containing various concentrations of an antifungal agent are inoculated with a standardized suspension of test organisms. The MIC is determined following 48- to 96-h incubation at 35°C.

II. MATERIALS**A. Test media**

The most suitable medium for AFST is determined by the organism being tested. The medium will be either RPMI 1640 (buffered with MOPS [morpholine propanesulfonic acid]) for yeasts and filamentous fungi or yeast nitrogen broth for *Cryptococcus neoformans*. In addition, Sabouraud glucose agar or potato dextrose agar is required to subculture the organisms for inoculum preparation.

B. Antifungal agents

The list of antifungal agents may include amphotericin B, 5-fluorocytosine, fluconazole, ketoconazole, itra-

conazole, posaconazole, ravuconazole, voriconazole, and terbinafine.

C. Equipment

1. Filter sterilization apparatus for preparation of RPMI 1640
2. 12- by 75-mm test tubes or 96-well U-shaped microdilution plates, and a microdilution plate reader
3. McFarland suspension standards and spectrophotometer at 530 nm
4. Volumetric pipettes (1 and 10 ml) and multichannel pipettes (adjustable, 40 to 200 µl)

III. PREPARATION OF ANTIFUNGAL STOCK SOLUTIONS**A. Test medium**

The synthetic medium RPMI 1640 with MOPS, hereafter referred to as RPMI, has been selected as the optimal growth medium for testing the susceptibility of *Candida* spp. to amphotericin B, 5-fluorocytosine, and the azoles. However, studies have demonstrated that RPMI may not be adequate to support the growth of some *C. neoformans* strains (1). Instead, yeast nitrogen broth has been proposed as an alternative medium for this organism (3). RPMI is a broth medium without sodium bicarbonate which is supplemented with L-glutamine and a pH

III. PREPARATION OF ANTIFUNGAL STOCK SOLUTIONS (*continued*)

indicator (04-525Y [American Bioorganic Company, Inc., Niagara Falls, N.Y., and BioWhittaker, Walkersville, Md.] and R-6504 [Sigma Chemical Co., St. Louis, Mo.]). Reconstituted RPMI powder should be filter sterilized, with a final pH of 7.0 at 25°C.

B. Stock solutions of antifungal agents

1. The susceptibility of yeast is tested against the following antifungal agents: amphotericin B (Bristol-Myers Squibb, Wallingford, Conn.), 5-fluorocytosine (Sigma Chemical Co.), and azoles, including fluconazole and voriconazole (Pfizer Pharmaceuticals Group, New York, N.Y.), ketoconazole and itraconazole (Janssen Pharmaceuticals, Titusville, N.J.), posaconazole (Schering-Plough, Kenilworth, N.J.), and ravuconazole (Bristol-Myers Squibb, New York, N.Y.). These drugs are obtained as pure reference powders directly from the manufacturers or from the U.S. Pharmacopeia (Rockville, Md.). The use of pharmaceutical preparations of these agents is not recommended. However, if pure powders are not available, as is often the case with amphotericin B, pharmaceutical preparations (Fungizone for injection; Bristol-Myers Squibb) may be substituted.
2. Stock solutions of antifungal agents do not commonly support the growth of contaminating organisms and can be considered sterile.
3. Fluconazole and 5-fluorocytosine are prepared in sterile distilled water and normal saline, respectively. Stock solutions of amphotericin B, itraconazole, ketoconazole, posaconazole, ravuconazole, and voriconazole are prepared in dimethyl sulfoxide (DMSO). Pharmaceutical preparations of amphotericin B are dissolved in sterile distilled water.
4. Because the assay units of a particular antifungal powder can differ widely from the actual weight of the powder, the antifungal solutions must be standardized according to the assays of each batch lot. One of the following formulae is used to determine the amount of powder or diluent needed: $\text{weight} = (\text{volume [in milliliters]} \times \text{concentration [in micrograms per milliliter]}) / \text{assay potency (in micrograms per milligram)}$ or $\text{volume} = (\text{weight [in milligrams]} \times \text{assay potency [in micrograms per milliliter]}) / \text{concentration (in micrograms per milliliter)}$. If possible, >100 mg of powder should be weighed initially. For example, to prepare 100 ml of a stock solution at a concentration of 1,280 µg/ml using a powder that has a potency of 750 µg/mg, use the first formula to establish the weight of powder needed: $\text{weight} = (\text{target volume [100 ml]} \times \text{desired concentration [1,280 µg/ml]}) / \text{potency (750 µg/mg)} = 170.7 \text{ mg}$. Using the second formula, and a weight in excess of that required (e.g., 182.6 mg), the volume of diluent is determined as in this example: $\text{volume} = (\text{weight [182.6 mg]} \times \text{potency [750 µg/mg]}) / \text{desired concentration (1,280 µg/ml)} = 107.0 \text{ ml}$. Thus, in the above example, 182.6 mg of powder is to be dissolved in 107.0 ml of diluent.

C. Working solutions of antifungal agents

1. Working antifungal solutions are prepared at 10 times the highest concentration to be tested for water-soluble drugs (e.g., fluconazole, 5-fluorocytosine, and pharmaceutical preparations of amphotericin B) and 100 times the highest concentration for water-insoluble drugs (ketoconazole, itraconazole, posaconazole, ravuconazole, voriconazole, and amphotericin B).
2. Dilution procedures for water-soluble drugs and for water-insoluble drugs are shown in Tables 8.10–1 and 8.10–2, respectively. Each of the intermediate concentrations should be diluted 1:10 in RPMI. This procedure will prevent precipitation of the compound, which would lead to dilution error.

Include QC information on reagent container and in QC records.

Table 8.10–1 Dilution procedure for water-soluble drugs

Step	Concn (µg/ml)	Source	Vol (ml)	+	Medium amt (ml)	=	Intermediate concn (µg/ml)	=	Final concn (µg/ml)
1	5,120	Stock	1		7		640		64
2	640	Step 1	1		1		320		32
3	640	Step 1	1		3		160		16

10	25	Step 7	0.5		3.5		3.13		0.0313

IV. STORAGE OF ANTIFUNGAL STOCK SOLUTIONS

Include QC information on reagent container and in QC records.

- A. Small volumes of antifungal stock solutions can be stored in sterile plastic vials, sealed, and frozen at a temperature between -80 and -20°C for up to 6 months. Vials are thawed on the day of testing, and any unused drug must be discarded.
- B. Prepared microdilution plates may be sealed in plastic bags and stored between -80° and -20°C for up to 6 months.

ANALYTICAL CONSIDERATIONS

V. QUALITY CONTROL

A. Yeast isolates and MIC ranges

Inclusion of QC isolates in susceptibility testing will allow monitoring of the precision and accuracy of the susceptibility test procedure, the performance of the reagents, the testing conditions, and the performance of testing personnel. QC strains are to be incorporated into each daily run of patient testing. Acceptable MIC ranges for QC isolates are outlined in Table 8.10–3.

B. Media

Ensure that all media and drugs are used within their expiration dates.

C. Equipment

Regularly clean and calibrate pipettes and the spectrophotometer to maintain accuracy and reduce the likelihood of contamination.

Table 8.10–3 Recommended 24- and 48-h MIC limits for two QC strains for broth microdilution^a

Organism	Antifungal agent	MIC (μg/ml) ranges for microdilution tests					
		Range	24-h mode	% within range	Range	48-h mode	% within range
<i>Candida parapsilosis</i> ATCC 22019	Amphotericin B	0.25–2.0	0.5	97	0.5–4.0	2.0	92
	5-Fluorocytosine	0.06–0.25	0.12	99	0.12–0.5	0.25	98
	Fluconazole	0.5–4.0	2.0	98	1.0–4.0	2.0	99
	Itraconazole	0.12–0.5	0.25	96	0.12–0.5	0.25	98
	Ketoconazole	0.03–0.25	0.06/0.12	98	0.06–0.5	0.12	98
	Voriconazole	0.016–0.12	0.06	100	0.03–0.25	0.06	100
	Ravuconazole	0.016–0.12	0.06	96	0.03–0.25	0.06	98
	Posaconazole	0.06–0.25	0.12	97	0.06–0.25	0.12	99
<i>Candida krusei</i> ATCC 6258	Amphotericin B	0.5–2.0	1.0	100	1.0–4.0	2.0	100
	5-Fluorocytosine	4.0–16	8.0	98	8.0–32	16	99
	Fluconazole	8.0–64	16	100	16–128	32	100
	Itraconazole	0.12–1.0	0.5	96	0.25–1.0	0.5	100
	Ketoconazole	0.12–1.0	0.5	96	0.25–1.0	0.5	99
	Voriconazole	0.06–0.5	0.25	98	0.25–1.0	0.5	100
	Ravuconazole	0.06–0.5	0.25	93	0.25–2.0	0.5	100
	Posaconazole	0.06–0.5	0.25	100	0.12–1.0	0.5	99

^a From A. L. Barry, M. A. Pfaller, S. D. Brown, A. Espinel-Ingroff, M. A. Ghannoum, C. Knapp, R. P. Rennie, J. H. Rex, and M. G. Rinaldi. 2000. Quality control limits for broth microdilution susceptibility tests of ten antifungal agents. *J. Clin. Microbiol.* **38**:3457–3459.

VI. PROCEDURES

A. Testing yeast isolates

1. Inoculum preparation

- All organisms should be subcultured onto Sabouraud glucose agar or potato dextrose agar and incubated at 35°C for 24 (*Candida* spp.) or 48 (*C. neoformans*) h.
- The inoculum should be prepared by picking five well-isolated colonies ≥ 1 mm in diameter and suspending the organisms in 5 ml of sterile saline.
- A suspension equal to a 0.5 McFarland standard (spectrophotometer reading at a λ of 530 nm) is prepared by adding sterile saline. This will yield a concentration of 1×10^6 to 5×10^6 cells per ml.
- A working suspension is prepared by adding 0.1 ml of the suspension from item c. above to 9.9 ml of RPMI. This is further diluted 1:20 with RPMI to give a concentration of 5×10^2 to 2.5×10^3 cells per ml.

2. Test inoculation and incubation (macrodilution method)

- Add 0.1 ml of each antifungal (at the intermediate concentration for water-soluble drugs and the intermediate concentration diluted 1:10 for water-insoluble drugs) to a sterile 12- by 75-mm test tube.
- A growth control tube should receive 0.1 ml of drug diluent without the antifungal agent. A second tube of drug diluent should remain uninoculated to serve as a sterility control.
- Within 15 min of inoculum preparation, 0.9 ml of the inoculum is added to each tube in the series (with the exception of the sterility control). This brings the antifungal agents to their final concentrations.
- Tubes should be incubated without agitation at 35°C for 46 to 50 (*Candida* spp.) or 70 to 74 (*C. neoformans*) h.

3. Reading results

- The amount of growth in each tube is compared to that of the growth control.
- For amphotericin B, the MIC is read as the lowest drug concentration that prevents any visible growth.

VI. PROCEDURES (continued)

- c. For 5-fluorocytosine, itraconazole, ketoconazole, posaconazole, ravuconazole, and voriconazole, the MIC is read as the lowest drug concentration that exhibits 80% inhibition. The azoles will often show “trailing endpoints,” where turbidity persists in all drug concentrations above the MIC. To reduce variability in reading these endpoints, the amount of allowable turbidity can be demonstrated by diluting 0.2 ml of the growth control in 0.8 ml of RPMI.
4. Microdilution modifications
 - a. Stock solutions of antifungal agents and their intermediate concentrations are prepared in the manner outlined above. The intermediate concentrations are diluted 1:5 with RPMI to achieve the $2\times$ concentration needed for the microdilution method.
 - b. A stock yeast suspension (1×10^6 to 5×10^6 cells per ml) is prepared as outlined above. This suspension is then diluted 1:50 and further diluted 1:20 with RPMI to achieve the $2\times$ test inoculum (1×10^3 to 5×10^3 CFU/ml). When combined with drug, the final concentration will be 0.5×10^3 to 2.5×10^3 CFU/ml.
 - c. Using a multichannel pipette, dispense 100 μ l of the $2\times$ antifungal concentrations into columns 1 to 10 of sterile-disposal 96-well (U-shaped) microdilution plates. Column 1 will contain the highest concentration, and column 10 will contain the lowest concentration of drug. Columns 11 and 12 should each receive 100 μ l of diluent.
 - d. Using a multichannel pipette, dispense 100 μ l of working yeast suspension into each well of columns 1 to 11. Column 11 will serve as the growth control. Column 12 should remain uninoculated and is used as a sterility control. QC organisms are to be incorporated into each daily run.
 - e. Incubate the plates as described above.
 - f. The plates are placed on a microdilution plate reader with a magnifying mirror; MICs are read in the same manner as described for macrodilution tubes.

B. Testing filamentous fungi

1. Test medium, antifungal stock, and working solutions
 - a. The test medium of choice for filamentous moulds is RPMI.
 - b. The preparation of both stock and working solutions of antifungal agents remains the same as described in item III above.
 - c. Allylamine terbinafine can be added to the list of antifungal agents, in particular when testing dermatophytes. Terbinafine is dissolved in DMSO and tested at final concentrations of 16 to 0.03 μ g/ml for filamentous moulds and 0.5 to 0.001 μ g/ml for dermatophytes.
2. Preparation of inoculum
 - a. Organisms should be grown on potato dextrose slants at 35°C for 7 days (*Aspergillus* spp., *Pseudallescheria boydii*, *Rhizopus*, and *Sporothrix*) or at 35°C for 2 to 3 days and then at room temperature until day 7 for *Fusarium* spp.
 - b. Slants are covered with sterile saline and conidia are harvested by agitation with a Pasteur pipette. The resulting suspension is removed to a sterile conical tube and allowed to settle for 3 to 5 min. The upper layer is removed to a second vial and vortexed. The optical density (OD) ($\lambda = 530$ nm) of this suspension is measured and adjusted with sterile saline according to the following guidelines: *Aspergillus* spp. and *Sporothrix*, 0.09 to 0.11 OD units; *Fusarium*, *P. boydii*, and *Rhizopus*, 0.15 to 0.17 OD units.

It is imperative that these cultures be handled in a biosafety hood.

VI. PROCEDURES (continued)

- c. Certain dermatophyte isolates pose special problems, as conidiation is often absent on potato dextrose agar. *Trichophyton rubrum* isolates can be induced to form conidia on cereal agar plates incubated at 30°C for 5 to 7 days (2). Conidia can be harvested to sterile saline by agitation with a sterile cotton-tipped swab.
 - d. Stock suspensions of conidia should then be diluted 1:50 in RPMI for microdilution testing and 1:100 in RPMI for macrodilution testing.
3. Test inoculation and reading
The procedures for setting up the macro- and microdilution tests are the same as described above for yeast isolates (item VI.A).

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING AND INTERPRETATION OF RESULTS

A. General considerations

In vitro susceptibility testing is designed to aid in the prediction of the in vivo response to treatment. However, low MICs for fungi do not necessarily predict clinical success. So far, breakpoints have been established for oropharyngeal candidiasis due to *Candida* spp. for fluconazole, itraconazole, and 5-fluorocytosine, enabling selection of a suitable therapeutic agent (see below). MIC testing for these organisms is merited if there are contraindications or refractory infection. The MIC breakpoints for other drug-organism combinations and for different disease settings have yet to be determined. Therefore, the sensitivity of an organism to a specific drug should be compared to the MIC range of other isolates of that species, thus indicating the likelihood of sensitivity or resistance.

B. Interpretation of MICs for yeast isolates

1. Amphotericin B
Interpretive breakpoints for amphotericin B have not been established. However, experience has shown that isolates for which the MIC is >1 µg/ml are likely to be resistant.
2. Ketoconazole
MICs of ketoconazole for yeast vary between 0.313 and 16 µg/ml. However, interpretive endpoints have not yet been established for this drug.
3. Other antifungal drugs
Interpretive breakpoints of fluconazole, 5-fluorocytosine, and itraconazole for *Candida* spp. are summarized in Table 8.10-4.

C. Interpretation of MICs for filamentous fungi

1. Amphotericin B
MICs for most filamentous moulds fall between 0.5 and 2.0 µg/ml, although MICs for *Aspergillus terreus*, *Acremonium strictum*, *Scedosporium apiospermum*, and *Scedosporium prolificans* can be ≥2.0 µg/ml. Correlation of the MIC and the outcome of clinical treatment cannot as yet be predicted for the filamentous fungi.

Table 8.10-4 Interpretive breakpoints for *Candida* spp.

Antifungal agent	Breakpoint (µg/ml)			
	Susceptible (S)	Susceptible dose dependent (S-DD)	Intermediate (I)	Resistant (R)
Fluconazole	≤8	16-32		≥64
Itraconazole	≤0.125	0.25-0.5		≥1
5-Fluorocytosine	≤4		8-16	≥32

VII. REPORTING AND INTERPRETATION OF RESULTS

(continued)

2. 5-Fluorocytosine
Most MICs are >64 µg/ml, and filamentous fungi are generally not susceptible. Exceptions include some *Aspergillus* spp. and certain dematiaceous fungi.
3. Fluconazole
Most MICs are >64 µg/ml, and filamentous fungi are generally not susceptible. Exceptions include dermatophytes and some isolates of the dimorphic fungi.
4. Ketoconazole
MICs for filamentous moulds range from 16 to 0.03 µg/ml; however, correlation of the MIC and the outcome of clinical treatment cannot as yet be predicted.
5. Itraconazole
MICs for filamentous moulds range from 16 to 0.03 µg/ml, with MICs for dermatophytes as low as 0.001 µg/ml. Interpretive breakpoints have not yet been established for filamentous moulds.
6. Terbinafine
MICs for dermatophytes range from 0.015 to 0.001 µg/ml. Interpretive guidelines for other filamentous moulds have not been established.

PART 1

Equipment

If necessary, maintenance procedures can be performed and documented more often than the minimal recommendations presented in this section.

I. MICROSCOPE

Good microscopes and light sources are mandatory for the examination of specimens for parasites. Identification of the majority of organisms depends on morphologic differences, most of which must be seen by using stereoscopic or regular microscopes. An explanation of how to calibrate the microscope can be found later in this section.

A. Stereoscopic

A stereoscopic microscope should be available for larger specimens (arthropods, tapeworm proglottids, various artifacts). The total magnification usually ranges from $\times 10$ to $\times 45$. Some microscopes have a zoom capacity from $\times 10$ to $\times 45$, and others have fixed objectives ($0.66\times$, $1.3\times$, $3\times$) that can be used with $5\times$ or $10\times$ oculars. Use the light source either from under the specimen or directed onto the top of the specimen.

B. Regular

The light microscope should be equipped with the following parts.

1. Head

A monocular head can be used, but a binocular type is recommended to reduce fatigue during lengthy examinations. The binocular head should contain a diopter adjustment to compensate for variation in focus between the eyes.

2. Oculars

$10\times$ are required; $5\times$ can be helpful but are not essential.

3. Objectives

$10\times$ (low power), $40\times$ to $45\times$ (high power), $97\times$ to $100\times$ (oil immersion).

4. Stage

A mechanical stage for X and Y movement is necessary. Graduated stages can be helpful and are recommended for recording the exact location of an organism in a permanently stained slide. This capability is essential for consultation and teaching responsibilities.

I. MICROSCOPE (*continued*)

5. Condenser
 - a. A bright-field condenser equipped with an iris diaphragm is required. The N.A. of the condenser should be equal to or greater than the N.A. of the highest objective.
 - b. An adjustable condenser is not required with the newer microscopes.
6. Filters

Both clear blue glass and white ground-glass filters are recommended.
7. Light source
 - a. The light source, along with an adjustable voltage regulator, should be contained in the microscope base. Align this light source as directed by the manufacturer.
 - b. If the light source is external, the microscope must be equipped with an adjustable mirror and a condensing system containing an iris diaphragm that can be released or lowered.
 - c. The light source should be a 75- to 100-W bulb.

C. Microscope maintenance

1. Remove dust from all optical surfaces with a camel hair brush.
2. Remove oil and finger marks on the lenses immediately with a clean soft cloth or several thicknesses of lens tissue. Single-thickness lens tissue may permit corrosive acids from the fingers to damage the lens. *Do not use any type of tissue other than lens tissue; otherwise you may scratch the lens.* Use very little pressure to clean the lenses in order not to remove the coatings on the external surfaces of the lenses.
3. Use water-based cleaning fluid for normal cleaning. Use organic solvents sparingly and only if absolutely necessary to remove oil from the lens. Since microscope manufacturers do not agree on a common solvent, the manufacturer of each microscope should be consulted. One recommended solvent is 1,1,1-trichloroethane; it is a good solvent for immersion oil and mounting media, but it will not soften the lens sealers and cements. Do not use xylene, any alcohols, acetone, or any other ketone.
4. Clean the lamp (cool, in off position) with lens tissue moistened in 70% isopropyl or ethyl alcohol (to remove oil transferred from the fingers to the lamp) after the lamp has been installed in the lamp holder.
5. Clean the stage with a small amount of disinfectant (70% isopropyl or ethyl alcohol) when it becomes contaminated with fecal material.
6. Cover the microscope when not in use. In extremely humid climates (a relative humidity of more than 50%), good ventilation is necessary to prevent fungal growth on the optical elements.
7. Clean and lubricate the substage condenser slide as needed. Petroleum jelly or light grease can be used as a lubricant.
8. Schedule a complete general cleaning and readjustment at least annually to be performed by a factory-trained and authorized individual. Record all data related to preventive maintenance and repair.

II. CENTRIFUGE**A. Requirements**

1. Either a table or floor model centrifuge, which should be able to accommodate 15-ml centrifuge tubes (for concentration procedures), is acceptable.
2. Regardless of the model, a free-swinging or horizontal head type is recommended. With this type of centrifuge, the sediment will deposit evenly on the bottom of the tube. The flat upper surface of the sediment facilitates the removal of the supernatant fluid from a loosely packed pellet.

B. Maintenance of the centrifuge

1. Check the carrier cups, trunnions, and rotor for corrosion and cracks before each run. If found to be defective, replace immediately.

II. CENTRIFUGE (*continued*)

2. Check for the presence of the proper cup cushions before each run.
3. Check the speed at all regularly used speeds at least quarterly by using a stroboscopic light to verify the accuracy of a built-in tachometer or speed settings. Record results.
4. Use 10% household bleach or phenolic solution to disinfect the centrifuge bowl, buckets, trunnions, and rotor following a breakage or spill and at least monthly. Following disinfection, rinse the parts in warm water, and give a final rinse in distilled water. It is imperative to thoroughly dry the parts with a clean absorbent towel to prevent corrosion.
5. Clean the inside of the cups in mild, warm soapy water, and scrub with a nylon brush. Use fine steel wool to remove stubborn deposits. The part should be rinsed in distilled water and thoroughly dried. This should be done as needed and at least quarterly.
6. Lubricate bearings (if not permanently lubricated) as specified by the manufacturer at least quarterly.
7. Check brushes, and replace if worn to 1/4 in. of the spring. Check semi-annually.
8. Check autotransformer brush, and replace if worn to 1/4 in. of the spring. Check semiannually.
9. Remove the head and dust cover, and add lubricant as specified by the manufacturer to fill the grease cup. Do this semiannually.
10. Replace grease in grease cup as specified by the manufacturer annually.
11. Record all data related to preventive maintenance and repair.

III. FUME HOOD**A. Requirements**

Although a fume hood is not required, many laboratories prefer to keep their staining reagents and formalin in a fume hood. Even with the substitution of dehydrating reagents other than xylene, fume hoods may be preferred in order to eliminate odors. In keeping with good laboratory practice, the placement of reagents and equipment into a hood should not interfere with the proper operation of the hood.

B. Maintenance of the fume hood

1. Check the air velocity with the sash fully open and the cabinet empty with a thermoanemometer (minimum acceptable face velocity is 100 ft [ca. 30 m]/min) (3, 8) at least quarterly.
2. Perform a smoke containment test with the cabinet empty to verify proper directional face velocity. Check at least quarterly.
3. Lubricate the sash guides as needed to provide for ease of operation.
4. See Appendix 9.10.7-1 at the end of this section for formalin exposure guidelines.

IV. BIOLOGICAL SAFETY CABINET**A. Requirements**

A biological safety cabinet is not required for processing routine specimens in a diagnostic parasitology laboratory. However, some laboratories use class I (open-face) or class II (laminar-flow) biological safety cabinets to process all unpreserved specimens.

B. Maintenance of the biological safety cabinet

1. Disinfect the work area after each use. Do not depend on UV irradiation to decontaminate the work surface. UV irradiation has very limited penetrating powers (21).
2. Clean UV lamps (in the off position) with 70% isopropyl or ethyl alcohol at least weekly.

IV. BIOLOGICAL SAFETY CABINET *(continued)*

3. Monitor UV output (UV intensity meter; any major laboratory supplier) quarterly to confirm that the effective radiation (excess of $40 \mu\text{W}/\text{cm}^2$ at a wavelength of 253.7 nm) is present at the work surface (8). If not, replace the lamp.
4. Have class I biological safety cabinets certified after installation but before use, after they have been relocated or moved, and at least annually. The certification should include the following.
 - a. Measurements of air velocity at the midpoint height approximately 1 in. behind the front opening. Make these measurements approximately every 6 in.
 - b. The average face velocity should be at least 75 linear ft/min. Use a thermoanemometer with a sensitivity of ± 2 linear ft/min (8).
 - c. Perform a smoke containment test with the cabinet containing the routine work items, such as a Bunsen burner, test tube rack, bacteriological loop and holder, etc., to determine the proper directional velocity.
 - d. Record the date of recertification and the name of the individual or company recertifying the cabinet.
5. Replace the filters as needed.
6. Have a class II biological safety cabinet certified to meet Standard 49 of the National Sanitation Foundation (Ann Arbor, Mich.) when it is installed (8).
7. Recertify the cabinet to meet Standard 49 when the cabinet is moved, after filters are replaced, after the exhaust motor is repaired or replaced, or after any gaskets are removed or replaced (8). Recertify at least annually, and record the date of service recertification along with the name of the individual or company performing the service.
8. Keep all airflow parts completely clear at all times.

V. REFRIGERATOR-FREEZER

A. Requirements

A general-purpose laboratory (non-explosion proof) or household-type refrigerator-freezer is adequate for use in the parasitology laboratory. The temperature should be approximately 5°C . Do not store solvents with flash points below refrigeration temperature even in modified (explosion-proof) refrigerators.

B. Maintenance of refrigerators-freezers

1. Monitor and record the temperature of the refrigerator on a daily basis. Place the thermometer into a liquid to permit stable temperature recording.
2. Monitor and record the temperature of the freezer on a daily basis. Place the thermometer into antifreeze (any brand with a freezing point below that of the freezer, such as ethylene glycol-water solutions, glycerol-water solutions, Prestone) to permit stable temperature recording.
3. Check the operation of the fan (if so equipped) inside the cabinet.
4. Monthly, check the door gasket for deterioration, cracks, and proper seal.
5. Semiannually, clean the condenser tubing and air grill with a vacuum cleaner.
6. Semiannually, check to ensure that the drain tubes are kept open.
7. Annually, wash the interior with a warm solution of baking soda and water (approximately 1 tablespoon/qt [ca. 13 to 14 g/0.946 liter]). Rinse with clean water, and dry.
8. Annually, decontaminate the interior as needed.
9. Annually, wash the door gasket and water collection tray with a mild soap and water. If the gasket accumulates a black mold, scrub with a 50% household bleach solution and a small brush. Rinse with clean water, and dry.

PART 2**Safety**

The standard safety considerations of any clinical laboratory (3–7, 12, 14–18, 20, 21) should be practiced in a parasitology laboratory. Specific attention should be given to personal practices, specimen and reagent handling, and equipment (*see* section 15).

I. PERSONAL PRACTICES

Since many parasitic infections are acquired via the oral route, it is imperative that the parasitologist practice good personal hygiene. Hand washing with soap and water and adherence to laboratory technique standards are two of the most important ways to guard against infection in a clinical laboratory. Gloves, while not mandatory, are recommended, and standard precautions must be followed at all times.

II. IMMUNIZATIONS

In addition to the routine childhood immunizations against polio and rubella, an immunization against hepatitis B is recommended for those individuals processing fresh unpreserved fecal specimens. At present, there are no effective immunizations for parasitic diseases.

III. SPECIMENS**A. Collection**

1. Collect fecal specimens and transport them to the laboratory in such a way that no one handling the container comes in direct contact with the specimen. Bag the test request slip separately from the specimen.
2. Usually, the specimen is placed in a waxed cardboard container with a tightly fitting lid.
3. If polyvinyl alcohol (PVA) fixative (containing mercuric chloride) is included in the collection kit, the following is strongly recommended.
 - a. The word “Poison,” the skull-and-crossbones symbol, and the statement “Causes Severe Burns” must be included on the specimen container label.
 - b. It is also recommended that the following first aid instructions be included on the collection kit insert:

Contains mercuric chloride. Avoid contact with eyes or mucous membranes or prolonged contact with skin. Wash hands thoroughly after use. If swallowed, give milk or egg whites. Call physician immediately. For contact with eyes or skin, flush thoroughly with water. For eyes, get prompt medical attention. Keep out of reach of children.

4. Blood specimens should be collected in a manner consistent with standard precautions (18).

B. Handling

1. The unpreserved stool specimen should be considered potentially infectious; gloves are recommended. All of the following may be infective: protozoan cysts; *Cryptosporidium* oocysts; microsporidial spores; eggs of *Taenia solium*, *Enterobius vermicularis*, and *Hymenolepis nana*; and larvae of *Strongyloides stercoralis*.
2. The fresh specimen may also contain *Salmonella* spp., *Shigella* spp., or other bacterial pathogens, and bloody stools may pose a special hazard as potential carriers of hepatitis A and B viruses, human immunodeficiency virus, and enteric non-A, non-B viruses (18).
3. Because the unpreserved specimen may contain these infectious agents, the specimen must be collected, handled, and shipped to the laboratory so

III. SPECIMENS (continued)

the handlers are prevented from coming in direct contact with the specimen.

4. A 5% solution of formalin may permit *Ascaris lumbricoides* (6, 7, 11) eggs to become embryonated in stool specimens and thereby become infective. A 10% solution of formalin reduces this potential hazard. Personnel are urged to use standard precautions at all times.

C. Processing

1. In processing the unpreserved specimen, avoid direct contact between the specimen and the parasitologist and/or the equipment being used. Use of a biological safety cabinet is often recommended.
 - a. For example, use a 3- by 2-in. microscope slide for preparing direct wet mounts.
 - b. Sealing the stool preparation with clear nail polish or petroleum jelly will reduce the possibility of direct contact, although this approach is often not practical for routine clinical laboratories.
 - c. Be careful when handling the preserved specimen. Maintain pressure on the stopper while shaking the specimen in the defatting step of the concentration procedure (use of ethyl acetate). Built-up pressure may cause an uncontrolled release of the contents.

D. Disposal

1. Unpreserved fecal and blood specimens can be safely discarded into a sanitary sewage system if local health codes permit (18).
2. Specimens preserved in formalin or PVA fixative may pose a unique disposal problem because of regulations regarding formalin and mercury-based compounds. PVA fixative contains Schaudinn's fluid (mercuric chloride base) to which PVA plastic powder is added. Consult state public health officials for proper disposal guidelines.

IV. REAGENTS

Know what chemical hazards are in the workplace (2). One way to make the hazards known is to make available the MSDS on the chemical(s) in use. The availability and location of these sheets should be well known by all laboratory personnel. Usually they are kept filed in a notebook rather than being posted.

A. Use

There are certain basic considerations when chemicals are used in the laboratory.

1. Use the smallest container of flammable solvents (flash point below 37.8°C) compatible with the work.
2. Do not use flammable solvents near open flames or microincinerators.

B. Storage

1. Because the parasitology laboratory is usually one of many sections within the clinical laboratory, the storage of reagents must be considered in terms of the complete clinical laboratory.
2. Be sure that the quantities of flammable solvents stored comply with the Code of the National Fire Protection Association, Quincy, Mass., and the relevant regulations of the OSHA (1), and store solvents so that incompatible chemicals are segregated.
3. Do not store flammable solvents having a flash point below 4°C in a refrigerator.
 - a. Evaporation can occur in these reagents even at this low temperature and cause dangerous levels of vapors to accumulate inside the refrigerator.
 - b. Refrigeration temperatures also cause solvents to pick up atmospheric moisture faster than does room temperature, and refrigeration does not retard the formation of dangerous peroxides in ethers.

IV. REAGENTS (*continued*)

- c. It is better to store these solvents in stoppered containers on well-ventilated open shelves away from open flames.
 - d. Some laboratories have elected to store these solvents in an explosion-proof fume hood.
4. As in the general laboratory, do an inventory of reagents at least annually, and discard all reagents that show signs of deterioration or that are beyond their expiration dates.

C. Disposal

Most water-soluble chemicals can safely be discarded in the sanitary sewer.

1. Neutralize acids and bases to within a pH range of 2 to 12.5, and then dilute them 1:20 with tap water prior to disposal (14).
2. Dilute small quantities of flammable solvents similarly prior to disposal in the sewer.
3. Since permissible substances and quantities will vary, contact state and local authorities for proper disposal guidelines.

D. Substitution of less hazardous reagents

The financial impact of various state and federal regulations governing the use and disposal of hazardous laboratory reagents serves as the impetus to search for less hazardous reagents. Some of the reagents for which there are substitutes are as follows.

1. Ethyl acetate (22) with a higher flash point (4.0°C) replaced ether (flash point of -45°C) in the formalin-ether concentration technique. Hemo-De (Medical Industries, Los Angeles, Calif., or Fisher Scientific, Los Angeles, Calif.) can also replace ethyl acetate in the concentration procedure (19). This reagent has a flash point of 57.8°C and is generally regarded as safe by the Food and Drug Administration.
2. Xylene, as used in the trichrome or iron hematoxylin staining of PVA-fixed fecal smears, is a potential toxic and fire hazard. Again, Hemo-De has successfully replaced xylene in both the carbol-xylene and xylene steps of the trichrome procedure (6, 7). There are other substitutes available as well (Hemo-Sol; Fisher Scientific). Check with your local pathology departments or reagent suppliers for other alternatives.
3. Mercuric chloride, used in PVA fixative and Schaudinn's fixative, presents both a toxic hazard and a disposal problem. Copper sulfate has been suggested as a substitute for mercuric chloride (6, 9); however, protozoan morphology will not be as clear and precise if this formula is used. Many single vial systems are now available; most fixatives use a zinc base. However, the total formulas for these stool preservatives are proprietary (6).
4. Before any of these substitute reagents are incorporated into the routine procedures, perform comparative studies.
5. Consult section 15 for further cautions.

V. EQUIPMENT**A. Microscope**

1. If the stage of the microscope becomes contaminated with fecal material, wipe it clean with a disinfectant (70% isopropyl or ethyl alcohol).
2. Observe the general safety precautions governing the use of electrical equipment; i.e., do not use near water, check for bare wires, turn off power before servicing, etc.

B. Centrifuge

1. Use plastic tubes to reduce the hazards of breakage during centrifugation. If glass centrifuge tubes are used, inspect them, and use only those free of defects.
2. Always balance the centrifuge prior to use.

V. EQUIPMENT (*continued*)

3. Close the centrifuge lid when the centrifuge is in operation. Should noise or vibration develop, stop the centrifuge and check for symmetrical loading of the head.

C. Fume hood

1. If a fume hood is used to store flammable solvents such as ethyl acetate, ether, or xylene, keep the hood in operation to prevent the buildup of dangerous or toxic levels of these reagents. An adequate face velocity of 60 to 100 ft/min is recommended (3).
2. If the hood is used for other purposes, place reagents so that they do not interfere with the proper operation of the hood.

PART 3**I. INTERNAL QUALITY CONTROL****Quality Control**

The internal QC component of a QC program generally consists of documenting the proper functioning of reagents and equipment at prescribed intervals and evaluating performance on split samples (day to day, batch to batch) and within-batch reproducibility studies (*see* section 14).

- A. Check the permanent staining procedure with known positive control specimens when the stain is prepared (or a new lot number is purchased) and at least weekly. Record all QC results.
- B. If positive specimens are not available, use smears of feces containing epithelial cells or pus cells (6, 10, 17).
- C. Check stains for blood parasites for staining quality at the time of preparation, when put into use, and quarterly. If positive blood smears are not available, use a negative smear.
- D. Introduce previously identified specimens as blind specimens to evaluate the overall performance of the parasitology laboratory. The use of these samples is of particular value in those laboratories that process few specimens and in those that receive a small number of positive specimens or lack a variety of specimens.

II. EXTERNAL QUALITY CONTROL PROFICIENCY TESTING

Every parasitology laboratory should subscribe to a proficiency testing program to provide an unbiased evaluation of its performance.

III. REFERENCE MATERIALS

- A. Reference materials should be available for comparison with unknown organisms, refresher training, and the training of additional personnel.
- B. Ideal reference materials include formalin-preserved specimens of helminth eggs, larvae, and protozoan cysts; stained fecal smears of protozoan oocysts, spores, cysts, and trophozoites; and positive blood smears.
- C. Color slides and atlases are recommended, although the level of microscopic focus cannot be changed.
- D. Reference books and manuals from a number of publishers are available, and selected ones should be part of the parasitology library.

PART 4**I. QUALITY ASSURANCE****Quality Assurance**

QA is the sum of all the activities necessary to produce consistently accurate test results. These include preanalytical, analytical, and postanalytical activities (*see* section 14).

I. QUALITY ASSURANCE (continued)

A. Preanalytical activities

These are all activities up to but not including the actual laboratory manipulation of the specimen that influence the quality of laboratory results.

1. Training of personnel

- a. The person advising the patient or medical staff must be adequately trained in all facets of specimen collection (preparation of the patient, specimen collection times, sample quality and volume, condition of specimen container, use of preservatives, and proper labeling).
- b. The person performing the parasitologic examination must be familiar with appropriate technical procedures to be used for each type of specimen and morphologic recognition and differentiation of parasites.

2. Preparation of the patient

This involves the use of proper laxatives and/or enemas and the proper method for handling the patient prior to collecting a pinworm specimen, i.e., before bowel movement and bathing.

3. Specimen collection

- a. Consideration must be given to the sequence of collecting multiple specimens, i.e., the time interval between administering antibiotics, X-ray dyes (barium), or nonabsorbable antidiarrheal preparations and the collection of the specimen and the time between subsequent collections.
- b. Blood collections for blood-borne parasites should be optimized for the suspected parasites (16).

4. Specimen quality and volume (*see* individual protocols)

5. Specimen handling and labeling (*see* individual protocols)

B. Analytical activities

1. These include the technical or laboratory procedures necessary to produce accurate test results.

- a. A procedure manual should include a detailed description of the procedures necessary to process the specimens and to identify the various parasites and their diagnostic stages.
- b. Description of procedures must be part of a written procedure manual (13) that is reviewed and, when approved by the laboratory director, becomes the legal protocol for the laboratory by which each laboratorian is to be held responsible for performing tests *exactly* as described.
- c. The procedure manual should be reviewed at least annually and before procedural changes are adopted by the laboratory director.

2. Also included are all aspects of QC and proficiency testing, including a corrective action plan when the appropriate results are not obtained. Preventive maintenance and equipment calibration data are also required.

C. Postanalytical activities

1. These activities include information that is transferred verbally, in writing, or by electronic means from the laboratory to the clinician and that provides the clinician with the meaningful laboratory report necessary to optimally manage the patient. This report includes the extent of laboratory procedures performed (i.e., complete workup or limited to direct smear), presence of abnormalities seen in the specimen, excessive amounts of blood or yeast cells, etc., in addition to the identity of the parasite(s) found.

2. Include qualifying statements regarding the quality of the specimen such as “inadequately preserved when received in the laboratory” or “contaminated with water or urine.”

II. QUALITY ASSURANCE DOCUMENTATION

All QA monitors must be properly documented. Use of the 10-step protocol developed by the JCAHO is recommended (5).

9.2.1

Collection of Fresh Specimens

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

One of the most important steps in the diagnosis of intestinal parasites is the proper collection of specimens (1–4). Improperly collected specimens can result in inaccurate results. Fresh specimens are manda-

tory for the recovery of motile trophozoites. However, unless strict collection and delivery times are adhered to, the specimen may have little value for diagnostic testing.

II. SPECIMEN

Observe standard precautions.

- A. Collect all fecal specimens prior to the administration of antibiotics or anti-diarrheal agents. Avoid the use of mineral oil, bismuth, and barium prior to fecal collection, since all of these substances may interfere with the detection or identification of intestinal parasites (1). The examination of purged specimens is less frequently performed and will not be discussed in this procedure. However, the same time limits for fixation and/or examination of diarrheic stools can be used for purged specimens submitted for examination.
- B. Collect the fecal specimen in a clean, widemouthed container or on newspaper, and transfer it to a container with a tight-fitting lid.
- C. Avoid contamination with urine or water from the toilet.
- D. Transport the specimen to the laboratory as soon as possible, or keep it refrigerated until transport is possible. Obviously, dried specimens (diarrheic, semi-formed, or formed) are not acceptable for fecal examination.

III. MATERIALS

- A. **Reagents**
None
- B. **Supplies**
 1. Collection container(s)
 2. Newspaper (optional)
- C. **Equipment**
Standard

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. There is no maximum limit on the amount of stool collected.
- B. As a minimum amount, collect several grams (or teaspoon amounts). Smaller amounts can be examined, but the specimen is likely to dry out before examination (unacceptable for testing).
- C. Reject any specimen that appears to be dry on the surface or edges.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. Sample areas of the feces that appear bloody, purulent, or watery for examination as direct wet smears, fecal concentration, and permanent stained smears.
- C. For adequate sampling of a formed fecal specimen, collect and examine material from the sides, ends, and middle by using fecal concentration procedures and permanent stained smears (4).

POSTANALYTICAL CONSIDERATIONS

VI. PROCEDURE NOTES

- A. To ensure the recovery of parasitic organisms that are passed intermittently and in fluctuating numbers, the examination of a minimum of three specimens collected over a 7- to 10-day period is recommended (1–4). Refer to Appendix 9.2.1–1 for other collection algorithms and options.
- B. Infections with *Entamoeba histolytica*/*E. dispar* or *Giardia lamblia* may require the examination of up to six specimens before the organism is detected.
- C. Liquid specimens should be received and examined or preserved by the laboratory within 30 min of passage, soft or semifformed specimens within 1 h of passage, and formed specimens on the same day of passage.

VII. LIMITATIONS OF THE PROCEDURE

- A. Protozoan trophozoites will not survive if the stool specimen begins to dry out. Cysts will not form once the specimen has been passed.
- B. Unless guidelines for delivery times are monitored and inappropriate specimens are replaced with appropriate ones, laboratory results may be incorrect. Include in the laboratory report a statement indicating that the results may be incorrect.

APPENDIX 9.2.1–1Fecal specimens for parasites: options for collection and processing^a

Option	Pros	Cons
Rejection of stools from inpatients who have been in-house for >3 days ^b	Patients may become symptomatic with diarrhea after they have been inpatients for a few days; symptoms are usually attributed not to parasitic infections but generally to other causes.	There is always the chance that the problem is related to a nosocomial parasitic infection (rare), but <i>Cryptosporidium</i> and microsporidia may be possible considerations.
Examination of a single stool (O&P examination). Data suggest that 40–50% of organisms present will be found with only a single stool exam.	Some feel that most intestinal parasitic infections can be diagnosed from examination of a single stool. If the patient becomes asymptomatic after collection of the first stool, then subsequent specimens may not be necessary.	Diagnosis from a single stool examination depends on experience of the microscopist, proper collection, and the parasite load in the specimen. In a series of 3 stool specimens, frequently not all 3 specimens are positive and/or they may be positive for different organisms.
Two O&P exams (concentration, permanent stained smear) are acceptable but are not always as good as three specimens (may be a relatively cost-effective approach); any patient remaining symptomatic would require additional testing.		
Examine a second stool only after the first is negative and the patient is still symptomatic.	With additional examinations, the yield of protozoa increases (<i>Entamoeba histolytica</i> , 22.7%; <i>Giardia lamblia</i> , 11.3%; <i>Dientamoeba fragilis</i> , 31.1%).	Assumes that the second (or third) stool is collected within the recommended 10-day time frame for a series of stools; protozoa are shed periodically. May be inconvenient for patient.
Examination of a single stool and an immunoassay (EIA, FA, cartridge) (<i>Giardia</i>). This approach is a mixture: one screen is acceptable; one O&P exam is not the best approach (review last option below).	If the examinations are negative and the patient's symptoms subside, then probably no further testing is required.	Patients may exhibit symptoms (off and on), so it may be difficult to rule out parasitic infections with only a single stool and immunoassay. If the patient remains symptomatic, then even if the <i>Giardia</i> immunoassay is negative, other protozoa may be missed (<i>E. histolytica</i> / <i>E. dispar</i> , <i>D. fragilis</i>).
Pool three specimens for examination; perform one concentrate and one permanent stain.	Three specimens are collected over 7–10 days and may save time and expense.	Organisms present in low numbers may be missed due to the dilution factor.
Pool three specimens for examination; perform a single concentrate and three permanent stained smears.	Three specimens are collected over 7–10 days; would maximize recovery of protozoa in areas of the country where these organisms are most common.	Might miss light helminth infection (eggs, larvae) due to the pooling of the three specimens for the concentration; however, with a permanent stain performed on each of the three specimens, this approach would probably be the next best option in lieu of the standard approach (concentration and permanent stained smear performed on every stool).
Actually collect three stools, but put sample of stool from all three into a single vial (patient given a single vial only).	Pooling of the specimens would require only a single vial.	This would complicate patient collection and very likely result in poorly preserved specimens, especially regarding the recommended ratio of stool to preservative and the lack of proper mixing of specimen and fixative.
Perform immunoassays on selected patients ^c using methods for <i>G. lamblia</i> , <i>Cryptosporidium parvum</i> and/or the <i>E. histolytica</i> / <i>E. dispar</i> group, or <i>E. histolytica</i> .	Would be more cost-effective than performing immunoassay procedures on all specimens; however, information required to group patients is often not received with specimens.	Laboratories rarely receive information that would allow them to place a patient in a particular risk group: children <5 yrs old, children from day care centers (may or may not be symptomatic), patients with immunodeficiencies, and patients from outbreaks. Performance of immunoassay procedures on every stool is not cost-effective, and the positivity rate will be low unless an outbreak situation is involved.

(continued)

APPENDIX 9.2.1–1 (continued)

Fecal specimens for parasites: options for collection and processing^a (continued)

Option	Pros	Cons
Perform immunoassays and O&P examinations on request for <i>G. lamblia</i> , <i>C. parvum</i> and/or <i>E. histolytica</i> / <i>E. dispar</i> group, or <i>E. histolytica</i>	Will limit the number of stools on which immunoassay procedures are performed for parasites.	Will require education of the physician clients regarding appropriate times and patients for whom immunoassays should be ordered. Educational initiatives must also include information on the test report indicating the pathogenic parasites that will <i>not</i> be detected using these methods. It is critical to make sure clients know that if patients have become asymptomatic, further testing may not be required. <i>However</i> , if the patient remains symptomatic, then further testing (O&P exams) is required. Remember that a single O&P may not reveal all organisms present.
A number of variables will determine the approach to immunoassay testing and the O&P examination (geography, organisms recovered, positivity rate, physician requests). Immunoassays and/or O&P examinations should be separately ordered and billed.	Immunoassay results do not have to be confirmed by any other testing (such as O&P examinations or modified acid-fast stains).	
		Present plan to physicians for approval: immunoassays or O&P examinations, procedure discussion, report formats, clinical relevance, limitations on each approach.

^a O&P, ova and parasite; FA, fluorescent-antibody assay.^b Two key references addressed this issue and served as guidelines for microbiologists in reviewing clinically relevant recommendations for specimen submission: Morris, A. J., M. L. Wilson, and L. B. Reller. 1992. Application of rejection criteria for stool ovum and parasite examinations. *J. Clin. Microbiol.* 30:3213–3216. Siegel, D. L., P. H. Edelstein, and I. Nachamkin. 1990. Inappropriate testing for diarrheal diseases in the hospital. *JAMA* 263:979–982.^c It is difficult to know when you may be in an early outbreak situation in which testing of all specimens for either *G. lamblia*, *C. parvum*, or both may be relevant. Extensive efforts are under way to encourage communication among laboratories, water companies, pharmacies, and public health officials regarding the identification of potential or actual outbreaks. If it appears that an outbreak is in the early stages, then performing the immunoassays on request can be changed to screening all stools.

Approaches to stool parasitology: test ordering

Patient(s) and/or situation	Test ordered ^a	Follow-up test ordered
Patient with diarrhea and AIDS or other cause of immune deficiency; potential waterborne outbreak (municipal water supply)	<i>Cryptosporidium</i> or <i>Giardia</i> / <i>Cryptosporidium</i> immunoassay	If immunoassays are negative and symptoms continue, special tests for microsporidia (modified trichrome stain) and other coccidia (modified acid-fast stain) and O&P exam should be performed.
Patient with diarrhea (person associated with a nursery school or day care center or a camper or backpacker); patient with diarrhea and potential waterborne outbreak (resort setting)	<i>Giardia</i> or <i>Giardia</i> / <i>Cryptosporidium</i> immunoassay	If immunoassays are negative and symptoms continue, special tests for microsporidia and other coccidia (see above) and O&P exam should be performed.
Patient with diarrhea and relevant travel history; patient with diarrhea who is a past or present resident of a developing country Patient in an area of the United States where parasites other than <i>Giardia</i> are found	O&P exam, <i>Entamoeba histolytica</i> / <i>E. dispar</i> immunoassay; immunoassay for confirmation of <i>E. histolytica</i> ; various tests for <i>Strongyloides</i> may be relevant (eosinophilia)	If exams are negative and symptoms continue, special tests for coccidia and microsporidia should be performed.
Patient with unexplained eosinophilia	May want to consider agar plate culture for <i>Strongyloides stercoralis</i>	If test is negative and symptoms continue, O&P exam and special tests for microsporidia and other coccidia should be performed.
Patient with diarrhea (suspected food-borne outbreak)	Test for <i>Cyclospora cayetanensis</i> (modified acid-fast stains)	If test is negative and symptoms continue, special procedures for microsporidia and other coccidia and O&P exam should be performed.

^a Depending on the particular immunoassay kit used, various single or multiple organisms may be included. Selection of a particular kit depends on many variables: clinical relevance, cost, ease of performance, training, personnel availability, number of test orders, training of physician clients, sensitivity, specificity, equipment, time to result, etc. Very few laboratories will handle this type of testing exactly the same. Many options are clinically relevant and acceptable for good patient care. It is critical that the laboratory report indicate specifically which organisms could be identified using the kit; a negative report should list the organisms relevant to that particular kit.

9.2.2

Preservation of Specimens

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Fecal specimens that cannot be processed and examined in the recommended time should be placed in an appropriate preservative or combination of preservatives for examination later (1, 2, 8, 9). Preservatives will prevent the deterioration of any par-

asites that are present. A number of fixatives for preserving protozoa and helminths are available. Each preservative has specific limitations, and no single solution enables all techniques to be performed with optimal results. The choice of

preservative should give the laboratory the capability to perform a concentration technique and prepare a permanent stained smear for every specimen submitted for fecal examination (1, 2, 8, 9).

II. SPECIMEN

Observe standard precautions.

The fecal specimen should be collected as described previously (*see* procedures 9.1 and 9.2.1). A portion of the specimen should be placed in the preservative immediately after passage. Excellent directions are available with stool collection vials and/or kits, and this approach eliminates many of the problems encountered with fresh stool collection. See Appendix 9.2.2–1 for a summary table on fecal preservatives and specimen collection.

III. MATERIALS

A. Ice cream sticks, applicator sticks, tongue depressors, or other appropriate implement for transferring and mixing the specimen

B. Reagents (*see* Appendix 9.2.2–1)

C. Equipment
Standard

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Obtain a fresh, anticoagulated blood specimen, and prepare a buffy coat sample.
- B. Mix approximately 2 g of soft, fresh fecal specimen (normal stool, containing no parasites) with several drops of the buffy coat cells.
- C. Prepare several fecal smears, and fix immediately in Schaudinn's fixative to be quality controlled.
- D. Mix the remaining feces-buffy coat mixture in 10 ml of polyvinyl alcohol (PVA), modified PVA, or sodium acetate-acetic acid-formalin (SAF) to be quality controlled.
- E. Allow 30 min for fixation, and then prepare several fecal smears. Allow to dry thoroughly (30 to 60 min) at room temperature.
- F. Stain slides by using normal staining procedure.
- G. After staining, if WBCs appear well fixed and display typical morphology, assume that any intestinal protozoa placed in the same lot number of preservative would also be well fixed, provided the fecal sample was fresh and fixed within the recommended time limits.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. Add a portion of fecal material to the preservative vial to give a 3:1 or 5:1 ratio of preservative to fecal material (a grape-sized formed specimen or about 5 ml of liquid specimen).
- C. Mix well by stirring with an applicator stick or the “Spork” insert that is attached to the fixative vial lid to give a homogeneous solution.
- D. Allow to stand for 30 min at room temperature to allow adequate fixation.
- E. If using commercial collection systems, follow the manufacturer’s directions concerning shaking the vials, etc.

POSTANALYTICAL CONSIDERATIONS

VI. PROCEDURE NOTES

- A. Most of the commercially available kits have a “fill to” line on the vial label to indicate how much fecal material to add to ensure adequate preservation of the fecal material.
- B. Although the two-vial system (one vial of 10% buffered formalin [concentration] and one vial of PVA [permanent stained smear]) has always been the “gold standard,” laboratories are beginning to use other options. Changes in the selection of fixatives are based on the following.
 1. Problems with disposal of mercury-based fixatives
 2. Cost of a two-vial system compared with that of a single collection vial
 3. Selection of specific stains (trichrome, iron-hematoxylin) to use with specific fixatives
 4. Immunoassay procedures (EIA, fluorescent-antibody assay [FA], immunochromatographic cartridge) cannot be performed on specimens preserved in certain fixatives; check with the manufacturer.

VII. LIMITATIONS OF THE PROCEDURE

- A. Adequate fixation still depends on the following.
 1. Meeting recommended time limits for lag time between passage of the specimen and fixation
 2. Use of the correct ratio of specimen to fixative
 3. Thorough mixing of the preservative and specimen
- B. Unless the appropriate stain is used with each fixative, the final permanent stained smear may be difficult to examine (organisms hard to see and/or identify).

APPENDIX 9.2.2-1

Include QC information on reagent container and in QC records.

Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. Schaudinn's fixative

This preservative is used with fresh stool specimens or samples from the intestinal mucosal surface. Many laboratories that receive specimens from in-house patients (no problem with delivery times) may select this approach. Permanent stained smears are then prepared from fixed material.

1. Mercuric chloride, saturated aqueous solution

- mercuric chloride (HgCl₂) 110 g
- distilled water 1,000 ml

Dissolve the mercuric chloride in distilled water by heating (use a hood if available); allow the solution to cool until crystals form. Filter the solution into a glass-stoppered bottle and store until needed for stock solution preparation.

2. Schaudinn's fixative (stock solution)

- mercuric chloride, saturated aqueous solution 600 ml
- ethyl alcohol, 95% 300 ml

Immediately before use, add 5 ml of glacial acetic acid per 100 ml of stock solution.

3. Advantages

- a. Designed to be used for the fixation of slides prepared from fresh fecal specimens or samples from the intestinal mucosal surfaces
- b. Prepared slides can be stored in the fixative for up to a week without distortion of protozoan organisms.
- c. Easily prepared in the laboratory
- d. Available from a number of commercial suppliers

4. Disadvantages

- a. Not recommended for use in concentration techniques
- b. Has poor adhesive properties with liquid or mucoid specimens
- c. Contains mercury compounds (mercuric chloride), which may cause disposal problems. Additional information can be found in section 15.

B. PVA

PVA (1, 2, 8) is a plastic resin that is normally incorporated into Schaudinn's fixative. The PVA powder serves as an adhesive for the stool material; i.e., when the stool-PVA mixture is spread onto the glass slide, it adheres because of the PVA component. Fixation is still accomplished by the Schaudinn's fluid itself. Perhaps the greatest advantage in the use of PVA is the fact that a permanent stained smear can be prepared. PVA fixative solution is highly recommended as a means of preserving cysts and trophozoites for examination at a later time. The use of PVA also permits specimens to be shipped (by regular mail service) from any location in the world to a laboratory for subsequent examination. PVA is particularly useful for liquid specimens and should be used at a ratio of 3 parts PVA to 1 part fecal specimen.

1. PVA fixative

- PVA 10.0 g
- ethyl alcohol, 95% 62.5 ml
- mercuric chloride, saturated aqueous solution 125.0 ml
- acetic acid, glacial 10.0 ml
- glycerin 3.0 ml

- a. Mix the liquid ingredients in a 500-ml beaker.
- b. Add the PVA powder (stirring is not recommended).
- c. Cover the beaker with a large petri dish, heavy waxed paper, or foil, and allow PVA to soak overnight.
- d. Heat the solution slowly to 75°C. When this temperature is reached, remove the beaker and swirl the mixture until a homogeneous, slightly milky solution is obtained (30 s).

APPENDIX 9.2.2-1 (continued)

2. Advantages
 - a. Ability to prepare permanent stained smears and perform concentration techniques
 - b. Good preservation of protozoan trophozoites and cyst stages
 - c. Long shelf life (months to years) in tightly sealed containers at room temperature
 - d. Commercially available from a number of sources
 - e. Allows shipment of specimens
3. Disadvantages
 - a. Some organisms (*Trichuris trichiura* eggs, *Giardia lamblia* cysts, *Isospora belli* oocysts) are not concentrated as well from PVA as from formalin-based fixatives, and morphology of some ova and larvae may be distorted.
 - b. Contains mercury compounds (Schaudinn's fixative), which may cause disposal problems
 - c. May turn white and gelatinous when aliquotted into small amounts (begins to dehydrate) or if refrigerated
 - d. Difficult to prepare in the laboratory

C. Modified PVA (copper base) (6)

Although there has been a great deal of interest in developing preservatives that do not use mercury compounds, substitute compounds may not provide good preservation of protozoan morphology on the permanent stained smear. Copper sulfate has been tried most frequently, but it does not provide results equal to those seen with mercuric chloride (4, 6).

1. Copper sulfate solution

CuSO ₄ · 5H ₂ O	20.0 g
distilled water	1,000 ml

Add the CuSO₄ · 5H₂O to 1,000 ml of distilled water heated to 100°C. Mix until dissolved.

2. Modified PVA fixative (stock solution)

copper sulfate solution	600 ml
ethyl alcohol, 95%	300 ml

Immediately before use, add 5 ml of glacial acetic acid per 100 ml of stock solution.

3. Advantages

- a. Can be used for concentration techniques and stained smears
- b. Contains no mercury compounds (usually prepared with copper sulfate)
- c. Commercially available from a number of suppliers. These products (commercial formulas) apparently contain other "fixation agents" that may produce better overall fixation than the formula presented above.

4. Disadvantages

- a. Does not provide high quality of preservation of protozoan morphology on stained slides (4)
- b. Staining characteristics of protozoan organisms are variable; identification may be difficult, particularly when compared with staining characteristics seen with mercuric chloride-based fixatives.

D. Modified PVA (zinc base) (5, 7)

A number of these fixatives are now available commercially, although they do not provide the same overall quality of fixation seen with mercury-based fixatives and the specific formulas are proprietary. Morphologic differences based on organism fixation can be placed in perspective as follows:

Mercury-based fixatives:	How beautiful is the organism?
Zinc-based fixatives:	Can you identify the organism?
(In terms of clinical relevance, the last is the critical question.)	

Although some of the organisms do not present with "textbook-quality" morphologic features, the majority of the time most organisms can be identified. In general, trophozoites tend to fix well, while cyst forms do not. The most difficult organisms to identify in zinc-preserved specimens are *Endolimax nana* cysts.

APPENDIX 9.2.2-1 (continued)

1. Advantages
 - a. Can be used for concentration techniques and stained smears
 - b. Contains no mercury compounds (usually prepared with zinc sulfate)
 - c. Commercially available from a number of suppliers. These products (commercial formulas) contain other "fixation agents" that are proprietary.
2. Disadvantages
 - a. Does not provide the same quality of preservation for good protozoan morphology on stained slides as seen in mercury-fixed solutions (5)
 - b. Staining characteristics of protozoan organisms are variable; identification may be difficult, particularly when compared with staining characteristics seen from mercuric chloride-based fixatives.

E. SAF

SAF (10) lends itself to both the concentration technique and the permanent stained smear and has the advantage of not containing mercuric chloride, as is found in Schaudinn's fluid and PVA. It is a liquid fixative much like 10% formalin. The sediment is used to prepare the permanent smear, and it is recommended that the stool material be placed on an albumin-coated slide to improve adherence to the glass. SAF is considered a "softer" fixative than mercuric chloride. The morphology of organisms will not be quite as sharp after staining as that of organisms originally fixed in solutions containing mercuric chloride. Staining SAF-fixed material with iron-hematoxylin appears to reveal organism morphology more clearly than staining SAF-fixed material with trichrome.

1. SAF fixative

sodium acetate	1.5 g
acetic acid, glacial	2.0 ml
formaldehyde, 37 to 40% solution	4.0 ml
distilled water	92.0 ml

2. Mayer's albumin

Equal parts egg white and glycerin. Place 1 drop on a microscope slide, and add 1 drop of SAF-preserved fecal sediment (from the concentration procedure). Allow the smear to dry at room temperature for 30 min prior to staining.

3. Advantages

- a. Can be used for concentration techniques and stained smears
- b. Contains no mercury compounds
- c. Long shelf life
- d. Easily prepared or commercially available from a number of suppliers

4. Disadvantages

- a. Has poor adhesive properties. Albumin-coated slides are recommended for stained smears.
- b. Protozoan morphology with trichrome stain not as clear as with PVA smears. Hematoxylin staining gives better results.
- c. More difficult for inexperienced workers to use

F. MIF

Merthiolate (thimerosal)-iodine-formalin (MIF) (1) is a good stain preservative for most kinds and stages of parasites found in feces and is useful for field surveys. It is used with all common types of stools and aspirates; protozoa, eggs, and larvae can be diagnosed without further staining in temporary wet mounts. Many laboratories using this fixative examine the material only as a wet preparation (direct smear and/or concentration sediment). MIF is prepared in two stock solutions that are stored separately and mixed immediately before use.

1. MIF fixative

a. Solution I (stored in a brown bottle)

distilled water	50 ml
formaldehyde (USP)	5 ml
thimerosal (tincture of merthiolate, 1:1,000)	40 ml
glycerin	1 ml

APPENDIX 9.2.2-1 (continued)

- b. Solution II (Lugol's solution: good for several weeks in a tightly stoppered brown bottle)

distilled water 100 ml
 potassium iodide (KI) crystals 10 g
 iodine crystals (add after KI dissolves) 5 g

Combine 9.4 ml of solution I with 0.6 ml of solution II just before use.

2. Advantages
 - a. Combination of preservative and stain (merthiolate), especially useful in field surveys
 - b. Protozoan cysts and helminth eggs and larvae can be diagnosed from temporary wet-mount preparations.
3. Disadvantages
 - a. Difficult to prepare permanent stained smears
 - b. Iodine component unstable; needs to be added immediately prior to use
 - c. Concentration techniques may give unsatisfactory results.
 - d. Morphology of organisms becomes distorted after prolonged storage.

G. 5 or 10% formalin (1, 2, 8, 9)

Formalin (1) is an all-purpose fixative that is appropriate for helminth eggs and larvae and protozoan cysts. Two concentrations are commonly used: 5% which is recommended for preservation of protozoan cysts, and 10%, which is recommended for helminth eggs and larvae. Most commercial manufacturers provide 10%, which is most likely to kill all helminth eggs. To help maintain organism morphology, formalin can be buffered with sodium phosphate buffers, i.e., neutral formalin.

1. 10% Formalin

formaldehyde (USP) 100 or 50 ml (for 5%)

Formaldehyde is normally purchased as a 37 to 40% HCHO solution; however, for dilution, it should be considered to be 100%.

0.85% NaCl 900 or 950 ml (for 5%)

Dilute 100 ml of formaldehyde with 900 ml of 0.85% NaCl solution. (Distilled water may be used instead of NaCl solution.)

If you want to use buffered formalin, the following approach is recommended.

Na_2HPO_4 6.10 g
 NaH_2PO_4 0.15 g

Mix the two thoroughly, and store the dry mixture in a tightly closed bottle. Prepare 1 liter of 10 or 5% formalin, and add 0.8 g of the buffer salt mixture.

2. Advantages
 - a. Good routine preservative for protozoan cysts and helminth eggs and larvae. Materials can be preserved for several years.
 - b. Can be used for concentration techniques (sedimentation techniques)
 - c. Long shelf life and commercially available
 - d. Neutral formalin (buffered with sodium phosphate) helps maintain organism morphology with prolonged storage.
3. Disadvantage
 - a. Permanent stained smears cannot be prepared from formalin-preserved fecal specimens.

APPENDIX 9.2.2–1 (continued)

Preservatives used in diagnostic parasitology (stool specimens) (1, 2, 3, 9)

Preservative	Concn	Permanent stained smear
5 or 10% formalin ^a	X	
5 or 10% buffered formalin	X	
MIF	X	X polychrome IV stain
SAF	X	X iron hematoxylin
PVA ^b	X	X trichrome or iron hematoxylin
PVA, modified ^c	X	X trichrome or iron hematoxylin
PVA, modified ^d	X	X trichrome or iron hematoxylin
Single-vial systems ^e	X	X trichrome or iron hematoxylin
Schaudinn's (without PVA) ^b		X trichrome or iron hematoxylin

^a Formaldehyde is normally purchased at a 37 to 40% HCHO solution; however, for dilution, it should be considered to be 100%. Example: 10% formalin = 10 ml of formaldehyde plus 90 ml of distilled water or buffered water.

^b This fixative uses the mercuric chloride base in the Schaudinn's fluid; this formulation is still considered to be the "gold standard," against which all other fixatives are evaluated (organism morphology after permanent staining). Additional fixatives prepared with non-mercuric chloride-based compounds are continuing to be developed and tested.

^c This modification uses a copper sulfate base rather than mercuric chloride.

^d This modification uses a zinc base rather than mercuric chloride and apparently works well with trichrome stain; trials using iron-hematoxylin are currently under way.

^e These modifications use a combination of ingredients (including zinc), but are prepared from proprietary formulas.

Considerations when selecting a stool fixative

- A. Overall fixation efficacy for trophozoites, cysts, oocysts, microsporidial spores, eggs, and larvae
- B. Ability to perform both the concentration and permanent stained smear from the preserved specimen
- C. Selection of a one- or two-vial collection system
- D. Preparation of reagents in-house or commercial purchase
- E. Decision to perform immunoassay procedures (EIA, fluorescent-antibody assay, cartridge formats) from preserved specimen
- F. Need to perform special stains from the preserved specimen (modified acid-fast stains for *Cryptosporidium*, *Cyclospora*, and *Isospora* and modified trichrome stains for microsporidia)

9.2.3

Shipment of Specimens

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

In outpatient situations, it may be necessary for a specimen to be shipped to the laboratory for examination. Only preserved fecal specimens should be shipped, as any delays in examination may result in

deterioration of parasitic organisms (1–3). Prior fixation also reduces the risk of infection from any etiologic agents present in the specimen. The U.S. Postal Service

regulates the shipment of clinical specimens through the mail. It is the responsibility of the sender to conform to these regulations (1–3).

II. SPECIMENS

Observe standard precautions.

- A. Preserved fecal specimens in collection vials
- B. Fecal smears for staining and examination for parasitic organisms
- C. Blood smears for staining and examination for blood parasites (thin blood films should be fixed in methyl alcohol prior to shipment)

III. MATERIALS

- A. Reagents
None
- B. Supplies
 1. Primary container (vial, test tube, or bottle) containing the clinical specimen (feces or blood)
 2. Secondary container in which the primary container will be placed (sealed and water tight, durable) with absorbent material to contain leakage
 3. Shock-absorbent material for protecting the contents (when shipping
- C. Equipment
None
- 4. Outer shipping container of fiberboard or other sturdy material in which the secondary container will be placed
- 5. Instructions for patient specimen collection and handling
- 6. Appropriate mailing labels

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Familiarity with U.S. postal regulations is mandatory. Post up-to-date regulations.
- B. Review relevant postal regulations at routine safety meetings for the staff, and document the review.

V. PROCEDURE

- A. Place the primary container of preserved fecal material into the secondary container (metal sleeve or a sealable bag), and seal.
- B. Place into the mailing container, and seal.
- C. Label appropriately for shipment.
- D. Wrap glass slides in shock-absorbent material to protect from breakage, or place them in a sturdy slide container.
- E. Slides need not be placed in double containers for shipping.
- F. Place padded slides in shipping container and label appropriately.

VI. PROCEDURE NOTES

- A. Some commercially available mailing containers consist of a screw-cap inner metal sleeve that will hold a preservative vial that is placed inside a screw-cap cardboard mailing sleeve. Absorbent material can be placed between the two containers to absorb any leakage. This container can be used to mail a single specimen.
- B. Padded envelopes for mailing sets of preservative vials are available in several sizes. The absorbent material is shredded newspaper inside the envelope layers.
- C. Clinical specimens exceeding 50 ml per parcel must be packaged in a fiberboard box or shipping container of equivalent strength.

VII. LIMITATIONS OF THE PROCEDURE

- A. The same limitations apply to all fixatives, regardless of whether they are delivered by mail.
- B. Each vial or tube containing liquid should be as full as possible. If it is only partly full, some of the liquid may get splashed onto the walls of the container and dry out during transit. Also, the larger the air space, the more shaking will occur, and this may be detrimental to any delicate organisms in the specimen (even if they are preserved).

9.3.1

Macroscopic Examination of Fecal
Specimens: Age and Physical
Description

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The age of fresh fecal specimens is an important factor in the diagnosis of parasitic infections (1–4). The date and time of passage must be provided for each specimen submitted to the laboratory. The physical characteristics of a fresh fecal specimen may aid in determining what types of organisms may be present (1–4). Fecal spec-

imens are described as formed, semiformed, soft, loose, or watery. Loose or watery specimens may contain trophozoites, whereas formed or semiformed specimens are more likely to contain cyst stages. Helminth eggs or larvae may be found in any type of specimen but are more difficult to find in liquid specimens

because of the dilution factor. One can also see if blood and/or mucus is present, although if present, neither one necessarily indicates a parasitic infection. When the fresh specimen is examined visually in the collection container, adult pinworms (*Enterobius vermicularis*) and tapeworm proglottids may also be seen.

II. SPECIMENS

(See procedure 9.2.1.)

Observe standard precautions.

- A. Fresh fecal specimen in waterproof container
- B. Preserve or examine liquid or soft stools containing blood or mucus within 30 min of passage.
- C. Preserve or examine semiformed specimens within 1 h of passage.
- D. Preserve or examine formed specimens within the same day.
- E. Fecal specimens that cannot be processed and examined in the recommended time period should be placed in an appropriate preservative or combination of preservatives for examination at a later time. Preservatives will prevent the deterioration of any parasites that are present. A number of fixatives are available (see Appendix 9.2.2–1) for preserving protozoan and helminth organisms. The choice of preservative should give the laboratory the capability to perform a concentration technique and prepare a permanent stained smear on every specimen submitted for fecal examination (2, 4).

ANALYTICAL CONSIDERATIONS

III. PROCEDURE

- A. Wear gloves when performing this procedure.
- B. Examine the specimen macroscopically to determine consistency.
- C. Examine the surface of the fecal specimen for the presence of blood or mucus.
- D. Sample areas of blood or mucus for examination for trophic amebae.
- E. Examine the surface of the specimen and the area underneath the specimen for possible organisms (adult pinworms or tapeworm proglottids).
- F. Check information for date and time of passage.

IV. RESULTS

- A. Adult helminths or portions of helminths may be recovered and seen with the naked eye. Examples include *E. vermicularis* adult worms, *Ascaris lumbricoides* adult worms, and tapeworm proglottids.
- B. Occasionally, other helminths may be recovered (hookworm, *Strongyloides stercoralis*), but identification requires the use of the microscope.

POSTANALYTICAL CONSIDERATIONS

V. REPORTING RESULTS

- A. Report the presence of adult helminths or portions of helminths. Morphology and size are usually adequate for identification of pinworm and *Ascaris* adults and tapeworm proglottids. (Identification to the species level will require India ink injection [see procedure 9.5.6].)
Examples: *Ascaris lumbricoides* adult worm identified.
Enterobius vermicularis adult worm identified.
Taenia saginata gravid proglottid identified.
- B. Report the presence of blood on or in the fecal specimen.
Example: Fresh blood seen on stool specimen.

VI. PROCEDURE NOTES

- A. Trophic amebae or flagellates are found most frequently in liquid or soft specimens and tend to disintegrate rapidly at room temperature.
- B. Trophozoites and cyst stages may be found in semifformed specimens.
- C. Cyst stages are found most frequently in formed specimens and will not lose characteristic morphology at room temperature for approximately 1 day.
- D. Eggs and larvae in fresh fecal specimens do not lose characteristic morphology at room temperature as rapidly as trophozoites or cysts. Some eggs (hookworm) may hatch if the specimen is kept unpreserved at room temperature for more than a day.
- E. Refrigeration of the fresh fecal specimen will delay deterioration of the parasitic organisms.
- F. Freezing of the fecal specimen is not recommended, as characteristic morphology of the parasitic organisms may be altered.
- G. Never incubate fecal specimens.
- H. Laboratories that receive the fecal specimen in preservative vials must rely on information that is submitted with the specimen as to the consistency of the specimen.
- I. Many commercially available kits contain vials with labels which allow the patient to indicate the original consistency of the specimen.
- J. A clean vial (containing no preservative) can be provided to patients for submitting a portion of the fresh specimen for determining consistency.
- K. Dark or tarry fecal specimens usually indicate bleeding in the upper gastrointestinal tract.
- L. Bright red blood indicates bleeding at a lower level or around the rectum.
- M. Barium causes feces to be light tan to white. These specimens should be rejected.
- N. Ingested iron and some antidiarrheal compounds may cause the specimen to be dark to black.
- O. Yellowish specimens may be noted in cases of fat malabsorption, which is seen commonly in infection with *Giardia lamblia*.
- P. Vegetable material is frequently seen in fecal specimens and must be differentiated from helminths. Size and gross morphology are used to differentiate vegetable material from helminth parasites (see Appendixes 9.10.1–1 and 9.10.3–1 at the end of this section).

VII. LIMITATIONS OF THE PROCEDURE

Although there are some benefits (organism motility) associated with the examination of fresh fecal specimens, many laboratories have switched to stool preservative collection kits. Many intestinal parasites tend to disintegrate soon after collection, particularly if there is a time lag between specimen collection and preservation. In order to eliminate time lag problems and ensure adequate organism morphology, stool collection kits are recommended. Also, remember that organisms other than parasites can cause diarrhea; you might want to check whether bacterial cultures have been ordered.

9.3.2

Calibration of Microscope with an Ocular Micrometer

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The identification of protozoa and other parasites depends on several factors, one of which is size. Any laboratory doing diagnostic work in parasitology should have a calibrated microscope available for precise measurements. Measurements are

made with a micrometer disk that is placed in the ocular of the microscope; the disk is usually calibrated as a line divided into 50 units. Depending on the objective magnification used, the divisions in the disk

represent different measurements. The ocular disk division must be compared with a known calibrated scale, usually a stage micrometer with a scale of 0.1- and 0.01-mm divisions (1) (Fig. 9.3.2-1).

II. MATERIALS

A. Supplies

1. Ocular micrometer disk (line divided into 50 U) (any laboratory supply distributor: Fisher, Baxter, Scientific Products, VWR, etc.)
2. Stage micrometer with a scale of 0.1- and 0.01-mm divisions (Fisher, Baxter, Scientific Products, VWR, etc.)
3. Immersion oil
4. Lens paper

B. Equipment

1. Binocular microscope with 10 \times , 40 \times , and 100 \times objectives. Other

objective magnifications (50 \times oil or 60 \times oil immersion lenses) may also be used.

2. Oculars should be 10 \times . Some may prefer 5 \times ; however, smaller magnification may make final identifications more difficult.
3. Single 10 \times ocular to be used to calibrate all laboratory microscopes (to be used when any organism is being measured)

ANALYTICAL CONSIDERATIONS

III. QUALITY CONTROL

- A. Recalibrate the microscope periodically. If the scope receives heavy use, once a year is recommended.
- B. Often the measurement of RBCs (approximately 7.5 μ m) is used to check the calibrations of the three magnifications (\times 100, \times 400, \times 1,000).
- C. Latex or polystyrene beads of a standardized diameter can be used to check the calculations and measurements (Sigma, J. T. Baker, etc.). Beads of 10 and 90 μ m are recommended.
- D. Record all measurements in QC records.

IV. PROCEDURE

- A. Unscrew the eye lens of a 10 \times ocular, and place the micrometer disk (engraved side down) within the ocular. Use lens paper to handle the disk; keep all surfaces free of dust or lint.

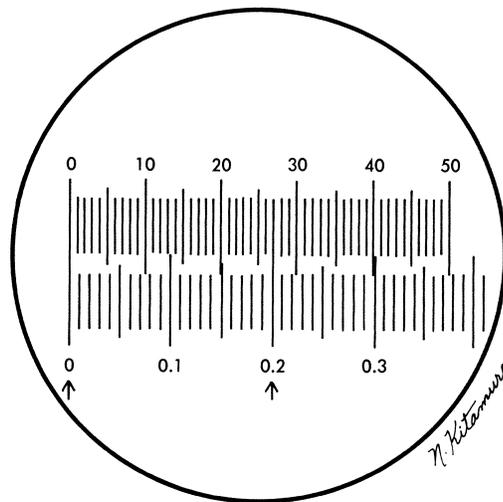

Figure 9.3.2-1 Ocular micrometer, top scale; stage micrometer, bottom scale (from **L. S. Garcia**, *Diagnostic Medical Parasitology*, 4th ed., 2001, ASM Press, Washington, D.C.).

IV. PROCEDURE (continued)

- B.** Place the calibrated micrometer on the stage, and focus on the scale. You should be able to distinguish the difference between the 0.1- and 0.01-mm divisions. Make sure you understand the divisions on the scale before proceeding.
- C.** Adjust the stage micrometer so that the “0” line on the ocular micrometer is exactly lined up on top of the 0 line on the stage micrometer.
- D.** When these two 0 lines are lined up, do not move the stage micrometer any farther. Look to the right of the 0 lines for another set of lines superimposed on each other. The second set of lines should be as far to the right of the 0 lines as possible; however, the distance varies with the objectives being used (Fig. 9.3.2-1).
- E.** Count the number of ocular divisions between the 0 lines and the point where the second set of lines is superimposed. Then, on the stage micrometer, count the number of 0.1-mm divisions between the 0 lines and the second set of superimposed lines.
- F.** Calculate the portion of a millimeter that is measured by a single small ocular unit.
- G.** When the high dry and oil immersion objectives are used, the 0 line of the stage micrometer will increase in size, whereas the ocular 0 line will remain the same size. The thin ocular 0 line should be lined up in the center or at one edge of the broad stage micrometer 0 line. Thus, when the second set of superimposed lines is found, the thin ocular line should be lined up in the center or at the corresponding edge of the broad stage micrometer line.
- H.** Calculate the factors as follows.

Examples:

$$\frac{\text{stage reading (mm)}}{\text{ocular reading}} \times \frac{1,000 \mu\text{m}}{1 \text{ mm}} = \text{ocular units } (\mu\text{m})$$

$$\text{Low power (10}\times\text{): } \frac{0.8 \text{ mm}}{100 \text{ U}} \times \frac{1,000 \mu\text{m}}{1 \text{ mm}} = 8.0 \mu\text{m (factor)}$$

$$\text{High dry power (40}\times\text{): } \frac{0.1 \text{ mm}}{50 \text{ U}} \times \frac{1,000 \mu\text{m}}{1 \text{ mm}} = 2.0 \mu\text{m (factor)}$$

$$\text{Oil immersion (100}\times\text{): } \frac{0.05 \text{ mm}}{62 \text{ U}} \times \frac{1,000 \mu\text{m}}{1 \text{ mm}} = 0.8 \mu\text{m (factor)}$$

IV. PROCEDURE (*continued*)

Examples: If a helminth egg measures 15 ocular units by 7 ocular units with the high dry objective, then multiply the measurements by the factor $2.0\ \mu\text{m}$ (for that objective). The egg then measures 30 by $14\ \mu\text{m}$ and is probably *Clonorchis sinensis*.

If a protozoan cyst measures 27 ocular units with the oil immersion objective, then multiply the measurement by the factor $0.8\ \mu\text{m}$ (for that objective). The cyst then measures $21.6\ \mu\text{m}$.

V. RESULTS

- A. For each objective magnification, a factor will be generated (1 ocular unit = certain number of micrometers).
- B. If standardized latex or polystyrene beads or an RBC is measured with various objectives, the size for the object measured should be the same (or very close), regardless of the objective magnification.

POSTANALYTICAL CONSIDERATIONS**VI. REPORTING RESULTS**

- A. Post the multiplication factor for each objective either on the base of the microscope or on a nearby wall or bulletin board for easy reference.
- B. Once the number of ocular lines per width and length of the organism is measured, then, depending on the objective magnification, the factor (1 ocular unit = certain number of micrometers) can be applied to the number of lines to obtain the width and length of the organism.
- C. Comparison of these measurements with reference measurements in various books and manuals should confirm the organism identification.

VII. PROCEDURE NOTES

- A. The final multiplication factors will be only as good as your visual comparison of the ocular 0 and stage micrometer 0 lines.
- B. As a rule of thumb, the high dry objective ($40\times$) factor should be approximately 2.5 times more than the factor obtained from the oil immersion objective ($100\times$). The low-power objective ($10\times$) factor should be approximately 10 times that of the oil immersion objective ($100\times$).

VIII. LIMITATIONS OF THE PROCEDURE

- A. After each objective has been calibrated, the oculars containing the disk and/or these objectives cannot be interchanged with corresponding objectives or oculars on another microscope.
- B. Each microscope used to measure organisms must be calibrated as a unit. The original oculars and objectives that were used to calibrate the microscope must also be used when an organism is measured.
- C. The objective containing the ocular micrometer can be stored until needed. This single ocular can be inserted when measurements are taken. However, this particular ocular containing the ocular micrometer disk must also have been used as the ocular during microscope calibration.

1. **Garcia, L. S.** 2001. *Diagnostic Medical Parasitology*, 4th ed., p. 723. ASM Press, Washington, D.C.

9.3.3

Microscopic Examination of Fecal Specimens: Direct Smears

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The microscopic examination of a direct smear has several purposes: to assess the worm burden of a patient, to provide a quick diagnosis of a heavily infected specimen, to check organism motility, and to diagnose parasites that may be lost in concentration techniques (1–4).

II. SPECIMEN

Observe standard precautions.

Any fresh stool specimen that has not been refrigerated is acceptable. Since trophozoites within preserved specimens would exhibit no motility on a direct smear, it is not necessary to perform this procedure on specimens submitted in preservatives (10% formalin, sodium acetate-acetic acid-formalin, and various types of polyvinyl alcohol, single-vial preservative collection systems).

III. MATERIALS

A. Reagents (see Appendix 9.3.3–1)

The reagents indicated below are available commercially.

1. 0.85% NaCl
2. D'Antoni's iodine or Lugol's iodine
Aliquot some of the iodine into a brown dropper bottle. The working solution should resemble a strong tea color and should be discarded when it lightens in color (usually within 10 to 14 days).

B. Supplies

1. Microscope slides (1 by 3 in. or larger)
2. Coverslips (no. 1, 22 by 22 mm or larger)

3. Pasteur pipettes and bulbs

4. Screw-cap test tubes (16 by 125 mm)

5. Beaker (500 ml)

6. Brown glass-stoppered bottle (250 ml)

7. Two brown glass dropper bottles

C. Equipment

1. Binocular microscope with 10×, 40×, and 100× objectives; phase-contrast and/or differential interference contrast optics preferred

2. Oculars should be 10×. Some may prefer 5×; however, smaller magnification may make final identifications more difficult.

3. Magnetic stirrer and stir bar

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

A. Check the working iodine solution each time it is used or periodically (once a week).

1. The iodine should be free of any signs of bacterial and/or fungal contamination.

IV. QUALITY CONTROL

(continued)

2. The color should be that of strong tea (discard if too light).
 3. Protozoan cysts should contain yellow-gold cytoplasm, brown glycogen material, and paler refractile nuclei. Human WBCs mixed with negative stool can be used as a QC specimen. The human cells will stain with the same color as that seen in the protozoa.
- B.** The microscope should be calibrated, and the original optics used for the calibration should be in place on the microscope. Post the calibration factors for all objectives on the microscope for easy access (*see* procedure 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- C.** Record all QC results.

V. PROCEDURE

- A.** Wear gloves when performing this procedure.
- B.** Place one drop of 0.85% NaCl on the left side of the slide and 1 drop of iodine (working solution) on the right side of the slide.
- C.** Take a very small amount of fecal specimen (about the amount picked up on the end of an applicator stick when introduced into the specimen), and thoroughly emulsify the stool in the saline and iodine preparations (use separate sticks for each).
- D.** Place a coverslip (22 by 22 mm) on each suspension.
- E.** Systematically scan both suspensions with the 10× objective. The entire coverslip area should be examined.
- F.** If you see something suspicious, use the 40× objective for more-detailed study. At least one-third of the coverslip should be examined with the 40× objective, even if nothing suspicious has been seen.

VI. RESULTS

Protozoan trophozoites and/or cysts and helminth eggs and larvae may be seen and identified.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A.** You may or may not be able to identify motile trophozoites to the species level (depending on the clarity of the morphology).
Example (positive report): *Giardia lamblia* trophozoites present.
- B.** You may or may not be able to identify protozoan cysts to the species level (depending on the clarity of the morphology).
Example (positive report): *Entamoeba coli* cysts present.
- C.** You may identify helminth eggs and/or larvae.
Examples: *Ascaris lumbricoides* eggs present.
Strongyloides stercoralis larvae present.
- D.** You may see artifacts and/or other structures. Report them.
Examples: Moderate Charcot-Leyden crystals present.
Few RBCs present.

VIII. PROCEDURE NOTES

- A.** In preserved specimens, formalin replaces the saline and can be used directly; however, you will not be able to see any organism motility (organisms are killed by 10% formalin).

VIII. PROCEDURE NOTES

(continued)

- B. Some workers prefer to make the saline and iodine mounts on separate slides. There is less chance of getting fluids on the microscope stage if separate slides are used (less total fluid on the slide and under the coverslip).
- C. The microscope light should be reduced for low-power observations, since most organisms will be overlooked with bright light. Illumination should be regulated so that some of the cellular elements in the feces show refraction. Most protozoan cysts will refract under these light conditions.

IX. LIMITATIONS OF THE PROCEDURE

- A. Results obtained with wet smears should usually be confirmed by permanent stained smears. Some protozoa are very small and difficult to identify to the species level by direct wet smears alone.
- B. Confirmation is particularly important in the case of *Entamoeba histolytica*/*E. dispar* versus *Entamoeba coli*.

APPENDIX 9.3.3–1

Include QC information on reagent container and in QC records.

Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. 0.85% NaCl

NaCl 0.85 g
distilled water 100.0 ml

1. Dissolve the sodium chloride in distilled water in a flask or bottle by using a magnetic stirrer.
2. Distribute 10 ml of the solution into each of 10 screw-cap tubes.
3. Label as 0.85% NaCl with an expiration date of 1 year.
4. Sterilize by autoclaving at 121°C for 15 min.
5. When cool, store at 4°C.

B. D'Antoni's iodine

potassium iodide (KI) 1.0 g
powdered iodine crystals 1.5 g
distilled water 100.0 ml

1. Dissolve the potassium iodide and iodine crystals in distilled water in a flask or bottle by using a magnetic stirrer.
2. Some excess crystals of iodine should remain on the bottom of the bottle.
3. Store in a brown, glass-stoppered bottle at room temperature.
4. The solution is ready for immediate use. Label as D'Antoni's iodine with an expiration date of 1 year (the stock solution remains good as long as an excess of iodine crystals remains on the bottom of the bottle).
5. Aliquot some of the iodine into a brown dropper bottle. The working solution should resemble strong tea and should be discarded when it lightens in color (usually within 10 to 14 days).

APPENDIX 9.3.3-1 (continued)

C. Lugol's iodine

- potassium iodide 10.0 g
- powdered iodine crystals5.0 g
- distilled water100.0 ml

1. Follow the directions given above for D'Antoni's iodine, including the expiration date of 1 year.
2. Dilute a portion 1:5 with distilled water for routine use (working solution).
3. Place this working solution into a brown dropper bottle. The working solution should resemble strong tea and should be discarded when it lightens in color (usually within 10 to 14 days).

Diagnostic characteristics of organisms in wet mounts

Specimen	Protozoa	Helminths
Stool, other specimens from the gastrointestinal tract or urogenital system	Size, shape, stage (trophozoite, precyst, cyst, oocyst), motility (fresh specimens only), refractility, cytoplasm inclusions (chromatoidal bars, glycogen vacuoles, axonemes, axostyles, median bodies, sporozoites)	Egg, larvae, or adult; size; internal structure, as follows: for the egg, embryonated, opercular shoulders, abopercular thickenings or projections, hooklets, polar filaments, and spines; for larvae, head and tail morphology and digestive tract; and for the adult, nematode, cestode, or trematode

9.3.4

Microscopic Examination of Fecal Specimens: Concentration by Formalin-Ethyl Acetate Sedimentation

Fecal concentration has become a routine procedure as a part of the complete ova and parasite examination for parasites and allows the detection of small numbers of organisms that may be missed by using only a direct wet smear. There are two

types of concentration procedures: flotation and sedimentation, both of which are designed to separate protozoan organisms and helminth eggs and larvae from fecal debris by centrifugation and/or differences in specific gravity.

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

By centrifugation, this concentration procedure leads to the recovery of all protozoa, eggs, and larvae present; however, the preparation contains more debris than the flotation procedure. Ethyl acetate is used as an extractor of debris and fat from the

feces and leaves the parasites at the bottom of the suspension. Concentration by formalin-ethyl acetate sedimentation is recommended because it is the easiest to perform, allows recovery of the broadest range of organisms, and is least subject to

technical error (1–5). It is also important to remember that concentrated fecal sediment is recommended for the modified acid-fast and modified trichrome stains used for the coccidia and microsporidia, respectively.

II. SPECIMEN

Observe standard precautions.

- A. The specimen must be fresh or formalinized stool (5 or 10% buffered or non-buffered formalin or sodium acetate-acetic acid-formalin [SAF]) (*see* procedures 9.1, 9.2.1, and 9.2.2).
- B. Polyvinyl alcohol (PVA)-preserved specimens can be used (*see* item VIII below), as can specimens preserved in the single-vial collection systems (zinc-based, proprietary formulas).

III. MATERIALS

Include QC information on reagent container and in QC records.

- A. **Reagents**
 - ☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.
 1. Ethyl acetate
 2. Formalin (5 or 10% buffered or nonbuffered or SAF)
 3. 0.85% NaCl
 4. D'Antoni's or Lugol's iodine
- B. **Supplies**
 1. Funnel
 2. Gauze
 3. Centrifuge tubes (15 ml)
 4. Applicator sticks
 5. Glass slides (1 by 3 in. or larger)
 6. Coverslips (22 by 22 mm; no. 1 or larger)
 7. Disposable glass or plastic pipettes
- C. **Equipment**
 1. Centrifuge (tabletop or floor model)
 2. Binocular microscope with 10×, 40×, and 100× objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
 3. Oculars should be 10×. Some workers prefer 5×; however, overall smaller magnification may make final organism identifications more difficult.

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Check the reagents each time they are used. The formalin and saline should appear clear, without any visible contamination.
- B. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements done with the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedure 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- C. Concentrate known positive specimens and verify organism recovery at least quarterly and particularly after the centrifuge has been recalibrated.
- D. Record all QC results.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. Transfer a half-teaspoon (about 4 g) of fresh stool into 10 ml of 10% formalin in a shell vial, unwaxed paper cup, or round-bottom tube (container may be modified to suit individual laboratory preferences). Mix the stool and formalin thoroughly. Let the mixture stand a minimum of 30 min for fixation. If the specimen is already in 5 or 10% formalin (or SAF or one of the other available single-vial collection system fixatives), restir the stool-formalin mixture.
- C. Depending on the amount and viscosity of the specimen, strain a sufficient quantity through wet gauze into a conical 15-ml centrifuge tube to give the desired amount of sediment (0.5 to 1 ml) in step V.D below. Usually, 8 ml of the stool-formalin mixture prepared in step V.B will be sufficient. If the specimen is received in vials of preservative, then approximately 3 to 4 ml will be sufficient unless there is very little stool in the vial.
- D. Add 0.85% NaCl (*see* item VIII below) almost to the top of the tube, and centrifuge for 10 min at $500 \times g$. The amount of sediment obtained should be approximately 0.5 to 1 ml.
- E. Decant the supernatant fluid, and resuspend the sediment in saline. Add saline almost to the top of the tube, and centrifuge again for 10 min at $500 \times g$. This second wash may be eliminated if the supernatant fluid after the first wash is light tan or clear.
- F. Decant the supernatant fluid, and resuspend the sediment on the bottom of the tube in 10% formalin. Fill the tube half full only. If the amount of sediment left in the bottom of the tube is very small or if the original specimen contained a lot of mucus, *do not add ethyl acetate* in step V.G; merely add the formalin, spin, decant, and examine the remaining sediment.
- G. Add 4 to 5 ml of ethyl acetate. Stopper the tube, and shake it vigorously for at least 30 s, exerting pressure on the stopper throughout. Hold the tube so the stopper is directed away from your face.
- H. After a 15- to 30-s wait, carefully remove the stopper.
- I. Centrifuge for 10 min at $500 \times g$. Four layers should result: a small amount of sediment (containing the parasites) in the bottom of the tube, a layer of formalin, a plug of fecal debris on top of the formalin layer, and a layer of ethyl acetate at the top (Fig. 9.3.4-1).
- J. Free the plug of debris by ringing the plug with an applicator stick; decant all of the supernatant fluid. After proper decanting, a drop or two of fluid remaining

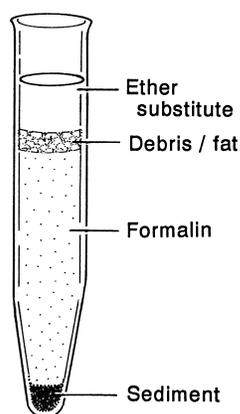

Figure 9.3.4-1 Diagram of specimen after centrifugation (sedimentation procedure).

V. PROCEDURE (continued)

on the side of the tube may run down into the sediment. Mix this fluid with the sediment.

- K. If the sediment is still somewhat solid, add a drop or two of saline to the sediment, mix, and add a small amount of material to a slide, add a coverslip, and examine.
- L. Systematically scan with the 10× objective. The entire coverslip area should be examined.
- M. If you see something suspicious, use the 40× objective for more-detailed study. At least one-third of the coverslip should be examined with the 40× objective, even if nothing suspicious has been seen. As in the direct wet smear, iodine can be added to enhance morphological detail.

VI. RESULTS

Protozoan trophozoites and/or cysts and helminth eggs and larvae may be seen and identified. Protozoan trophozoites are less likely to be seen.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. You may or may not be able to identify protozoan cysts to the species level (depending on the clarity of the morphology).
Example (positive report): *Giardia lamblia* cysts present.
- B. You may identify helminth eggs and/or larvae.
Example: *Trichuris trichiura* eggs present.
- C. You may also see artifacts and/or other structures. Report them.
Examples: Few Charcot-Leyden crystals present.
Moderate PMNs present.

VIII. PROCEDURE NOTES

- A. Tap water may be substituted for 0.85% NaCl throughout this procedure, although the addition of water to fresh stool will cause *Blastocystis hominis* cyst forms to rupture. In addition to the original 10% formalin fixation, some workers prefer to use 10% formalin for all the rinses throughout the procedure.
- B. Ethyl acetate is widely recommended as a substitute for ether. It can be used the same way in the procedure and is much safer. Hemo-De can also be used (6).
 - 1. After the plug of debris is rimmed and excess fluid is decanted, while the tube is still upside down, swab the sides of the tube with a cotton-tipped applicator stick to remove excess ethyl acetate. This is particularly important if you are working with plastic centrifuge tubes. If the sediment is too dry after the tube has been swabbed, add several drops of saline before preparing your wet smear for examination.
 - 2. If you have excess ethyl acetate in the smear of the sediment prepared for examination, bubbles will obscure the material you are trying to see.
- C. If specimens are received in SAF, then begin at step V.B.
- D. If specimens are received in PVA or one of the other available single vial collection system fixatives, modify the first two steps of the procedure (steps V.A and B) as follows:
 - 1. Immediately after stirring the stool-fixative mixture with applicator sticks, pour approximately one-half of the mixture into a tube (container optional) and add 0.85% saline almost to the top of the tube.
 - 2. Filter the stool-fixative-saline mixture through wet gauze into a 15-ml centrifuge tube. Follow the standard procedure from here to completion, beginning with step V.C.

VIII. PROCEDURE NOTES*(continued)*

- E. Too much or too little sediment will result in an ineffective concentration.
- F. Let the centrifuge reach the recommended speed before you begin to monitor centrifugation time. If the centrifugation time at the proper speed is reduced, some organisms (*Cryptosporidium* oocysts or microsporidial spores) may not be recovered in the sediment.

IX. LIMITATIONS OF THE PROCEDURE

- A. Results obtained with wet smears should usually be confirmed by permanent stained smears. Some protozoa are very small and difficult to identify to the species level by direct wet smears alone.
- B. Confirmation is particularly important in the case of *Entamoeba histolytica*/*E. dispar* versus *Entamoeba coli*.
- C. Certain organisms, such as *G. lamblia*, hookworm eggs, and occasionally *Trichuris* eggs, may not concentrate as well from PVA-preserved specimens as they do from those preserved in formalin. However, if there are enough *G. lamblia* organisms present to concentrate from formalin, then PVA should contain enough for detection on the permanent stained smear. In clinically important infections, the number of helminth eggs present would ensure detection regardless of the type of preservative used. Also, the morphology of *Strongyloides stercoralis* larvae is not as clear from PVA as from specimens fixed in formalin.
- D. For unknown reasons, *Isospora belli* oocysts concentrated from PVA-preserved specimens are routinely missed in the concentrate sediment.
- E. At the centrifugation speed and time recommended in this procedure, there is anecdotal evidence to strongly indicate that *Cryptosporidium* oocysts and microsporidial spores should be recovered if present in the specimen. *The current recommendation is centrifugation at 500 × g for a minimum of 10 min for the recovery of coccidia and microsporidia.*

APPENDIX 9.3.4–1**Automated Workstation for the Microscopic Analysis of Fecal Concentrates**

The FE-2 (DiaSys Corporation, Waterbury, Conn.) is a countertop workstation that automates the microscopic analysis of fecal concentrates (Fig. 9.3.4–A1). The system automates the aspiration, resuspension, staining or dilution (based on user preference), transfer, presentation, and disposal of fecal concentrates. When the sample button is pressed, within 5 s two samples of fecal concentrate are automatically and simultaneously aspirated from the concentrate tube and transported to the glass dual-flow cells of the Optical Slide Assembly (Fig. 9.3.4–A2). Based on user preference, the FE-2 will also simultaneously stain or dilute one of the two samples to be examined. After the microscopic examination of the fecal suspension within the glass viewing chambers, the flow chambers can be purged and cleaned so that they are ready for the next specimen. The dual-flow-cell Optical Slide Assembly is designed to fit within the stage clips of any standard, upright microscope. The Optical Slide Assembly accommodates bright-field, phase-contrast, polarized-light, and other common forms of microscopy. The system can be moved from one microscope to another or can be set up as a semipermanent station for fecal concentrate microscopy. Removal to another microscope just involves removing the Optical Slide Assembly from the microscope stage.

APPENDIX 9.3.4–1 (continued)

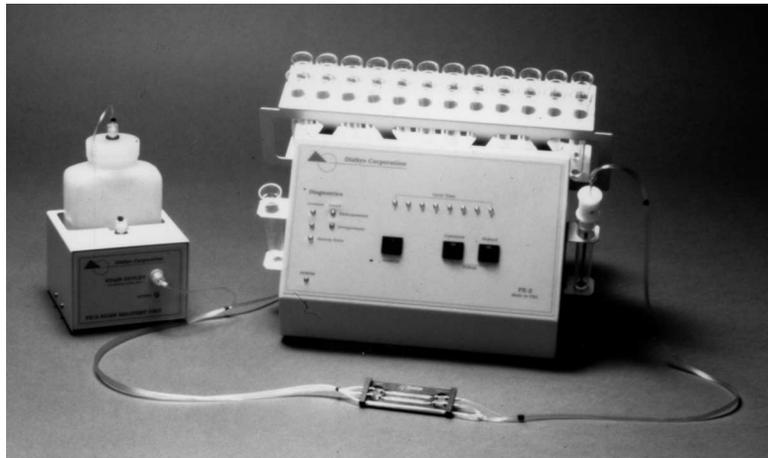

Figure 9.3.4–A1 Countertop workstation that automates the microscopic analysis of fecal concentrates (DiaSys Corp.) (from **L. S. Garcia**, *Diagnostic Medical Parasitology*, 4th ed., 2001, ASM Press, Washington, D.C.).

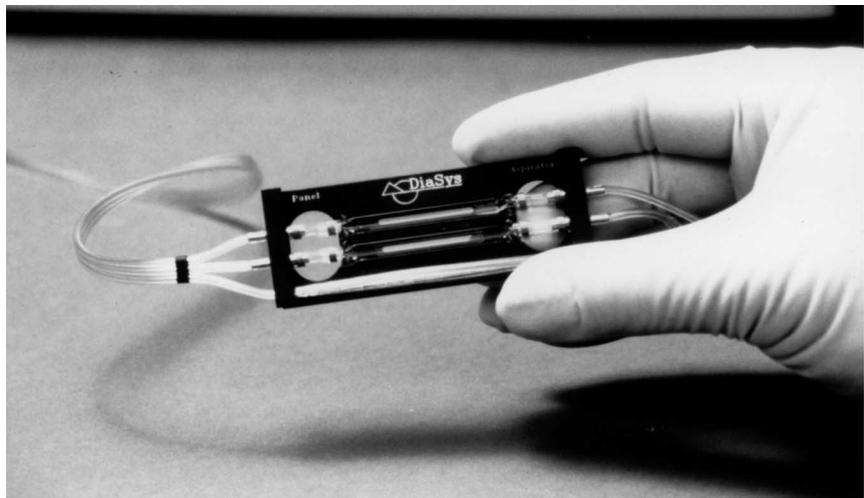

Figure 9.3.4–A2 Dual-flow-cell Optical Slide Assembly (DiaSys Corp.) that fits into the stage clips of any standard upright microscope (from **L. S. Garcia**, *Diagnostic Medical Parasitology*, 4th ed., 2001, ASM Press, Washington, D.C.).

9.3.5

Microscopic Examination of Fecal Specimens: Concentration by Zinc Sulfate Flotation

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The flotation procedure permits the separation of protozoan cysts and certain helminth eggs from excess debris through the use of a liquid with a high specific gravity. The parasitic elements are recovered in the surface film, and the debris remains in the bottom of the tube. This technique yields

a cleaner preparation than the sedimentation procedure; however, some helminth eggs (operculated eggs and/or very dense eggs such as unfertilized *Ascaris* eggs) do not concentrate well with the flotation method (1–5). The specific gravity of the zinc sulfate may be increased, although

this usually causes more distortion in the organisms present and is not recommended for routine clinical use. To ensure detection of all possible organisms, examine both the surface film and the sediment. For most laboratories, this is not a practical approach.

II. SPECIMEN

Observe standard precautions.

The specimen must be fresh or formalinized stool (5 or 10% buffered or nonbuffered formalin or sodium acetate-acetic acid-formalin [SAF]).

III. MATERIALS

A. Reagents (see Appendix 9.3.5–1)

1. Formalin (5 or 10% buffered or nonbuffered) or SAF
2. 0.85% NaCl
3. Zinc sulfate (33% aqueous solution)

B. Supplies

1. Funnel
2. Gauze
3. Centrifuge tubes (15 ml)
4. Applicator sticks
5. Glass slides (1 by 3 in. or larger)
6. Coverslips (22 by 22 mm; no. 1 or larger)
7. Disposable glass or plastic pipettes
8. Wire loop (bacteriology)
9. Graduated cylinder

C. Equipment

1. Centrifuge (tabletop or floor model)
Swinging buckets are preferred to a fixed-head model.
2. Binocular microscope with 10×, 40×, and 100× objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
3. Oculars should be 10×. Some workers prefer 5×; however, overall smaller magnification may make final organism identifications more difficult.
4. Hydrometer (with a range that includes 1.18 to 1.20)

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Check the reagents each time they are used.
The formalin, saline, and zinc sulfate should appear clear, without any visible contamination.
- B. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the micro-

IV. QUALITY CONTROL (continued)

scope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (see procedure 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.

- C. Concentrate known positive specimens, and verify organism recovery at least quarterly and particularly after the centrifuge has been recalibrated.
- D. Record all QC results.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. Transfer a half-teaspoon (about 4 g) of fresh stool into 10 ml of 10% formalin in a shell vial, unwaxed paper cup, or round-bottom tube (container may be modified to suit individual laboratory preferences). Mix the stool and formalin thoroughly. Let the mixture stand a minimum of 30 min for fixation. If the specimen is already in 5 or 10% formalin (or SAF), restir the stool-formalin mixture.
- C. Depending on the size and density of the specimen, strain a sufficient quantity through wet gauze into a conical 15-ml centrifuge tube to give the desired amount of sediment (0.5 to 1 ml) in step V.D below. Usually, 8 ml of the stool-formalin mixture prepared in step V.B will be sufficient. If the specimen is received in vials of preservative (10% formalin or SAF), then approximately 3 to 4 ml will be sufficient unless the specimen has very little stool in the vial.
- D. Add 0.85% NaCl (see item VIII below) almost to the top of the tube, and centrifuge for 10 min at $500 \times g$. The amount of sediment obtained should be approximately 0.5 to 1 ml. Too much or too little sediment will result in an ineffective concentration.
- E. Decant the supernatant fluid, resuspend the sediment in 0.85% NaCl almost to the top of the tube, and centrifuge for 10 min at $500 \times g$. This second wash may be eliminated if the supernatant fluid after the first wash is light tan or clear.
- F. Decant the supernatant fluid, and resuspend the sediment on the bottom of the tube in 1 to 2 ml of zinc sulfate. Fill the tube to within 2 to 3 mm of the rim with additional zinc sulfate.
- G. Centrifuge for 1 min at $500 \times g$. Allow the centrifuge to come to a stop without interference or vibration. Two layers should result: a small amount of sediment in the bottom of the tube and a layer of zinc sulfate. The protozoan cysts and some helminth eggs will be in the surface film; some operculated and/or heavy eggs will be in the sediment (Fig. 9.3.5-1).
- H. Without removing the tube from the centrifuge, remove 1 or 2 drops of the surface film with a Pasteur pipette or a freshly flamed (and allowed to cool) wire loop and place them on a slide. Do not use the loop as a "dipper"; simply touch the surface (bend the loop portion of the wire 90° so the loop is parallel with the surface of the fluid). Make sure the pipette tip or wire loop is not below the surface film.
- I. Add a coverslip to the preparation. Iodine may be added to the preparation.
- J. Systematically scan with the $10\times$ objective. The entire coverslip area should be examined.
- K. If you see something suspicious, use the $40\times$ objective for more-detailed study. At least one-third of the coverslip should be examined with the $40\times$ objective, even if nothing suspicious has been seen. As in the direct wet smear, iodine can be added to enhance morphological detail.

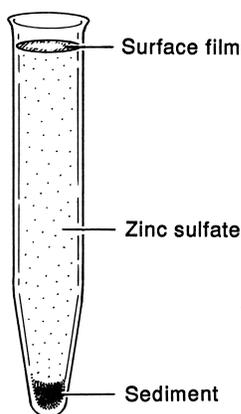

Figure 9.3.5-1 Diagram of specimen after centrifugation (flotation procedure).

VI. RESULTS

Protozoan trophozoites and/or cysts and helminth eggs and larvae may be seen and identified.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. You may or may not be able to identify protozoan cysts to the species level (depending on the clarity of the morphology).
Example: *Giardia lamblia* cysts present.
- B. You may identify helminth eggs and/or larvae.
Example: *Trichuris trichiura* eggs present.
- C. You may see and report artifacts and/or other structures.
Examples: Few Charcot-Leyden crystals present.
Moderate PMNs present.

VIII. PROCEDURE NOTES

- A. Tap water (*see* step V.D below) may be substituted for 0.85% NaCl throughout this procedure; some workers prefer to use 10% formalin for all the rinses throughout the procedure.
- B. If fresh stool is used (nonformalin preservatives), then the zinc sulfate should be prepared with a specific gravity of 1.18.
- C. If specimens are received in SAF, then begin at step V.B.
- D. If fresh specimens are received, the standardized procedure requires the stool to be rinsed in distilled water prior to the addition of zinc sulfate in step V.F. *However, the addition of fresh stool to distilled water will destroy any Blastocystis hominis organisms present and is not a recommended approach.*
- E. Some workers prefer to remove the tubes from the centrifuge prior to sampling the surface film. This is acceptable; however, there is more chance that the surface film will be disturbed prior to sampling.
- F. Some workers prefer to add a small amount of zinc sulfate to the tube so that the fluid forms a slightly convex meniscus. A coverslip is then placed on top of the tube so that the undersurface touches the meniscus. Leave undisturbed for 5 min. Carefully remove the coverslip, and place it on a slide for examination.
- G. When using the hydrometer (with the solution at room temperature), mix the solution well. Float the hydrometer in the solution, giving it a slight twist to see that it is completely free from the sides of the container. Read the bottom meniscus, and correct for temperature if necessary. Most hydrometers are calibrated at 20°C. A difference of 3°C between the solution temperature (room temperature) and the hydrometer calibration temperature requires a correction of 0.001, to be added if above 20°C and subtracted if below 20°C.
- H. The longer centrifugation times for the wash steps (V.D and E) are necessary for the possible recovery of *Cryptosporidium* oocysts or microsporidial spores.

IX. LIMITATIONS OF THE PROCEDURE

- A. Results obtained with wet smears should usually be confirmed by permanent stained smears. Some protozoa are very small and difficult to identify to the species level by direct wet smears alone.
- B. Confirmation is particularly important in the case of *Entamoeba histolytica*/*E. dispar* versus *Entamoeba coli*.
- C. Protozoan cysts and thin-shelled helminth eggs are subject to collapse and distortion when left in contact with high-specific-gravity zinc sulfate for more than a few minutes. Remove the surface film for examination within 5 min of the time the centrifuge comes to a stop. The longer the organisms are in contact with the zinc sulfate, the more distortion you will see on microscopic examination of the surface film.

IX. LIMITATIONS OF THE PROCEDURE (continued)

- D. If zinc sulfate is the only concentration method used, examine both the surface film and the sediment to ensure detection of all possible organisms.

APPENDIX 9.3.5–1

Include QC information on reagent container and in QC records.

Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

- A. Formalin (5 or 10% buffered or nonbuffered) or SAF (see procedure 9.2.2)
- B. 0.85% NaCl
- C. Zinc sulfate (33% aqueous solution)

zinc sulfate	330 g
distilled water	670 ml

1. Dissolve the zinc sulfate in distilled water in an appropriate flask or beaker with a magnetic stirrer.
 2. Adjust the specific gravity to 1.20 by adding more zinc sulfate or distilled water. Use a specific gravity of 1.18 when using fresh stool (nonformalinized).
- D. Store in a glass-stoppered bottle with an expiration date of 24 months.

☑ **NOTE:** There are no specific guidelines for how often the specific gravity of the zinc sulfate solution should be checked. However, due to the possibility of evaporation, the specific gravity of the solution should probably be checked twice each year. If the zinc sulfate flotation concentration method is used routinely, the specific gravity of the solution will be checked after preparation and then twice each year. Remember to store the solution in a tightly stoppered bottle.

9.3.6

Microscopic Examination of Fecal Specimens: Permanent Stained Smear (Trichrome)

It is generally recognized that stained fecal films are the single most productive means of stool examination for intestinal protozoa. The permanent stained smear facilitates detection and identification of cysts and trophozoites and affords a permanent

record of the protozoa encountered. Small protozoa missed by direct smear and concentration techniques are often seen on the stained smear. It also allows laboratories to refer the slide to a specialist for help when they have encountered an organism

with an unusual morphology or have difficulty with the identification. *For these reasons, the permanent stained smear is recommended for use with every stool specimen submitted for a routine parasite examination (1, 2, 4–6).*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The trichrome technique of Wheatley (8) for fecal specimens is a modification of Gomori's original staining procedure for tissue (3). It is a rapid, simple procedure that produces uniformly well-stained smears of intestinal protozoa, human cells, yeast cells, and artifact material.

II. SPECIMEN

Observe standard precautions.

- A. The specimen usually consists either of unconcentrated fresh stool smeared on a microscope slide and immediately fixed in Schaudinn's fixative or of polyvinyl alcohol (PVA)-preserved stool smeared on a slide and allowed to air dry (*see* procedure 9.2.2).
- B. Stool preserved in sodium acetate-acetic acid-formalin (SAF) or any of the single-vial fixatives for parasitology can also be used (*see* procedure 9.2.2).

III. MATERIALS

- A. **Reagents** (*see* Appendix 9.3.6–1)
Trichrome stain
- B. **Supplies**
 1. Disposable glass or plastic pipettes
 2. Glass slides (1 by 3 in., or larger if you prefer)
 3. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)
 4. 12 covered Coplin jars or staining dishes (with slide rack)
- C. **Equipment**
 1. Binocular microscope with 10 \times , 40 \times , and 100 \times objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
 2. Oculars should be 10 \times . Some workers prefer 5 \times ; however, overall smaller magnification may make final organism identifications more difficult.
 3. Fume hood to contain staining setup (optional)

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. For QC of Schaudinn's, SAF, or PVA fixative, see procedure 9.2.2.
- B. Stool samples used for QC can be either fixed stool specimens known to contain protozoa or PVA-preserved negative stools to which buffy coat cells have been added. Use a QC smear prepared from a positive PVA specimen or PVA containing buffy coat cells when a new stain is prepared or at least once each month. Cultured protozoa can also be used.
- C. Include a QC slide when you use a new lot number of reagents, when you add new reagents after cleaning the dishes, and at least monthly.
- D. If the xylene becomes cloudy or has an accumulation of water in the bottom of the staining dish, use fresh 100% ethanol and xylene.
- E. Cover all staining dishes to prevent evaporation of reagents.
- F. Depending on the volume of slides stained, change staining solutions on an as-needed basis.
- G. When the smear is thoroughly fixed and the stain is performed correctly, the cytoplasm of protozoan trophozoites will be blue-green, with sometimes a tinge of purple. Cysts tend to be slightly more purple. Nuclei and inclusions (chromatoid bodies, RBCs, bacteria, and Charcot-Leyden crystals) are red, sometimes tinged with purple. The background material usually stains green, providing a nice color contrast with the protozoa. This contrast is more distinct than that obtained with the hematoxylin stain.
- H. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- I. Known positive microscope slides, Kodachrome 2-by-2 projection slides, and photographs (reference books) should be available at the workstation.
- J. Record all QC results, including a description of QC specimens tested.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. Slide preparation
 - 1. Fresh fecal specimens
 - a. When the specimen arrives, prepare two slides with applicator sticks and *immediately* (without drying) place them in Schaudinn's fixative (*see* procedure 9.2.2). Allow the specimen to fix for a minimum of 30 min; overnight fixation is acceptable. The stool smeared on the slide should be thin enough that newsprint can be read through the smear. Proceed with the trichrome staining procedure (*see* item V.C.1 below).
 - b. If the fresh specimen is liquid, place 3 or 4 drops of PVA (*see* procedure 9.2.2) on the slide, mix several drops of fecal material with the PVA, spread the mixture, and allow it to dry for several hours in a 37°C incubator or overnight at room temperature (25°C). Proceed with the trichrome staining procedure by placing the slides in iodine-alcohol (*see* item V.B.2 below).

V. PROCEDURE (*continued*)

2. PVA-preserved fecal specimens (mercuric chloride base) (*see* procedure 9.2.2)
 - a. Allow the stool specimens that are preserved in PVA to fix for at least 30 min. Thoroughly mix the contents of the PVA bottle with two applicator sticks.
 - b. Pour some of the PVA-stool mixture onto a paper towel, and allow it to stand for 3 min to absorb the PVA. *Do not eliminate this step.*
 - c. With an applicator stick, apply some of the stool material from the paper towel to two slides, and allow them to dry for several hours in a 37°C incubator or overnight at room temperature (25°C).
 - d. Place the dry slides into iodine-alcohol (*see* item V.C.2 below).
 - e. If the stool was not thoroughly mixed with PVA by the patient, apply some stool material to two slides and immediately immerse in Schaudinn's fixative for a minimum of 30 min; then proceed with the trichrome method (*see* item V.C.1 below).
3. Modified PVA-preserved fecal specimens (copper or zinc base, single-vial systems)
 - a. Allow the stool specimens that are preserved in PVA or another fixative to fix for at least 30 min. Thoroughly mix the contents of the fixative vial with two applicator sticks.
 - b. Pour some of the fixative-stool mixture onto a paper towel, and allow it to stand for 3 min to absorb the PVA. *Do not eliminate this step if the fixative contains PVA.*
 - c. With an applicator stick, apply some of the stool material from the paper towel to two slides, and allow them to dry for several hours in a 37°C incubator or overnight at room temperature (25°C).
 - d. Begin the trichrome staining process at step V.C.4 or V.C.5.
4. SAF-preserved fecal specimens (*see* procedure 9.2.2)
 - a. Thoroughly mix the SAF-stool mixture, and strain through gauze into a 15-ml centrifuge tube.
 - b. After centrifugation (10 min at 500 × g), decant the supernatant fluid. The final sediment should be about 0.5 to 1.0 ml. If necessary, adjust by repeating step V.B.1 or by suspending the sediment in saline (0.85% NaCl) and removing part of the suspension.
 - c. Prepare a smear from the sediment for later staining.
 - d. After drying, place the smear in 70% alcohol (*see* item V.C.3 below) (iodine-alcohol step can be eliminated).

C. Staining smears

1. Remove slide from Schaudinn's fixative, and place slide in 70% ethanol for 5 min.
2. Place slide in 70% ethanol plus iodine for 1 min for fresh specimens or 5 to 10 min for PVA-preserved air-dried smears. All slides exposed to mercuric-chloride-based fixatives must be placed in the iodine dish to remove the mercury. The subsequent rinses in ethanol remove the iodine. At the point the slide is placed into trichrome stain, both the mercury and iodine have been removed from the fecal smear.
3. Place slide in 70% ethanol for 5 min.*
4. Place in 70% ethanol again for 3 min.* Fecal smears prepared from SAF-preserved stool material do not require the iodine step (V.C.2 above) and can be placed in this alcohol dish before trichrome staining.
5. Place in trichrome stain for 10 min. Fecal smears prepared from modified PVA-fixed material (copper or zinc base) do not require the iodine step (V.C.2 above) or subsequent alcohol rinses (V.C.3 and 4 above) but can be placed directly into the trichrome stain (this step). One alcohol rinse may

V. PROCEDURE (continued)

- be used (*see* item V.C.4) before this trichrome step; some labs prefer this approach.
6. Place in 90% ethanol plus acetic acid for 1 to 3 s. Immediately drain the rack (*see* item VIII below), and proceed to the next step. Do not allow slides to remain in this solution.
 7. Dip several times in 100% ethanol. Use this step as a rinse.
 8. Place in two changes of 100% ethanol for 3 min each.*
 9. Place in xylene for 5 to 10 min.*
 10. Place in xylene again for 5 to 10 min.*
 11. Mount with coverslip (no. 1 thickness) by using mounting medium (e.g., Permount).
 12. Allow the smear to dry overnight or for 1 h at 37°C.
 13. Examine the smear microscopically with the 100× objective. Examine at least 200 to 300 oil immersion fields.

*Slides may be held for up to 24 h in these solutions without harming the quality of the smear or the stainability of organisms.

VI. RESULTS

- A. Protozoan trophozoites and cysts will be readily seen.
- B. Helminth eggs and larvae may not be easily identified; therefore, examine wet mounts of concentrates.
- C. Yeast and human cells can be identified. Human cells include macrophages, PMNs, and RBCs. Yeasts include single and budding cells and pseudohyphae.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the organism and stage (do not use abbreviations).
Example: *Entamoeba histolytica*/*E. dispar* trophozoites
- B. Quantitate the number of *Blastocystis hominis* seen (rare, few, moderate, many). Do not quantitate other protozoa.
- C. Note and quantitate the presence of human cells.
Example: Moderate WBCs, many RBCs, few macrophages, rare Charcot-Leyden crystals
- D. Report and quantitate yeast cells.
Example: Moderate budding yeast cells and few pseudohyphae
- E. Save positive slides for future reference. Record information prior to storage (name, patient number, organisms present).
- F. Quantitation of parasites, cells, yeast cells, and artifacts
Few = ≤2 per 10 oil immersion fields (×1,000)
Moderate = 3 to 9 per 10 oil immersion fields (×1,000)
Many = ≥10 per 10 oil immersion fields (×1,000)

VIII. PROCEDURE NOTES

- A. Fixation of specimens is important. Improperly fixed specimens will result in protozoan forms that are nonstaining or predominantly red.
- B. Spread the PVA-stool mixture to the edges of the glass slide; this will cause the film to adhere to the slide during staining. It is also important to thoroughly dry the slides to prevent the material from washing off during staining.
- C. Always drain slides between solutions. Touch the end of the slide to a paper towel for 2 s to remove excess fluid before proceeding to the next step.
- D. Incomplete removal of mercuric chloride (Schaudinn's fixative and PVA) may cause the smear to contain highly refractive granules that may prevent finding or identifying any organisms present (1). Since the 70% ethanol-iodine solution

VIII. PROCEDURE NOTES

(continued)

removes the mercury complex, it should be changed at least weekly to maintain the strong-tea color.

- E. To restore weakened trichrome stain, remove cap and allow the ethanol to evaporate (ethanol carried over on staining rack from previous dish). After a few hours, add fresh stain to restore lost volume. Older, more concentrated stain produces more intense colors and may require slightly longer destaining times (an extra dip).
- F. Smears that are predominantly green may be due to the inadequate removal of iodine by the 70% ethanol (*see* items VIII.D and E above). Lengthening the time of these steps or changing the 70% ethanol more frequently will help.
- G. In the final stages of dehydration (steps V.C.8, 9, and 10), keep the 100% ethanol and the xylenes as free from water as possible. Coplin jars must have tight-fitting caps to prevent both evaporation of reagents and absorption of moisture. If the xylene becomes cloudy after addition of slides from the 100% ethanol, return the slides to fresh 100% ethanol, and replace the xylene.
- H. If the smears peel or flake off, the specimen might have been inadequately dried on the slide (in the case of PVA-fixed specimens) or the slides might have been greasy. Slides do not have to be cleaned with alcohol prior to use.
- I. If the stain appears unsatisfactory and it is not possible to obtain another slide to stain, restain the unsatisfactory slide. Place the slide in xylene to remove the coverslip, and reverse the dehydration steps by adding 50% ethanol as the last step. Destain the slide in 10% acetic acid for several hours, and then wash it thoroughly first in water, then in 50% ethanol, and then in 70% ethanol. Place the slide in the trichrome stain for 8 min, and complete the staining procedure (7).

IX. LIMITATIONS OF THE PROCEDURE

- A. The permanent stained smear is not recommended for staining helminth eggs or larvae. However, occasionally they may be recognized and identified.
- B. Examine the smear under the oil immersion lens (100×) for the identification of protozoa, human cells, Charcot-Leyden crystals, yeast cells, and artifact material.
- C. This high-magnification examination is recommended for protozoa.
- D. Screening the smear under the low-magnification lens (10×) might reveal eggs or larvae, but this is not recommended as a routine approach.
- E. Helminth eggs and larvae and *Isospora belli* oocysts are best seen in wet preparations.
- F. *Cryptosporidium parvum* and *Cyclospora cayetanensis* are generally not seen on a trichrome-stained smear (modified acid-fast stains or immunoassays are recommended).
- G. Microsporidial spores will not be seen on a trichrome-stained smear (modified trichrome stains are recommended).

APPENDIX 9.3.6–1

Include QC information on reagent container and in QC records.

Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. Trichrome stain

chromotrope 2R	0.6 g
light green SF	0.3 g
phosphotungstic acid	0.7 g
acetic acid (glacial)	1.0 ml
distilled water	100 ml

Prepare the stain by adding 1.0 ml of acetic acid to the dry components. Allow the mixture to stand (ripen) for 15 to 30 min at room temperature. Add 100 ml of distilled water. Properly prepared stain will be purple. Store in a glass or plastic bottle at room temperature. The shelf life is 24 months.

B. 70% Ethanol

C. 70% Ethanol plus iodine

Prepare a stock solution by adding iodine crystals to 70% alcohol until you obtain a dark solution (1 to 2 g/100 ml). To use, dilute the stock solution with 70% alcohol until a dark reddish brown (strong-tea color) is obtained. As long as the color is acceptable, new working solution does not have to be replaced. Replacement time will depend on the number of smears stained and the size of the container (one to several weeks).

D. 90% Ethanol, acidified

90% ethanol	99.5 ml
acetic acid (glacial)	0.5 ml

Prepare by combining.

E. 100% Ethanol

F. Xylene (or xylene substitute)

APPENDIX 9.3.6–2

As an alternative to using mounting fluid on every slide, the following method can be used. This approach saves time (drying the slides after they are mounted) and eliminates the need for routine use of mounting fluids.

- A. Remove the stained slides from the last dehydrating dish (step V.C.10 above).
- B. Allow the slide to air dry (minimum of 30 min, especially if using xylene substitutes).
- C. Place a drop of immersion oil directly onto the dry stool smear.
- D. Allow the oil to “sink in” for a minimum of ~15 min.
- E. Place a no. 1 coverslip onto the oil-covered stool smear.
- F. Add 1 drop of immersion oil onto the coverslip and proceed to examine the smear using the 100× oil immersion objective. A 50× or 60× oil immersion objective can be used for screening.
- G. Do not use this approach unless you add the coverslip before examination of the smear. The dry stool material may be quite hard; the objective lens could accidentally be scratched if the stool smear is not covered before reading.

9.3.7

Microscopic Examination of Fecal Specimens: Iron Hematoxylin Stain (Modified Spencer-Monroe Method)

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The iron hematoxylin stain is one of a number of stains used to make a permanent stained slide for detecting and quantitating parasitic organisms. Iron hematoxylin was the stain used for most of the original morphological descriptions of intestinal protozoa found in humans (1–3). Under oil immersion power ($\times 1,000$), one can examine the diagnostic features used to identify the protozoan parasite.

II. SPECIMEN

Observe standard precautions.

- A. The specimen usually consists either of unconcentrated fresh stool smeared on a microscope slide and immediately fixed in Schaudinn's fixative or of polyvinyl alcohol (PVA)-preserved stool smeared on a slide and allowed to air dry (*see* procedure 9.2.2).
- B. Stool preserved in sodium acetate-acetic acid-formalin (SAF) can also be used (*see* procedure 9.2.2).

III. MATERIALS

- A. **Reagents** (*see* Appendix 9.3.7–1)
 1. Iron hematoxylin stain
 2. D'Antoni's iodine solution
- B. **Supplies**
 1. Glass slides (1 by 3 in.)
 2. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)
 3. Coplin jars or other suitable staining containers
 4. Hematoxylin, crystals or powder
 5. Ferrous ammonium sulfate $[\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}]$
 6. Ferric ammonium sulfate $[\text{FeNH}_4(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}]$
 7. Hydrochloric acid, concentrated (HCl)
 8. Potassium iodide (KI)
 9. Iodine crystals, powdered (I_2)
 10. Permout or other suitable mounting medium
- C. **Equipment**
 1. Binocular microscope with $10\times$, $40\times$, and $100\times$ objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
 2. Oculars should be $10\times$. Some workers prefer $5\times$; however, overall smaller magnification may make final organism identifications more difficult.
 3. Fume hood to contain staining setup (optional)

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. For QC of Schaudinn's SAF or PVA fixatives, see procedure 9.2.2.
- B. Stool samples used for QC can be either fixed stool specimens known to contain protozoa or PVA-preserved negative stools to which buffy coat cells have been added. A QC smear prepared from a positive PVA specimen or PVA containing buffy coat cells should be used when a new stain is prepared or at least once each month. Cultured protozoa can also be used (1).
- C. Include a QC slide when you use a new lot number of reagents, when you add new reagents after cleaning the dishes, and at least monthly.
- D. If the xylene becomes cloudy or has an accumulation of water in the bottom of the staining dish, use fresh 100% ethanol and xylene.
- E. Cover all staining dishes to prevent evaporation of reagents.
- F. Depending on the volume of slides stained, change staining solutions on an as-needed basis.
- G. Background material will stain blue-gray. Cells and organisms will stain various intensities of blue-gray. Inclusions, chromatoidal bodies, and nuclear structures will stain darker than the surrounding cytoplasm.
- H. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- I. Known positive microscope slides, Kodachrome 2-by-2 projection slides, and photographs (reference books) should be available at the work station.
- J. Record all QC results, including a description of QC specimens tested.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. Slide preparation
 - 1. Fresh fecal specimens
 - a. When the specimen arrives, prepare two slides with applicator sticks and *immediately* (without drying) place them in Schaudinn's fixative (*see* procedure 9.1). Allow the slides to fix for a minimum of 30 min; overnight fixation is acceptable. The amount of stool smeared on the slide should be thin enough that newsprint can be read through the smear.
 - b. If the fresh specimen is liquid, place 3 or 4 drops of PVA (*see* procedure 9.1) on the slide, mix several drops of fecal material with the PVA, spread the mixture, and allow it to dry for several hours in a 37°C incubator or overnight at room temperature (25°C).
 - c. Proceed with the hematoxylin staining procedure by placing the dry slides in iodine-alcohol (*see* item V.B.2 below).
 - 2. PVA-preserved fecal specimens (*see* procedure 9.1)
 - a. Allow the stool specimens that are preserved in PVA to fix at least 30 min. Thoroughly mix the contents of the PVA bottle with two applicator sticks.
 - b. Pour some of the PVA-stool mixture onto a paper towel, and allow it to stand for 3 min to absorb the PVA. *Do not eliminate this step.*

V. PROCEDURE (*continued*)

- c. With an applicator stick, apply some of the stool material from the paper towel to two slides, and allow them to dry for several hours in a 37°C incubator or overnight at room temperature.
 - d. Place the dry slides in iodine-alcohol (*see* item V.C.2 below).
 - e. If the stool was not thoroughly mixed with PVA by the patient, apply some stool material to two slides, and immediately immerse in Schaudinn's fixative for a minimum of 30 min; then proceed with the hematoxylin method.
3. SAF-preserved fecal specimens (*see* procedure 9.1)
 - a. Thoroughly mix the SAF-stool mixture, and strain through gauze into a 15-ml centrifuge tube.
 - b. After centrifugation (10 min at 500 × *g*), decant the supernatant fluid. The final sediment should be about 0.5 to 1.0 ml. If necessary, adjust by repeating step 1 or by suspending the sediment in saline (0.85% NaCl) and removing part of the suspension.
 - c. Prepare a smear from the sediment for later staining.
 - d. After drying, place the smear into 70% alcohol (*see* item V.C.3 below) (iodine-alcohol step can be eliminated).

C. Staining smears

1. Place slide in 70% ethanol for 5 min.
2. Place slide in iodine–70% ethanol (70% alcohol to which is added enough D'Antoni's iodine to obtain a strong tea color) solution for 2 to 5 min.
3. Place in 70% ethanol for 5 min. Begin procedure for SAF-fixed slides at this point.*
4. Wash slide in running tap water (constant stream of water into the container) for 10 min.
5. Place slide in iron hematoxylin working solution for 4 to 5 min.
6. Wash slide in running tap water (constant stream of water into the container) for 10 min.
7. Place slide in 70% ethanol for 5 min.*
8. Place slide in 95% ethanol for 5 min.*
9. Place slide in two changes of 100% ethanol for 5 min each.*
10. Place slide in two changes of xylene for 5 min each.*
11. Add Permout to the stained area of the slide, and cover with a coverslip.
12. Examine the smear microscopically with the 100× objective. Examine at least 200 to 300 oil immersion fields.

*Slides may be held for up to 24 h in these solutions without harming the quality of the smear or the stainability of organisms.

VI. RESULTS

- A. Protozoan trophozoites and cysts will be readily seen.
- B. Helminth eggs and larvae may not be easily identified; therefore, examine wet-mount concentrates.
- C. Yeast and human cells can be identified. Human cells include macrophages, PMNs, and RBCs. Yeast cells include single and budding cells and pseudohyphae.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the complete scientific name (genus and species) of the organism and the stage seen.
Example: *Entamoeba histolytica/E. dispar* trophozoites
- B. Quantitate the number of *Blastocystis hominis* seen (rare, few, moderate, many). Do not quantitate other protozoa.
- C. Note and quantitate the presence of human cells.
Examples: Moderate WBCs, many RBCs, few macrophages, rare Charcot-Leyden crystals
- D. Report and quantitate yeast cells.
Example: Moderate budding yeast cells and few pseudohyphae
- E. Save positive slides for future reference. Record information prior to storage (name, patient number, organisms present).
- F. Quantitation of parasites, cells, yeast cells, and artifacts
Few = \leq per 10 oil immersion fields ($\times 1,000$)
Moderate = 3 to 9 per 10 oil immersion fields ($\times 1,000$)
Many = ≥ 10 per 10 oil immersion fields ($\times 1,000$)

VIII. PROCEDURE NOTES

- A. Once the staining process has begun, do not allow the slides to dry until they have been placed in xylene.
- B. Always drain slides between solutions. Touch the end of the slide to a paper towel for 2 s to remove excess fluid before proceeding to the next step.
- C. Incomplete removal of mercuric chloride (Schaudinn's fixative and PVA) may cause the smear to contain highly refractive granules that may prevent finding or identifying any organisms present (3). Since the 70% ethanol-iodine solution removes the mercury complex, it should be changed at least weekly to maintain the port wine or strong tea color.
- D. When large numbers of slides are stained, the working hematoxylin solution may be diluted and affect the quality of the stain. If dilution occurs, discard the working solution, and prepare a fresh working solution.
- E. The shelf life of the stock hematoxylin solutions may be extended by keeping the solutions in the refrigerator at 4°C. Because of crystal formation in the working solutions, it may be necessary to filter them before preparing a new working solution.
- F. In the final stages of dehydration (*see* items V.C.9 and 10 above), keep the 100% ethanol and the xylenes as free from water as possible. Coplin jars must have tight-fitting caps to prevent both evaporation of reagents and absorption of moisture. If the xylene becomes cloudy after addition of slides from the 100% ethanol, return the slides to fresh 100% ethanol, and replace the xylene.
- G. If the smears peel or flake off, the specimen might have been inadequately dried on the slide (in the case of PVA-fixed specimens) or the slides might have been greasy. Slides do not have to be cleaned with alcohol prior to use.
- H. Other iron hematoxylin formulations may call for 10 g of stain per 100 ml of 95 or 100% ethanol. These are also acceptable.

IX. LIMITATIONS OF THE PROCEDURE

- A. The permanent stained smear is not recommended for staining helminth eggs or larvae. However, occasionally they may be recognized and identified.
- B. The smear should be examined with the oil immersion lens ($100\times$) for the identification of protozoa, human cells, Charcot-Leyden crystals, yeast cells, and artifact material.
- C. This high-magnification examination is recommended for protozoa.

IX. LIMITATIONS OF THE PROCEDURE *(continued)*

- D.** Screening the smear under low magnification (10×) might reveal eggs or larvae, but this is not recommended as a routine approach.
- E.** Helminth eggs and larvae and *Isospora belli* oocysts are best seen in wet preparations.
- F.** *Cryptosporidium parvum* will not be seen on an iron hematoxylin-stained smear (acid-fast stains or immunoassays are recommended).
- G.** Microsporidial spores will not be seen on an iron hematoxylin-stained smear (modified trichrome stains are recommended).

APPENDIX 9.3.7-1

Include QC information on reagent container and in QC records.

Reagents

- ☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. Iron hematoxylin stain

1. Solution 1

hematoxylin (crystal or powder)10 g
ethanol (absolute)1,000 ml

Place solution in a stoppered clear flask or bottle, and allow to ripen in a lighted room for at least 1 week at room temperature.

2. Solution 2

ferrous ammonium sulfate
[Fe(NH₄)₂(SO₄)₂·6H₂O]10 g
ferric ammonium sulfate
[FeNH₄(SO₄)₂·12H₂O]10 g
hydrochloric acid (HCl) (concentrated)10 ml
distilled water1,000 ml

3. Working solution

Mix equal volumes of solutions 1 and 2. The working solution should be made fresh every week.

B. D'Antoni's iodine solution

potassium iodide (KI) 1 g
distilled water 100 ml

Add 1.5 g of powdered iodine crystals to the KI solution to saturate the solution. Undissolved iodine crystals should be present. Store the solution in the dark in a brown bottle (stock solution). Working solutions should be made fresh every 2 weeks and can be made by filtering the stock solution to remove undissolved crystals.

C. Ethanol: 70, 95, and 100%**D. Xylene (or xylene substitute)**

APPENDIX 9.3.7-2

Modified Iron Hematoxylin Stain (Incorporating Carbol Fuchsin Step)

The following combination staining method for SAF-preserved fecal specimens was developed to allow the microscopist to screen for acid-fast organisms in addition to other intestinal parasites. For those laboratories using iron hematoxylin stains in combination with SAF-fixed material and modified acid-fast stains for *C. parvum*, *Cyclospora cayetanensis*, and *I. belli*, this modification represents an improved approach to current staining methods. This combination stain provides savings in both time and personnel use. Any fecal specimen submitted in SAF fixative can be used. Fresh fecal specimens after fixation in SAF for 30 min can also be used. This combination stain approach is not recommended for specimens preserved in Schaudinn's fixative or PVA.

I. REAGENTS

A. Mayer's albumin

Add an equal quantity of glycerin to a fresh egg white. Mix gently and thoroughly. Store at 4°C and indicate an expiration date of 3 months. Mayer's albumin from commercial suppliers can normally be stored at 25°C for 1 year [e.g., product 756; E. M. Diagnostic Systems Inc., 480 Democrat Rd., Gibbstown, NJ 08027; (800) 443-3637].

B. Stock solution of hematoxylin stain

hematoxylin powder10 g
ethanol (95 or 100%)1,000 ml

1. Mix well until dissolved.
2. Store in a clear glass bottle in a light area. Allow to ripen for 14 days before use.
3. Store at room temperature with an expiration date of 1 year.

C. Mordant

ferrous ammonium sulfate
[Fe(NH₄)₂(SO₄)₂·6H₂O]10 g
ferric ammonium sulfate
[FeNH₄(SO₄)₂·12H₂O]10 g
hydrochloric acid (concentrated)10 ml
distilled water to1,000 ml

D. Working solution of hematoxylin stain

1. Mix equal quantities of stock solution of stain and mordant.
2. Allow mixture to cool thoroughly before use (prepare at least 2 h prior to use).
The working solution should be made fresh every week.

E. Picric acid

Mix equal quantities of distilled water and an aqueous saturated solution of picric acid to make a 50% saturated solution.

F. Acid-alcohol decolorizer

hydrochloric acid (concentrated)30 ml
alcohol to1,000 ml

G. 70% alcohol and ammonia

70% alcohol50 ml
ammonia0.5 to 1.0 ml

Add enough ammonia to bring the pH to approximately 8.0.

H. Carbol fuchsin

1. To make basic fuchsin (solution A), dissolve 0.3 g of basic fuchsin in 10 ml of 95% ethanol.
2. To make phenol (solution B), dissolve 5 g of phenol crystals in 100 ml of distilled water. (Gentle heat may be needed.)
3. Mix solution A with solution B.
4. Store at room temperature. Solution is stable for 1 year.

APPENDIX 9.3.7–2 (continued)

II. PROCEDURE

- A. Prepare slide.
 1. Place 1 drop of Mayer's albumin on a labeled slide.
 2. Mix the sediment from the SAF concentration well with an applicator stick.
 3. Add approximately 1 drop of the fecal concentrate to the albumin and spread the mixture over the slide.
- B. Allow slide to air dry at room temperature (smear will appear opaque when dry).
- C. Place slide in 70% alcohol for 5 min.
- D. Wash in container (not running water) of tap water for 2 min.
- E. Place slide in Kinyoun's stain for 5 min.
- F. Wash slide in running tap water (constant stream of water into container) for 1 min.
- G. Place slide in acid-alcohol decolorizer for 4 min.
 - **NOTE:** This step can also be performed as follows.
 1. Place slide in acid-alcohol decolorizer for 2 min.
 2. Wash slide in running tap water (constant stream of water into container) for 1 min.
 3. Place slide in acid-alcohol decolorizer for 2 min.
 4. Wash slide in running tap water (constant stream of water into container) for 1 min.
 5. Continue staining sequence with step II.I below (iron-hematoxylin working solution).
- H. Wash slide in running tap water (constant stream of water into container) for 1 min.
- I. Place slide in iron hematoxylin working solution for 8 min.
- J. Wash slide in distilled water (in container) for 1 min.
- K. Place slide in picric acid solution for 3 to 5 min.
- L. Wash slide in running tap water (constant stream of water into container) for 10 min.
- M. Place slide in 70% alcohol plus ammonia for 3 min.
- N. Place slide in 95% alcohol for 5 min.
- O. Place slide in 100% alcohol for 5 min.
- P. Place slide in two changes of xylene for 5 min.

III. PROCEDURE NOTES

- A. The first 70% alcohol step acts with the Mayer's albumin to "glue" the specimen to the glass slide. The specimen may wash off if insufficient albumin is used or if the slides are not completely dry prior to staining.
- B. The working hematoxylin stain should be checked each day of use by adding a drop of stain to alkaline tap water. If a blue color does not develop, prepare fresh working stain solution.
- C. The picric acid differentiates the hematoxylin stain by removing more stain from fecal debris than from the protozoa and removing more stain from the organism cytoplasm than from the nucleus. When properly stained, the background should be various shades of gray-blue and protozoa should be easily seen with medium blue cytoplasm and dark blue-black nuclei.

9.3.8

Calcofluor White for Detection of Microsporidial Spores and *Acanthamoeba* Cysts

PREANALYTICAL CONSIDERATIONS

The diagnosis of intestinal microsporidiosis (*Enterocytozoon bieneusi*, *Encephalitozoon intestinalis*) has depended on the use of invasive procedures and subsequent examination of biopsy specimens, often by electron microscopy methods. However, the need for a practical method for the routine clinical laboratory has stim-

ulated some work in the development of additional methods. Slides prepared from fresh or formalin-fixed stool specimens can be stained using calcofluor white (CFW) (optical brightening agent) and can be examined using fluorescence microscopy. This staining method is based on the

fact that routine stain penetration of the microsporidial spore is very difficult; thus, the use of CFW enhances the ability of the spores to be seen. The spore coat will stain with CFW, but the stain is nonspecific and may also stain other structures within the specimen (yeast, etc.).

I. PRINCIPLE

Acanthamoeba, a free-living amoeba found in soil, sewage, and fresh, salt, or brackish water, can cause painful keratitis that may lead to eye removal or loss of eye function and has also been implicated in granulomatous amoebic encephalitis (1) (see also procedure 9.9.2). A key to successful treatment of *Acanthamoeba*-caused infec-

tion is the rapid detection of the organisms in patient samples. Cultures may require several days, delaying diagnosis and treatment.

CFW can be used for direct detection of *Acanthamoeba* cysts from clinical specimens (4). The active ingredient is the disodium salt of 4,4'-bis-(4-anilino-bis-di-

ethylamino-5-triazin-2-ylamino)-2,2'-stilbene disulfonic acid, which is a nonspecific fluorescent dye binding to the polysaccharide polymers of amoebic cysts and microsporidial spores (3). It is very simple to use and provides a rapid and reliable means of demonstrating these organisms.

II. SPECIMEN

Observe standard precautions.

With the exception of stool, collect all specimens aseptically, and hold them at room temperature (24 to 28°C). Do not freeze or refrigerate specimens. Use sterile containers and solutions where indicated; any remaining specimen may be used to inoculate culture media.

A. Stool

1. The specimen can be fresh stool or stool that has been preserved in 5 or 10% formalin, sodium acetate-acetic acid-formalin (SAF), or some of the newer single-vial system fixatives.
2. Any specimen other than tissue thought to contain microsporidia could be stained by these methods.
3. Polyvinyl alcohol-preserved fecal material is not recommended.

B. CSF

1. Centrifuge at $250 \times g$ for 10 min.
2. Remove and place into another sterile tube all except 0.5 ml of the supernatant fluid.
3. Suspend the sediment with remaining supernatant fluid for examination.

II. SPECIMEN (*continued*)**C. Tissue**

Triturate a small portion in sterile water or saline.

1. Brain
2. Corneal scrapings or biopsy specimen
3. Lung
4. Skin lesion

D. Swab of conjunctiva or corneal ulcer

1. Place swab in 2 ml of sterile water or saline in a tube.
2. Vigorously shake the cotton-tipped portion of the swab in the liquid to suspend specimen.
3. Remove swab from tube, and return to original holder.
4. The sterile water can be examined directly or concentrated by centrifugation if a larger volume is used.

E. Contact lens paraphernalia

1. Contact lens solutions
Solutions must be from opened containers already used by patient. If volume of solution is greater than 2 ml, then centrifuge prior to examination ($250 \times g$ for 10 min).
2. Contact lenses
Submit in 2 ml of sterile water or saline. Examine a small portion of lens and the fluid containing the lens.

F. Water samples

1. Collect at least 100 ml of water in a sterile container.
2. Concentrate specimen by filtration or centrifugation prior to examination (2).

G. Slide prepared by physician

Submit at least two slides.

1. Place specimen in the center of the slide, covering no more than a dime-sized area.
2. Circle the material with a wax pencil or magic marker to denote location of the specimen.
3. Air dry slides thoroughly.
4. Place the slide in a slide holder or envelope for staining in the laboratory.

III. MATERIALS**A. Reagents** (*see* Appendix 9.3.8–1)**B. Supplies**

1. Microscope slides (1 by 3 in.), one ring (15 mm), frosted
2. Microscope slides (1 by 3 in.), two rings (12 mm), frosted
3. Coverslip (24 by 40 mm), no. 1 thickness
4. Sterile polystyrene, round-bottom tubes (with cap), 12 by 75 mm
5. Sterile transfer pipettes
6. Sterile wooden applicator sticks
7. Sterile swabs
8. Disposable latex gloves
9. Biohazard container for disposal of contaminated supplies and patient specimens.
10. Positive fecal specimen (microsporidial spores)

11. *Acanthamoeba castellanii* ATCC 30010 stock culture

12. *Escherichia coli* ATCC 25922 stock culture

13. Wax pencil or magic marker

C. Equipment

1. Epifluorescence microscope equipped with an exciter filter that transmits the 250- to 400-nm group of intense mercury spectral emission lines (Zeiss UGI or G365). View through a barrier filter (Zeiss 41 or LP420), which removes UV while transmitting visible blue light and longer wavelengths (1, 3).
2. Biological safety cabinet

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. A QC slide must be run with each batch of specimens stained with CFW.
- B. Unfortunately, the only way to perform acceptable QC procedures for this method is to use actual microsporidial spores as the control organisms (Medical Chemical Corporation; <http://www.med-chem.com>). Obtaining these positive controls may be somewhat difficult. It is particularly important to use the actual organisms because the spores are difficult to stain and the size is very small (1 to 2.5 μm). Prepare control slides for microsporidia as follows:
 - 1. Using a 10- μl aliquot of *concentrated* (formalin-ethyl acetate sedimentation concentration; centrifugation at $500 \times g$ for 10 min), preserved liquid stool (5 or 10% formalin or SAF), prepare the smear by spreading the material over an area of 45 by 25 mm.
 - 2. Allow the smear to air dry.
- C. Prepare control slides for amebae as follows.
 - 1. Make a suspension of *A. castellanii* from stock culture with sterile water or Page ameba saline.
 - 2. Make a suspension of *E. coli* from stock culture with sterile water or Page ameba saline.
 - 3. Add 1 drop of the *A. castellanii* suspension to one of the rings of a two-ring slide and 1 drop of the *E. coli* suspension to the other ring.
 - 4. Allow the smear to air dry.
 - 5. Fix the smear in absolute methanol for 3 to 5 min.
 - 6. Store at room temperature. The smears are stable for 1 year.
- D. Positive control
 - 1. *Acanthamoeba* cysts are doubled walled (10 to 25 μm), and outer wall is wrinkled. The cysts will fluoresce.
 - 2. The spores will be ovoid and refractile, and the spore wall will fluoresce. Occasionally, the polar tube can be seen either as a stripe or as a diagonal line across the spore; however, the internal spore contents will normally not be visible.
- E. Negative control
 - 1. *E. coli* will not fluoresce.
 - 2. Most of the bacteria and other debris will not fluoresce. However, there will still be some yeast and debris that may also fluoresce.
- F. Perform all scheduled maintenance on all equipment.
- G. Record all QC results, including a description of QC specimens tested.
- H. Known positive microscope slides, projection slides (2 by 2 in.), photographs, and reference books should be available at the workstation.

V. PROCEDURE

- A. **Slide preparation of clinical specimens**
 - 1. Using a sterile swab, stick, or pipette, thinly spread the specimen evenly over the area circumscribed by the ring.
 - ☑ **NOTE:** Do not apply excessive specimen on the slide, because the smear may be too thick to visualize any organisms present.
 - 2. Allow the smear to air dry.
 - 3. Fix the smear in absolute methanol for 3 to 5 min.
 - 4. Air dry.
- B. **Stain procedure**
 - 1. Add 3 or 4 drops of CFW and 3 or 4 drops of Evan's blue into a tube (12 by 75 mm) and mix well.
 - 2. Add several drops of this mixture to the specimen and allow to stand for 5 min.

V. PROCEDURE (*continued*)

3. Turn slide on its side and allow excess stain to run off.
4. Add coverslip, blot excess stain from slide, and examine immediately.

VI. RESULTS

- A. Microsporidial spores will fluoresce.
- B. *Acanthamoeba* cysts will fluoresce. Cysts are double walled (10 to 25 μm), and the outer cyst wall is wrinkled (hexacanth cyst). Although more rare than *Acanthamoeba*, the cysts of *Balamuthia mandrillaris* are usually spherical, appear to have two walls (outer irregular wall and inner round wall), and measure 6 to 30 μm in diameter. *Naegleria* cysts can be confirmed from culture plates but are not seen in clinical specimens. They tend to measure from 7 to 15 μm and have a thick double wall.
- C. Yeast cells, pseudohyphae, hyphae, and other fungal elements will stain with CFW (2).
- D. *Pneumocystis carinii* can be detected with CFW (3).
- E. Bacteria will not fluoresce.
- F. Epithelial cells and blood cells will stain red by Evan's blue counterstain.
- G. Cotton fibers will fluoresce strongly and can be distinguished as artifacts.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. **Positive**
Report as microsporidial spores or *Acanthamoeba* cysts seen. Notify physician immediately.
- B. **Negative**
No organisms seen.

VIII. PROCEDURE NOTES

- A. Collagen, elastin, and keratin also fluoresce.
- B. Other microorganisms (e.g., yeast cells, fungi) will fluoresce.
- C. Although bacteria will not fluoresce, microsporidial spores (approximately the same size as some small yeasts and bacteria [1 to 2 μm]) will fluoresce. These organisms have been implicated as a cause of eye disease and have been found in other body tissues. The use of modified trichrome stains would be helpful in differentiating microsporidial spores from other organisms.
- D. One drop of 10% KOH can be added to the CFW reagent, and a wet mount can be made of the specimens which require clearing or teasing (e.g., skin scrapings, hair, or viscous specimens).
- E. Various concentrations of CFW and Evan's blue are commercially available. Some work better than others.
- F. Confirm findings (positive or negative) with culture.
- G. Depending on what filter combination is used, the cysts will fluoresce either blue-white or apple green.
- H. If *Naegleria* cysts are present, they may be seen using calcofluor.

APPENDIX 9.3.8–1

Include QC information on reagent container and in QC records.

Reagents
A. Commercially available solution of CFW with an Evan's blue counterstain (such as Fungi-Fluor kit, catalog no. 17442; Polysciences, Inc., Warrington, Pa.) or solution prepared as follows:
1. 0.1% CFW

CFW M2R, purified	0.1 g
distilled water	99.9 ml

Mix. Filter, and store in dark container. The mixture is stable at room temperature for 1 year.

2. 0.5% Evan's blue

Evan's blue	0.5 g
distilled water	99.5 ml

Mix. The mixture is stable at room temperature for 1 year.

B. Page's ameba saline (1×)

NaCl	6 mg
MgSO ₄ ·7H ₂ O	0.2 mg
CaCl ₂ ·2H ₂ O	0.2 mg
Na ₂ HPO ₄	7.1 mg
KH ₂ PO ₄	6.8 mg
distilled water	500 ml

Autoclave at 121°C for 15 min. Store refrigerated in a glass bottle. The mixture is stable for 3 months.

C. Absolute methanol
D. Sterile distilled water

9.4.1

Special Stains for Coccidia, Including *Cyclospora cayetanensis*: Modified Kinyoun's Acid-Fast Stain (Cold)

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Cryptosporidium and *Isospora* species have been recognized as causes of severe diarrhea in immunocompromised hosts, but they can also cause diarrhea in immunocompetent hosts. Oocysts in clinical

specimens may be difficult to detect without special staining. *Cyclospora cayetanensis* has also been reported to be acid fast. Modified acid-fast stains are recommended for demonstrating these organ-

isms. Unlike the Ziehl-Neelsen modified acid-fast stain, the modified Kinyoun acid-fast stain does not require heating the reagents used for staining and uses a mild decolorizer (1–3).

II. SPECIMEN

Concentrated sediment of fresh or formalin-preserved stool may be used. Other types of clinical specimens such as duodenal fluid, bile, or pulmonary (induced sputum, bronchial washings, biopsy specimens) may also be stained after centrifugation.

III. MATERIALS

Observe standard precautions.

A. Reagents (see Appendix 9.4.1–1)

1. Absolute methanol
2. 50% Ethanol
3. Kinyoun carbol fuchsin
4. 1% Sulfuric acid
5. Methylene blue

B. Supplies

1. Disposable glass or plastic pipettes
2. Glass slides (1 by 3 in., or larger if you prefer)
3. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)

C. Equipment

1. Binocular microscope with 10 \times , 40 \times , and 100 \times objectives (or the

approximate magnifications for low-power, high dry power, and oil immersion examination)

2. Oculars should be 10 \times . Some workers prefer 5 \times ; however, overall smaller magnification may make final organism identifications more difficult.
3. Tabletop centrifuge
4. Staining rack

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. A control slide of *Cryptosporidium parvum* from a 10% formalin-preserved specimen is included with each staining batch run. If the cryptosporidia stain well, any *Isospora belli* oocysts present will also take up the stain, as will *C. cayetanensis*.

IV. QUALITY CONTROL (continued)

- B. Cryptosporidia stain pink-red. Oocysts are 4 to 6 μm in diameter, and four sporozoites may be present internally. The background should stain uniformly blue.
- C. Check the specimen (macroscopically) for adherence to the slide.
- D. Record all QC results.

V. PROCEDURE

- A. Smear 1 or 2 drops of specimen on the slide, and allow it to air dry. Do not make the smears too thick (you should be able to see through the wet material before it dries). Prepare two smears.
- B. Fix with absolute methanol for 1 min.
- C. Flood slide with Kinyoun's carbol fuchsin, and stain for 5 min.
- D. Rinse slide briefly (3 to 5 s) with 50% ethanol.
- E. Rinse thoroughly with water.
- F. Decolorize with 1% sulfuric acid for 2 min or until no more color runs from the slide.
- G. Rinse slide with water. Drain.
- H. Counterstain with methylene blue for 1 min.
- I. Rinse slide with water. Air dry.
- J. Examine using low-power or high dry power objectives. To see internal morphology, use oil immersion objective (100 \times).

VI. RESULTS

- A. With this cold Kinyoun acid-fast method, *C. cayetanensis* and the oocysts of *Cryptosporidium* and *Isospora* will stain pink to red to deep purple. Some of the four sporozoites may be visible in the *Cryptosporidium* oocysts. Some of the *Isospora* immature oocysts (entire oocyst) will stain, while in oocysts that are mature, the two sporocysts within the oocyst wall will usually stain pink to purple and there will be a clear area between the stained sporocysts and the oocyst wall. The background will stain blue. If *Cyclospora* oocysts are present (uncommon), they tend to be approximately 8 to 10 μm , they resemble *C. parvum* but are larger, and they have no definite internal morphology; the acid-fast staining will tend to be more variable than that seen with *Cryptosporidium* or *Isospora* spp. Modified acid-fast stains stain the *Cyclospora* oocysts from light pink to deep red, and some of the oocysts will contain granules or have a bubbly appearance, often being described as looking like "wrinkled cellophane." Even with the 1% acid decolorizer, some oocysts of *Cyclospora* may appear clear or very pale. If the patient has a heavy infection with microsporidia (immunocompromised patient), small (1- to 2- μm) spores may be seen but may not be recognized as anything other than bacteria or small yeast cells.
- B. There is usually a range of color intensity in the organisms present.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the organism and stage (oocyst or *C. cayetanensis*). Do not use abbreviations.
Examples: *Cryptosporidium parvum* oocysts or *Isospora belli* oocysts or *Cyclospora cayetanensis* oocysts
- B. Call the physician when these organisms are identified.

VIII. PROCEDURE NOTES

- A. Routine stool examination stains are not recommended; however, the sedimentation concentration is acceptable ($500 \times g$ for 10 min) for the recovery and identification of *Cryptosporidium* and *Cyclospora* spp. Routine concentration (formalin-ethyl acetate) can be used to recover *Isospora* oocysts, but routine permanent stains are not reliable for this purpose.
- B. Polyvinyl alcohol-preserved specimens are not acceptable for staining with the modified acid-fast stain. However, specimens preserved in SAF are perfectly acceptable.
- C. Avoid the use of wet gauze filtration (an old, standardized method of filtering stool prior to centrifugation) with too many layers of gauze that may trap organisms and prevent them from flowing into the fluid to be concentrated. It is recommended that no more than two layers of gauze be used; another option is to use the commercially available concentrators that use no gauze but instead use plastic or metal screens.
- D. Other organisms, such as acid-fast bacteria and some *Nocardia* spp., stain positive.
- E. It is very important that smears not be too thick. Thick smears may not adequately destain.
- F. Concentration of the specimen is essential for demonstrating organisms ($500 \times g$ for 10 min). The number of organisms seen in the specimens may vary from numerous to very few.
- G. Because of their mucoid consistency, some specimens require treatment with 10% KOH. Add 10 drops of 10% KOH to the sediment, and vortex until homogeneous. Rinse with 10% formalin, and centrifuge ($500 \times g$ for 10 min). Without decanting the supernatant, take 1 drop of the sediment and smear it thinly on a slide.
- H. Commercial concentrators and reagents are available (see Appendix 9.10.6–1 at the end of this section).
- I. Weak concentrations of sulfuric acid (1.0 to 3.0%) are normally used. Stronger concentrations will remove too much stain.
- J. There is some debate about whether organisms lose their abilities to take up the acid-fast stain after long-term storage in 10% formalin. Use of the hot modified acid-fast method might eliminate this problem (1).
- K. Centrifuge specimens in capped tubes, and wear gloves during all phases of specimen processing.
- L. Currently, no commercial immunoassays are available for *C. cayetanensis*. However, several reagents are in the research phase.

IX. LIMITATIONS OF THE PROCEDURE

- A. Light infections (low number of oocysts) may be missed. Immunoassay methods for *C. parvum* are more sensitive.
- B. Multiple specimens must be examined, since the numbers of oocysts in the stool will vary from day to day. A series of three specimens submitted on alternate days is recommended.

APPENDIX 9.4.1–1

Include QC information on reagent container and in QC records.

Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. 50% Ethanol

1. Add 50 ml of absolute ethanol to 50 ml of distilled water.
2. Store at room temperature. Stable for 1 year.

B. Kinyoun carbol fuchsin

1. Dissolve 4 g of basic fuchsin in 20 ml of 95% ethanol (solution A).
2. Dissolve 8 g of phenol crystals in 100 ml of distilled water (solution B).
3. Mix solutions A and B together.
4. Store at room temperature. Stable for 1 year.

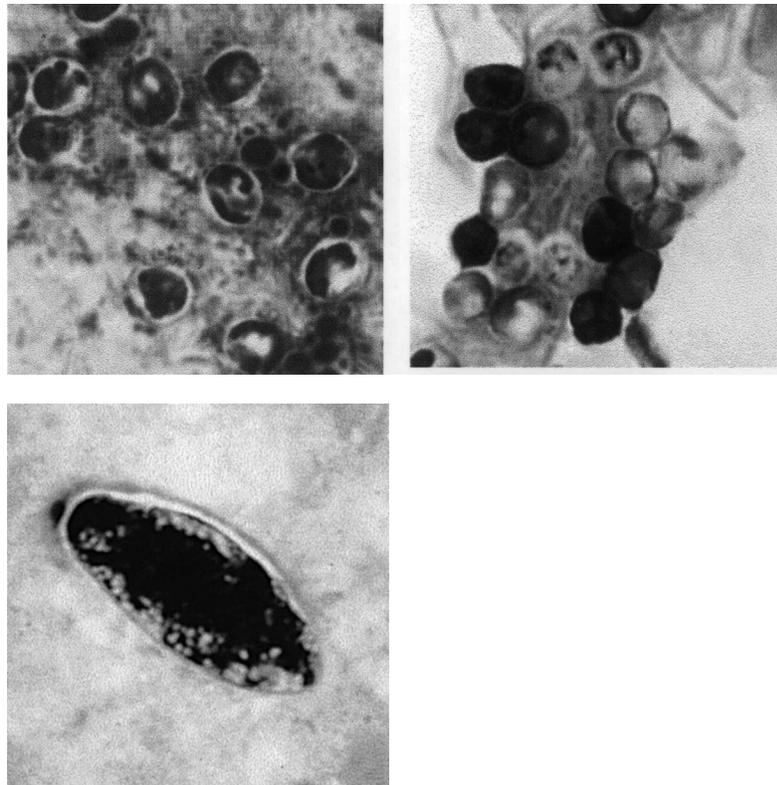

C. 1% Sulfuric acid

1. Add 1 ml of concentrated sulfuric acid to 99 ml of distilled water.
2. Store at room temperature. Stable for 1 year.

D. Methylene blue

1. Dissolve 0.3 g of methylene blue in 100 ml of 95% ethanol.
2. Store at room temperature. Stable for 1 year.

APPENDIX 9.4.1–2

(Top) *C. parvum* oocysts; sporozoites are visible within some oocysts. (Bottom) *I. belli* immature oocyst; note that the entire oocyst stains with modified acid-fast stain.

9.4.2

Special Stains for Coccidia, Including *Cyclospora cayetanensis*: Modified Ziehl-Neelsen Acid-Fast Stain (Hot)

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Cryptosporidium and *Isospora* species have been recognized as causes of severe diarrhea in immunocompromised hosts, but they can also cause diarrhea in immunocompetent hosts. Oocysts in clinical specimens may be difficult to detect without special staining. *Cyclospora cayeta-*

ensis has also been reported to be acid fast. Modified acid-fast stains are recommended for demonstrating these organisms. Application of heat to carbol fuchsin assists in the staining, and the use of a mild decolorizer allows the organisms to retain their pink-red color (1–5).

II. SPECIMENS

Observe standard precautions.

Concentrated sediment of fresh or formalin-preserved stool may be used. Other types of clinical specimens such as duodenal fluid, bile, or pulmonary (induced sputum, bronchial washings, biopsy specimens) may also be stained, after centrifugation.

III. MATERIALS

A. Reagents (see Appendix 9.4.2–1)

1. Carbol fuchsin
2. 5% Sulfuric acid
3. Methylene blue

B. Supplies

1. Disposable glass or plastic pipettes
2. Glass slides (1 by 3 in., or larger if you prefer)
3. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)

C. Equipment

1. Binocular microscope with 10 \times , 40 \times , and 100 \times objectives (or the

approximate magnifications for low-power, high dry power, and oil immersion examination)

2. Oculars should be 10 \times . Some workers prefer 5 \times ; however, overall smaller magnification may make final organism identifications more difficult.
3. Tabletop centrifuge
4. Staining rack
5. 70 $^{\circ}$ C heating block
6. Alcohol lamp or Bunsen burner

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

A. A control slide of *Cryptosporidium parvum* from a 10% formalin-preserved specimen is included with each staining batch run. If the cryptosporidia stain well, any *Isospora belli* oocysts present will also take up the stain, as will *C. cayetanensis*.

B. Cryptosporidia stain pink-red. Oocysts are 4 to 6 μ m in diameter, and four sporozoites may be present internally. The background should stain uniformly blue.

C. Check the specimen (macroscopically) for adherence to the slide.

D. Record all QC results, including a description of QC specimens tested.

V. PROCEDURE

- A. Smear 1 or 2 drops of specimen on the slide, and allow it to air dry. Do not make the smears too thick (you should be able to see through the wet material before it dries). Prepare two smears.
- B. Dry on a heating block (70°C) for 5 min, or air dry.
- C. Place slide on staining rack, and flood with carbol fuchsin.
- D. With alcohol lamp or Bunsen burner, gently heat slide to steaming by passing flame under slide. Discontinue heating once the stain begins to steam. Do not boil.
- E. Allow to stain 5 min. If slide dries, add more stain without additional heating.
- F. Rinse thoroughly with water. Drain.
- G. Decolorize with 5% sulfuric acid for 30 s. (Thicker smears may require longer to destain.)
- H. Rinse with water. Drain.
- I. Flood slide with methylene blue for 1 min.
- J. Rinse with water, drain, and air dry.
- K. Examine with low-power or high dry power objectives. To see internal morphology, use oil immersion objective (100×).

VI. RESULTS

- A. With this modified acid-fast method, the oocysts of *C. cayetanensis*, *Cryptosporidium*, and *Isospora* will stain pink to red to deep purple. Some of the four sporozoites may be visible in the *Cryptosporidium* oocysts. Some of the *Isospora* immature oocysts (entire oocyst) will stain, while in oocysts that are mature, the two sporocysts within the oocyst wall will stain pink to purple and there will be a clear area between the stained sporocysts and the oocyst wall. The background will stain blue. If *Cyclospora* oocysts are present (uncommon), they tend to be approximately 8 to 10 μm, they resemble *C. parvum* but are larger, and they have no definite internal morphology; the acid-fast staining will tend to be more variable than that seen with *Cryptosporidium* or *Isospora* spp. Modified acid-fast stains stain the *Cyclospora* oocysts from light pink to deep red, and some of the oocysts will contain granules or have a bubbly appearance, often being described as looking like “wrinkled cellophane.” With the 5% acid decolorizer, some oocysts of *Cyclospora* may appear clear or very pale. If the patient has a heavy infection with microsporidia (immunocompromised patient), small (1- to 2-μm) spores may be seen but may not be recognized as anything other than bacteria or small yeast cells.
- B. There is usually a range of color intensity in the organisms present.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the organism and stage (oocyst or *C. cayetanensis*). Do not use abbreviations.
Examples: *Cryptosporidium parvum* oocysts or *Isospora belli* oocysts or *Cyclospora cayetanensis* oocysts
- B. Call the physician when these organisms are identified.

VIII. PROCEDURE NOTES

- A. Routine stool examination stains are not recommended for the recovery and identification of *Cryptosporidium* and *Cyclospora* spp.; however, the sedimentation concentration is acceptable (500 × g for 10 min). Routine concentration (formalin-ethyl acetate) can be used to recover *Isospora* oocysts, but routine permanent stains are not reliable for this purpose.

VIII. PROCEDURE NOTES*(continued)*

- B.** Polyvinyl alcohol-preserved specimens are not acceptable for staining with the modified acid-fast stain. However, specimens preserved in sodium acetate-acetic acid-formalin are perfectly acceptable.
- C.** Avoid the use of wet gauze filtration (an old, standardized method of filtering stool prior to centrifugation) with too many layers of gauze that may trap organisms and prevent them from flowing into the fluid to be concentrated. It is recommended that no more than two layers of gauze be used; another option is to use the commercially available concentrators that use no gauze but instead use plastic or metal screens.
- D.** Other organisms, such as acid-fast bacteria and some *Nocardia* spp., stain positive.
- E.** It is very important that smears not be too thick. Thick smears may not adequately destain.
- F.** Concentration of specimen is essential for demonstrating organisms. The number of organisms seen in the specimen may vary from numerous to very few.
- G.** Because of their mucoid consistency, some specimens require treatment with 10% KOH. Add 10 drops of 10% KOH to the sediment, and vortex until homogeneous. Rinse with 10% formalin, and centrifuge ($500 \times g$ for 10 min). Without decanting the supernatant, take 1 drop of the sediment and smear it thinly on a slide.
- H.** Commercial concentrators and reagents are available (*see* Appendix 9.10.6–1 at the end of this section).
- I.** Do not boil stain. Gently heat until steam rises from the slide. Do not allow the stain to dry on the slide.
- J.** Various concentrations of sulfuric acid (0.25 to 10%) may be used, but destaining time will vary according to the concentration used. Generally, a 1 or 5% solution is used.
- K.** There is some debate about whether organisms lose their abilities to take up the acid-fast stain after long-term storage in 10% formalin. Use of this hot modified acid-fast method might eliminate the problem (1).
- L.** Centrifuge specimens in capped tubes, and *wear gloves during all phases of specimen processing.*
- M.** Currently, no commercial immunoassays are available for *C. cayetanensis*. However, several reagents are in the research phase.

IX. LIMITATIONS OF THE PROCEDURE

- A.** Light infections (low number of oocysts) may be missed. Immunoassay methods for *C. parvum* are more sensitive.
- B.** Multiple specimens must be examined, since the numbers of oocysts in the stool will vary from day to day. A series of three specimens submitted on alternate days is recommended.

APPENDIX 9.4.2-1

Include QC information on reagent container and in QC records.

Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. Carbol fuchsin

1. Basic fuchsin (solution A)
Dissolve 0.3 g of basic fuchsin in 10 ml of 95% ethanol.
2. Phenol (solution B)
Dissolve 5 g of phenol crystals in 100 ml of distilled water. (Gentle heat may be needed.)
3. Mix solution A with solution B.
4. Store at room temperature. Stable for 1 year.

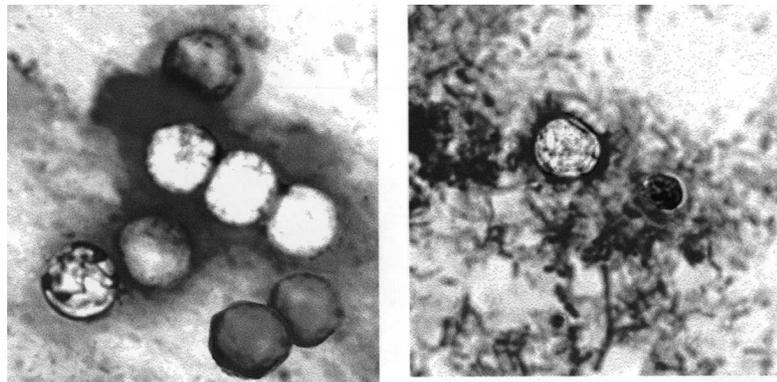

B. 5% Sulfuric acid

1. Add 5 ml of concentrated sulfuric acid to 95 ml of distilled water.
2. Store at room temperature. Stable for 1 year.

C. Methylene blue

1. Dissolve 0.3 g of methylene blue chloride in 100 ml of distilled water.
2. Store at room temperature. Stable for 1 year.

APPENDIX 9.4.2-2

(Left) *C. cayetanensis* oocysts (note variation in staining). (Right) The large, clear object is a *C. cayetanensis* oocyst (8 to 10 μm); the darker object to the right is a *C. parvum* oocyst (4 to 6 μm). Note that *Cyclospora* tends to look like wrinkled cellophane when it does not stain well.

9.4.3

Special Stains for Microsporidia: Weber Green

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The diagnosis of intestinal microsporidiosis (*Enterocytozoon bieneusi*, *Encephalitozoon intestinalis*) has depended on the use of invasive procedures and subsequent examination of biopsy specimens, often by electron microscopy methods. However, the need for a practical method for the routine clinical laboratory has stim-

ulated some work in the development of additional methods. Slides prepared from fresh or formalin-fixed stool specimens can be stained by a new chromotrope-based technique and can be examined with light microscopy. This staining method is based on the fact that stain penetration of the microsporidial spore is very difficult;

thus, the dye content in the chromotrope 2R is higher than that routinely used to prepare Wheatley's modification of Gomori's trichrome method, and the staining time is much longer (90 min) (1–3). At least several of these stains are available commercially from a number of suppliers.

II. SPECIMEN

Observe standard precautions.

The specimen can be fresh stool or stool that has been preserved in 5 or 10% formalin, sodium acetate-acetic acid-formalin (SAF), or some of the newer single-vial system fixatives. Actually, any specimen other than tissue thought to contain microsporidia could be stained by these methods. Polyvinyl alcohol-preserved fecal material is not recommended.

III. MATERIALS

A. Reagents (see Appendix 9.4.3–1)

B. Supplies

1. Disposable glass or plastic pipettes
2. Glass slides (1 by 3 in., or larger if you prefer)
3. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)
4. Glass or plastic centrifuge tubes (15 ml)
5. Coplin jars or other suitable staining containers
6. Chromotrope 2R
7. Aniline blue
8. Phosphotungstic acid

9. Acetic acid (glacial)

10. Distilled water

C. Equipment

1. Binocular microscope with 10 \times , 40 \times , and 100 \times objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
2. Oculars should be 10 \times . Some workers prefer 5 \times ; however, overall smaller magnification may make final organism identifications more difficult.
3. Tabletop centrifuge

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Unfortunately, the only way to perform acceptable QC procedures for this method is to use actual microsporidial spores as the control organisms. Obtaining these positive controls may be somewhat difficult. It is particularly important to use the actual organisms because the spores are difficult to stain and the size is very small (1 to 2.5 μm).
- B. A QC slide should be included with each run of stained slides, particularly if the staining setup is used infrequently.
- C. All staining dishes should be covered to prevent evaporation of reagents (screw-cap Coplin jars or glass lids).
- D. Depending on the volume of slides stained, staining solutions will have to be changed on an as-needed basis.
- E. When the smear is thoroughly fixed and the stain is performed correctly, the spores will be ovoid and refractile, with the spore wall being bright pinkish red. Occasionally, the polar tube can be seen either as a stripe or as a diagonal line across the spore. The majority of the bacteria and other debris will tend to stain green. However, there will still be some bacteria and debris that will stain red.
- F. The specimen is also checked for adherence to the slide (macroscopically).
- G. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope). Although recalibration every 12 months may not be necessary, this will vary from laboratory to laboratory, depending on equipment care and use. Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- H. Known positive microscope slides, Kodachrome 2-by-2 projection slides, and photographs (reference books) should be available at the workstation.
- I. Record all QC results; the laboratory should also have an action plan for "out-of-control" results.

V. PROCEDURE

- A. Using a 10- μl aliquot of *concentrated* (formalin-ethyl acetate sedimentation concentration; centrifugation at $500 \times g$ for 10 min), preserved liquid stool (5 or 10% formalin or SAF), prepare the smear by spreading the material over an area of 45 by 25 mm.
- B. Allow the smear to air dry.
- C. Place the smear in absolute methanol for 5 min.
- D. Allow the smear to air dry.
- E. Place in trichrome stain for 90 min.
- F. Rinse in acid-alcohol for no more than 10 s.
- G. Dip slides several times in 95% alcohol. Use this step as a rinse.
- H. Place in 95% alcohol for 5 min.
- I. Place in 100% alcohol for 10 min.
- J. Place in xylene substitute for 10 min.
- K. Mount with coverslip (no. 1 thickness), using mounting medium (this step is optional).
- L. Examine smears under oil immersion (1,000 \times) and read at least 100 fields; the examination time will probably be at least 10 min per slide.

VI. RESULTS

- A. Microsporidial spores might be seen. The spore wall should stain pinkish to red, with the interior of the spore being clear or perhaps showing a horizontal or diagonal stripe that represents the polar tube. The background will appear green (Weber stain).
- B. Other bacteria, some yeast cells, and some debris will stain pink to red; the shapes and sizes of the various components may be helpful in differentiating the spores from other structures.
- C. The results from this staining procedure should be reported only if the positive control smears are acceptable. The production of immunoassay reagents should provide a more specific and sensitive approach to the identification of the microsporidia in fecal specimens.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the organism and stage. Do not use abbreviations.
Examples (stool specimens): Microsporidial spores present.
Enterocytozoon bieneusi or *Encephalitozoon (Septata) intestinalis* present (if from fecal specimen); the two organisms cannot be differentiated on the basis of size or morphology.
Example (from urine): *Encephalitozoon (Septata) intestinalis* present (identification to the species level highly likely); generally this organism is involved in disseminated cases from the gastrointestinal tract to kidneys and will be found in urine.
- B. Quantitate the number of spores seen (rare, few, moderate, many).

VIII. PROCEDURE NOTES

- A. It is mandatory that positive control smears be stained and examined each time patient specimens are stained and examined.
- B. Because of the difficulty in getting stain penetration through the spore wall, prepare thin smears and do not reduce the staining time in trichrome. Also, make sure that the slides are not left too long in the decolorizing agent (acid-alcohol). If the control organisms are too light, leave them in the trichrome longer and shorten the time to two dips in the acid-alcohol solution. Also, remember that the 95% alcohol rinse after the acid-alcohol should be performed quickly to prevent additional destaining from the acid alcohol reagent.
- C. When you purchase the chromotrope 2R, obtain the highest dye content available. Two sources are Harleco (Gibbstown, N.J.) and Sigma Chemical Co. (St. Louis, Mo.) (dye content among the highest [85%]). Fast green and aniline blue can be obtained from Allied Chemical and Dye (New York, N.Y.).
- D. In the final stages of dehydration, the 100% ethanol and the xylenes (or xylene substitutes) should be kept as free from water as possible. Coplin jars must have tight-fitting caps to prevent both evaporation of reagents and absorption of moisture. If the xylene becomes cloudy after addition of slides from 100% alcohol, return the slides to 100% alcohol and replace the xylene with fresh stock.

IX. LIMITATIONS OF THE PROCEDURE

- A. Although this staining method will stain the microsporidia, the range of stain intensity and the small size of the spores will cause some difficulty in identifying these organisms. Since this procedure will result in many other organisms or objects staining in stool specimens, differentiation of the microsporidia from surrounding material will still be very difficult. There also tends to be some slight size variation among the spores.

IX. LIMITATIONS OF THE PROCEDURE *(continued)*

- B.** If the patient has severe watery diarrhea, there will be less artifact material in the stool to confuse with the microsporidial spores. However, if the stool is semiformed or formed, the amount of artifact material will be much greater; thus, the spores will be much harder to detect and identify. Also, remember that the number of spores will vary according to the stool consistency (the more diarrhetic, the more spores that will be present).
- C.** Those who developed some of these procedures feel that concentration procedures result in an actual loss of microsporidial spores; thus, there is a strong recommendation to use unconcentrated, formalinized stool. However, there are no data indicating what centrifugation speeds, etc., were used in the study.
- D.** *In the UCLA Clinical Microbiology Laboratory, data (unpublished) have been generated to indicate that centrifugation at $500 \times g$ for 10 min increases dramatically the number of microsporidial spores available for staining (from the concentrate sediment). This is the same protocol used in that laboratory for centrifugation of all stool specimens, regardless of the suspected organism.*
- E.** Avoid the use of wet gauze filtration (an old, standardized method of filtering stool prior to centrifugation) with too many layers of gauze that may trap organisms and prevent them from flowing into the fluid to be concentrated. It is recommended that no more than two layers of gauze be used. Another option is to use the commercially available concentration systems that use metal or plastic screens for filtration.

APPENDIX 9.4.3–1

Include QC information on reagent container and in QC records.

Reagents

A. Trichrome stain (modified for microsporidia) (Weber green)

chromotrope 2R	6.0 g*
fast green	0.15 g
phosphotungstic acid	0.7 g
acetic acid (glacial)	3.0 ml
distilled water	100.0 ml

*10 times the normal trichrome stain formula

1. Prepare the stain by adding 3.0 ml of acetic acid to the dry ingredients. Allow the mixture to stand (ripen) for 30 min at room temperature.
2. Add 100 ml of distilled water. Properly prepared stain will be dark purple.
3. Store in a glass or plastic bottle at room temperature. The shelf life is at least 24 months.

B. Acid-alcohol

90% ethyl alcohol	995.5 ml
Acetic acid (glacial)	4.5 ml

Prepare by combining the two solutions.

9.4.4

Special Stains for Microsporidia: Ryan Blue

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The diagnosis of intestinal microsporidiosis (*Enterocytozoon bienersi*, *Encephalitozoon intestinalis*) has depended on the use of invasive procedures and subsequent examination of biopsy specimens, often by electron microscopy methods. However, the need for a practical method for the routine clinical laboratory has stimulated some work in the development of additional methods. Slides prepared from fresh or formalin-fixed stool

specimens can be stained by a new chromotrope-based technique and can be examined with light microscopy. This staining method is based on the fact that stain penetration of the microsporidial spore is very difficult; thus, the dye content in the chromotrope 2R is higher than that routinely used to prepare Wheatley's modification of Gomori's trichrome method, and the staining time is much longer (90 min) (1–3).

A number of variations to the modified trichrome (Weber green) were tried in an attempt to improve the contrast between the color of the spores and the background staining. Optimal staining was achieved by modifying the composition of the trichrome solution. This stain is also available commercially from a number of suppliers.

II. SPECIMEN

Observe standard precautions.

The specimen can be fresh stool or stool that has been preserved in 5 or 10% formalin, sodium acetate-acetic acid-formalin (SAF), or some of the newer single-vial system fixatives. Actually, any specimen other than tissue thought to contain microsporidia could be stained by these methods. PVA-preserved fecal material is not recommended.

III. MATERIALS

A. Reagents (see Appendix 9.4.4–1)

B. Supplies

2. Glass slides (1 by 3 in., or larger if you prefer)
3. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)
4. Glass or plastic centrifuge tubes (15 ml)
5. Coplin jars or other suitable staining containers
6. Chromotrope 2R
7. Aniline blue
8. Phosphotungstic acid

9. Acetic acid (glacial)

10. Distilled water

C. Equipment

1. Binocular microscope with 10 \times , 40 \times , and 100 \times objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
2. Oculars should be 10 \times . Some workers prefer 5 \times ; however, overall smaller magnification may make final organism identifications more difficult.
3. Tabletop centrifuge

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Unfortunately, the only way to perform acceptable QC procedures for this method is to use actual microsporidial spores as the control organisms. Obtaining these positive controls may be somewhat difficult. It is particularly important to use the actual organisms because the spores are difficult to stain and the size is very small (1 to 2.5 μm).
- B. A QC slide should be included with each run of stained slides, particularly if the staining setup is used infrequently.
- C. All staining dishes should be covered to prevent evaporation of reagents (screw-cap Coplin jars or glass lids).
- D. Depending on the volume of slides stained, staining solutions will have to be changed on an as-needed basis.
- E. When the smear is thoroughly fixed and the stain is performed correctly, the spores will be ovoid and refractile, with the spore wall being bright pinkish red. Occasionally, the polar tube can be seen either as a stripe or as a diagonal line across the spore. The majority of the bacteria and other debris will tend to stain blue. However, there will still be some bacteria and debris that will stain red.
- F. The specimen is also checked for adherence to the slide (macroscopically).
- G. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope). Although recalibration every 12 months may not be necessary, this will vary from laboratory to laboratory, depending on equipment care and use. Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- H. Known positive microscope slides, Kodachrome 2-by-2 projection slides, and photographs (reference books) should be available at the workstation.
- I. Record all QC results; the laboratory should also have an action plan for "out-of-control" results.

V. PROCEDURE

- A. Using a 10- μl aliquot of *concentrated* (formalin-ethyl acetate sedimentation concentration; centrifugation at $500 \times g$ for 10 min), preserved liquid stool (5 or 10% formalin or SAP), prepare the smear by spreading the material over an area of 45 by 25 mm.
- B. Allow the smear to air dry.
- C. Place the smear in absolute methanol for 5 or 10 min.
- D. Allow the smear to air dry.
- E. Place in trichrome stain for 90 min.
- F. Rinse in acid-alcohol for no more than 10 s.
- G. Dip slides several times in 95% alcohol. Use this step as a rinse (no more than 10 s).
- H. Place in 95% alcohol for 5 min.
- I. Place in 95% alcohol for 5 min.
- J. Place in 100% alcohol for 10 min.
- K. Place in xylene substitute for 10 min.
- L. Mount with coverslip (no. 1 thickness), using mounting medium (this step is optional).

V. PROCEDURE (*continued*)

- M. Examine smears under oil immersion (1,000×) and read at least 100 fields; the examination time will probably be at least 10 min per slide.

VI. RESULTS

- A. Microsporidial spores might be seen. The spore wall should stain pinkish to red, with the interior of the spore being clear or perhaps showing a horizontal or diagonal stripe that represents the polar tube. The background will appear blue (Ryan stain).
- B. Other bacteria, some yeast cells, and some debris will stain pink to red; the shapes and sizes of the various components may be helpful in differentiating the spores from other structures.
- C. The results from this staining procedure should be reported only if the positive control smears are acceptable. The production of immunoassay reagents should provide a more specific and sensitive approach to the identification of the microsporidia in fecal specimens.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the organism and stage. Do not use abbreviations.
Examples (stool specimens): Microsporidial spores present.
Enterocytozoon bieneusi or *Encephalitozoon (Septata) intestinalis* present (if from fecal specimen); the two organisms cannot be differentiated on the basis of size or morphology.
Example (from urine): *Encephalitozoon (Septata) intestinalis* present (identification to species highly likely); generally this organism is involved in disseminated cases from the gastrointestinal tract to kidneys and will be found in urine.
- B. Quantitate the number of spores seen (rare, few, moderate, many).

VIII. PROCEDURE NOTES

- A. It is mandatory that positive control smears be stained and examined each time patient specimens are stained and examined.
- B. Because of the difficulty in getting stain penetration through the spore wall, prepare thin smears and do not reduce the staining time in trichrome. Also, make sure that the slides are not left too long in the decolorizing agent (acid-alcohol). If the control organisms are too light, leave them in the trichrome longer and shorten the time to two dips in the acid-alcohol solution. Also, remember that the 95% alcohol rinse after the acid-alcohol should be performed quickly to prevent additional destaining from the acid-alcohol reagent.
- C. When you purchase the chromotrope 2R, obtain the highest dye content available. Two sources are Harleco (Gibbstown, N.J.) and Sigma Chemical Co. (St. Louis, Mo.) (dye content among the highest [85%]). Fast green and aniline blue can be obtained from Allied Chemical and Dye (New York, N.Y.).
- D. In the final stages of dehydration, the 100% ethanol and the xylenes (or xylene substitutes) should be kept as free from water as possible. Coplin jars must have tight-fitting caps to prevent both evaporation of reagents and absorption of moisture. If the xylene becomes cloudy after addition of slides from 100% alcohol, return the slides to 100% alcohol and replace the xylene with fresh stock.

IX. LIMITATIONS OF THE PROCEDURE

- A. Although this staining method will stain the microsporidia, the range of stain intensity and the small size of the spores will cause some difficulty in identifying these organisms. Since this procedure will result in many other organisms or objects staining in stool specimens, differentiation of the microsporidia from surrounding material will still be very difficult. There also tends to be some slight size variation among the spores.
- B. If the patient has severe watery diarrhea, there will be less artifact material in the stool to confuse with the microsporidial spores. However, if the stool is semiformed or formed, the amount of artifact material will be much greater; thus, the spores will be much harder to detect and identify. Also, remember that the number of spores will vary according to the stool consistency (the more diarrhetic, the more spores that will be present).
- C. Those who developed some of these procedures feel that concentration procedures result in an actual loss of microsporidial spores; thus, there is a strong recommendation to use unconcentrated, formalinized stool. However, there are no data indicating what centrifugation speeds, etc., were used in the study.
- D. *In the UCLA Clinical Microbiology Laboratory, data (unpublished) have been generated to indicate that centrifugation at 500 × g for 10 min increases dramatically the number of microsporidial spores available for staining (from the concentrate sediment). This is the same protocol used in that laboratory for centrifugation of all stool specimens, regardless of the suspected organism.*
- E. Avoid the use of wet gauze filtration (an old, standardized method of filtering stool prior to centrifugation) with too many layers of gauze that may trap organisms and prevent them from flowing into the fluid to be concentrated. It is recommended that no more than two layers of gauze be used. Another option is to use the commercially available concentration systems that use metal or plastic screens for filtration.

APPENDIX 9.4.4–1

Include QC information on reagent container and in QC records.

Reagents

A. Trichrome stain (modified for microsporidia) (Ryan blue)

chromotrope 2R	6.0 g*
aniline blue	0.5 g
phosphotungstic acid	0.25 g
acetic acid (glacial)	3.0 ml
distilled water	100.0 ml

*10 times the normal trichrome stain formula

1. Prepare the stain by adding 3.0 ml of acetic acid to the dry ingredients. Allow the mixture to stand (ripen) for 30 min at room temperature.
2. Add 100 ml of distilled water and adjust the pH to 2.5 with 1.0 M HCl. Properly prepared stain will be dark purple. The staining solution should be protected from light.
3. Store in a glass or plastic bottle at room temperature. The shelf life is at least 24 months.

APPENDIX 9.4.4-1 (continued)

B. Acid-alcohol

90% ethyl alcohol	995.5 ml
acetic acid (glacial)	4.5 ml

Prepare by combining the two solutions.

APPENDIX 9.4.4-2

Modified Trichrome Stain for the Microsporidia (1) (Kokoskin Hot Method)

Changes in temperature from room temperature to 50°C and the staining time from 90 to 10 min have been recommended as improvements for the modified trichrome staining methods. The procedure is as follows.

1. Using a 10- μ l aliquot of unconcentrated, preserved liquid stool (5 or 10% formalin or SAF), prepare the smear by spreading the material over an area of 45 by 25 mm.
2. Allow the smear to air dry.
3. Place the smear in absolute methanol for 5 min.
4. Allow the smear to air dry.
5. Place in trichrome stain for 10 min at a temperature of 50°C.
6. Rinse in acid-alcohol for no more than 10 s.
7. Dip slides several times in 95% alcohol. Use this step as a rinse (no more than 10 s).
8. Place in 95% alcohol for 5 min.
9. Place in 100% alcohol for 10 min.
10. Place in xylene substitute for 10 min.
11. Mount with coverslip (no. 1 thickness), using mounting medium.
12. Examine smears under oil immersion (1,000 \times) and read at least 100 fields; the examination time will probably be at least 10 min per slide.

9.4.5

Special Stains for Microsporidia: Acid-Fast Trichrome Stain for *Cryptosporidium* and the Microsporidia

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The detection of *Cryptosporidium parvum* and the microsporidia from stool specimens has depended on two separate stains. However, a method is now available that will stain both organisms, an important improvement since dual infections have been demonstrated in AIDS patients. This

acid-fast trichrome stain yields results comparable to those obtained by the Kinoun and modified trichrome methods and considerably reduces the time necessary for microscopic examination. Also, it appears that modified trichrome stains and

staining with fluorochromes are equally useful in the diagnosis of microsporidiosis; however, a combination of both methods may be more sensitive in cases where the number of spores is very low (1, 2).

II. SPECIMEN

Observe standard precautions.

The specimen can be fresh stool or stool that has been preserved in 5 or 10% formalin, SAF, or some of the newer single-vial system fixatives. Actually, any specimen other than tissue thought to contain microsporidia could be stained by these methods. PVA-preserved fecal material is not recommended.

III. MATERIALS

A. Reagents (see Appendix 9.4.5–1)

B. Supplies

1. Disposable glass or plastic pipettes
2. Glass slides (1 by 3 in., or larger if you prefer)
3. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)
4. Glass or plastic centrifuge tubes (15 ml)
5. Coplin jars or other suitable staining containers
6. Chromotrope 2R
7. Aniline blue
8. Phosphotungstic acid
9. Carbol fuchsin

10. Phenol

11. Acetic acid (glacial)

12. Distilled water

C. Equipment

1. Binocular microscope with 10 \times , 40 \times , and 100 \times objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
2. Oculars should be 10 \times . Some workers prefer 5 \times ; however, overall smaller magnification may make final organism identifications more difficult
3. Tabletop centrifuge

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

A. Unfortunately, the only way to perform acceptable QC procedures for this method is to use actual microsporidial spores as the control organisms. Obtaining these positive controls may be somewhat difficult. It is particularly important to use the actual organisms because the spores are difficult to stain and the size is very small (1 to 1.5 μ m).

IV. QUALITY CONTROL

(continued)

- B. A QC slide should be included with each run of stained slides, particularly if the staining setup is used infrequently.
- C. All staining dishes should be covered to prevent evaporation of reagents (screw-cap Coplin jars or glass lids).
- D. Depending on the volume of slides stained, staining solutions will have to be changed on an as-needed basis.
- E. When the smear is thoroughly fixed and the stain is performed correctly, the spores will be ovoid and refractile, with the spore wall being bright pinkish red. Occasionally, the polar tube can be seen either as a stripe or as a diagonal line across the spore. The majority of the bacteria and other debris will tend to stain blue. However, there will still be some bacteria and debris that will stain red. The coccidia (*Cryptosporidium*, *Cyclospora*, *Isospora*) will stain as with any modified acid-fast stain: from pink to violet.
- F. The specimen is also checked for adherence to the slide (macroscopically).
- G. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope). Although recalibration every 12 months may not be necessary, this will vary from laboratory to laboratory, depending on equipment care and use. Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- H. Known positive microscope slides, Kodachrome 2-by-2 projection slides, and photographs (reference books) should be available at the workstation.
- I. Record all QC results; the laboratory should also have an action plan for “out-of-control” results.

V. PROCEDURE

- A. Using a 10- μ l aliquot of *concentrated* (formalin-ethyl acetate sedimentation concentration; centrifugation at $500 \times g$ for 10 min), preserved liquid stool (5 or 10% formalin or SAF), prepare the smear by spreading the material over an area of 45 by 25 mm.
- B. Allow the smear to air dry.
- C. Place the smear in absolute methanol for 5 or 10 min.
- D. Allow the smear to air dry.
- E. Place in carbol fuchsin solution for 10 min (no heat required).
- F. Briefly rinse with tap water.
- G. Decolorize with 0.5% acid-alcohol.
- H. Briefly rinse with tap water.
- I. Place in trichrome stain for 30 min at 37°C.
- J. Rinse in acid-alcohol for no more than 10 s.
- K. Dip slides several times in 95% alcohol. Use this step as a rinse (no more than 10 s).
- L. Place in 95% alcohol for 30 s.
- M. Allow slides to air dry.
- N. Examine smears under oil immersion (1,000 \times) and read at least 100 fields; the examination time will probably be at least 10 min per slide.

VI. RESULTS

- A. Microsporidial spores might be seen. The spore wall should stain pink, with the interior of the spore being clear or perhaps showing a horizontal or diagonal stripe that represents the polar tube. A vacuole may also be visible in some spores. The *Cryptosporidium* oocysts will stain bright pink or violet. The background will appear green.
- B. Other bacteria, some yeast cells, and some debris will stain pink to red; the shapes and sizes of the various components may be helpful in differentiating the spores from other structures.
- C. The results from this staining procedure should be reported only if the positive control smears are acceptable. The production of immunoassay reagents should provide a more specific and sensitive approach to the identification of the microsporidia in fecal specimens.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the organism and stage. Do not use abbreviations.
Examples (stool specimens): Microsporidial spores present.
Enterocytozoon bienersi or *Encephalitozoon (Septata) intestinalis* present (if from fecal specimen); the two organisms cannot be differentiated on the basis of size or morphology.
Example (from urine): *Encephalitozoon (Septata) intestinalis* present (identification to species level highly likely); generally this organism is involved in disseminated cases from the gastrointestinal tract to kidneys and will be found in urine.
- B. Quantitate the number of spores seen (rare, few, moderate, many).

VIII. PROCEDURE NOTES

- A. It is mandatory that positive control smears be stained and examined each time patient specimens are stained and examined.
- B. Because of the difficulty in getting stain penetration through the spore wall, prepare thin smears and do not reduce the staining time in trichrome. Also, make sure that the slides are not left too long in the decolorizing agent (acid-alcohol). If the control organisms are too light, leave them in the trichrome longer and shorten the time to two dips in the acid-alcohol solution. Also, remember that the 95% alcohol rinse after the acid-alcohol should be performed quickly to prevent additional destaining from the acid-alcohol reagent.
- C. When you purchase the chromotrope 2R, obtain the highest dye content available. Two sources are Harleco (Gibbstown, N.J.) and Sigma Chemical Co. (St. Louis, Mo.) (dye content among the highest [85%]). Fast green and aniline blue can be obtained from Allied Chemical and Dye (New York, N.Y.).
- D. In the final stages of dehydration, the 100% ethanol and the xylenes (or xylene substitutes) should be kept as free from water as possible. Coplin jars must have tight-fitting caps to prevent both evaporation of reagents and absorption of moisture. If the xylene becomes cloudy after addition of slides from 100% alcohol, return the slides to 100% alcohol and replace the xylene with fresh stock.

IX. LIMITATIONS OF THE PROCEDURE

- A. Although this staining method will stain the microsporidia, the range of stain intensity and the small size of the spores will cause some difficulty in identifying these organisms. Since this procedure will result in many other organisms or objects staining in stool specimens, differentiation of the microsporidia from

IX. LIMITATIONS OF THE PROCEDURE *(continued)*

- surrounding material will still be very difficult. There also tends to be some slight size variation among the spores.
- B.** If the patient has severe watery diarrhea, there will be less artifact material in the stool to confuse with the microsporidial spores. However, if the stool is semiformed or formed, the amount of artifact material will be much greater; thus, the spores will be much harder to detect and identify. Also, remember that the number of spores will vary according to the stool consistency (the more diarrhetic, the more spores that will be present).
 - C.** Those who developed some of these procedures feel that concentration procedures result in an actual loss of microsporidial spores; thus, there is a strong recommendation to use unconcentrated, formalinized stool. However, there are no data indicating what centrifugation speeds, etc., were used in the study.
 - D.** *In the UCLA Clinical Microbiology Laboratory, data (unpublished) have been generated to indicate that centrifugation at $500 \times g$ for 10 min increases dramatically the number of microsporidial spores available for staining (from the concentrate sediment). This is the same protocol used in that laboratory for centrifugation of all stool specimens, regardless of the suspected organism.*
 - E.** Avoid the use of wet gauze filtration (an old, standardized method of filtering stool prior to centrifugation) with too many layers of gauze that may trap organisms and allow them to flow into the fluid to be concentrated. It is recommended that no more than two layers of gauze be used. Another option is to use the commercially available concentration systems that use metal or plastic screens for filtration.

APPENDIX 9.4.5-1

Include QC information on reagent container and in QC records.

Reagents

A. Trichrome stain (modified for microsporidia)

chromotrope 2R	6.0 g*
aniline blue	0.5 g
phosphotungstic acid	0.7 g
acetic acid (glacial)	3.0 ml
distilled water	100.0 ml

*10 times the normal trichrome stain formula

1. Prepare the stain by adding 3.0 ml of acetic acid to the dry ingredients. Allow the mixture to stand (ripen) for 30 min at room temperature.
2. Add 100 ml of distilled water and adjust the pH to 2.5 with 1.0 M HCl. Properly prepared stain will be dark purple. The staining solution should be protected from light.
3. Store in a glass or plastic bottle at room temperature. The shelf life is at least 24 months.

B. Carbol fuchsin solution

Phenol solution	
phenol	25.0 g
distilled water	500.0 ml
Saturated alcoholic fuchsin solution	
basic fuchsin	2.0 g
96% ethanol	25.0 ml

Add the mixture of phenol and water to 25.0 ml of the saturated alcoholic fuchsin solution.

C. Acid-alcohol

90% ethyl alcohol	995.5 ml
acetic acid (glacial)	4.5 ml

Prepare by combining the two solutions.

9.5.1

“Culture” of Larval-Stage Nematodes: Baermann Technique

Strongyloides stercoralis larvae are usually the only larvae found in stool specimens. Depending on bowel transit time and the condition of the patient, rhabditiform and, rarely, filariform larvae may be present. If there is delay in examination of the stool, then embryonated ova and larvae of hookworm may be present. Culture of feces for larvae is useful to (i) reveal the presence of larvae when they are too scanty to be detected by concentration methods, (ii) distinguish whether the in-

fection is due to *Strongyloides* or hookworm on the basis of rhabditiform larval morphology by allowing hookworm eggs to hatch and release first-stage larvae, and (iii) allow development of larvae into the filariform stage for further differentiation.

The use of certain fecal-culture methods (sometimes referred to as coproculture) is especially helpful in detecting light infections of hookworm, *Strongyloides* spp., and *Trichostrongylus* spp. and for specifically identifying parasites. Addi-

tionally, such techniques are useful for obtaining a large number of infective-stage larvae for research purposes. Three culture techniques and one enhanced-recovery method are described in this section.

Occasionally, it is necessary to examine stool specimens for scolices and proglottids of cestodes and for adult nematodes and trematodes to confirm the diagnosis and/or to identify a species. A method for the recovery of these stages is also described in procedure 9.5.6.

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The Baermann technique uses a special apparatus and relies on the principle that active larvae will migrate out of a fecal specimen that has been placed on a wire mesh covered with several layers of gauze (1, 2). Larvae migrate through the gauze into the water and settle to the bottom of the funnel, where they can be collected

and examined. Modifications to simplify the procedure have been reported elsewhere (5). Besides being useful for diagnosis from stool specimens directly or after enhancement by culture, this technique can be used by epidemiologists to examine soil specimens for larvae.

II. SPECIMEN

Observe standard precautions.

The specimen must be fresh stool that has not been refrigerated.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Reagent

- Indicate the expiration date on the label and in the work record or on the manufacturer's label.
- Bleach (full strength)

B. Supplies

1. Glass funnel (6 in. across at the mouth)
2. Rubber tubing to fit end of funnel
3. Clamp
4. Wire gauze screen or nylon filter
5. Centrifuge tubes (15-ml capacity)
6. Glass slides (1 by 3 in. or larger)
7. Disposable glass or plastic pipettes
8. Wooden applicator sticks (non-sterile)

9. Gauze

10. Ring stand and ring for holding funnel

11. Glass beaker (500 ml)

C. Equipment

1. Binocular microscope with 10×, 40×, and 100× objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
2. Oculars should be 10×. Some workers prefer 5×; however, overall smaller magnification may make final organism identifications more difficult.
3. Centrifuge, tabletop

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. To ensure reliable results, follow routine procedures for optimal collection and handling of specimens for parasitologic examination.
- B. If available, examine known positive and negative samples of stools (from laboratory animals) to make sure that the procedure is precise.
- C. Review larval diagrams (any parasitology text) for confirmation of larval identification.
- D. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- E. Record all QC results.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. If possible, use a fresh fecal specimen that has been obtained after administration of a mild saline cathartic, not a stool softener. Soft stool is recommended, but any fresh fecal specimen is acceptable.
- C. Set up a clamp supporting a 6-in.-mouth glass funnel. Attach rubber tubing and a pinch clamp to the bottom of the funnel. Place a collection beaker underneath (*see* Fig. 9.5.1–1).
- D. Place wire gauze or a nylon filter over the top of the funnel (or resting within the funnel), and then place a pad consisting of two layers of gauze over that.
- E. Close the pinch clamp at the bottom of the tubing, and fill the funnel with tap water until it just soaks the gauze padding.
- F. Spread a large amount of fecal material on the gauze padding so the specimen is in contact with water. If the fecal material is very firm, emulsify in water.
- G. Allow the apparatus to stand for 2 or more hours, draw off 10 ml of fluid into the beaker by releasing the pinch clamp, centrifuge for 2 min at $500 \times g$, and examine the sediment under the microscope ($100\times$ and $400\times$) for the presence of motile larvae. *Make sure that the end of the tubing is well inside the beaker before slowly releasing the pinch clamp. Infective larvae may be present; wear gloves when performing this procedure.*
- H. If there are no larvae seen, allow the apparatus to stand at room temperature for 8 to 12 h and examine additional fluid (after centrifugation). Discard after 12 h.

VI. RESULTS

- A. Larval nematodes (hookworm, *Strongyloides* spp., or *Trichostrongylus* spp.) may be recovered.
- B. Both infective and noninfective *Strongyloides* larvae may be recovered, particularly in a heavy infection.

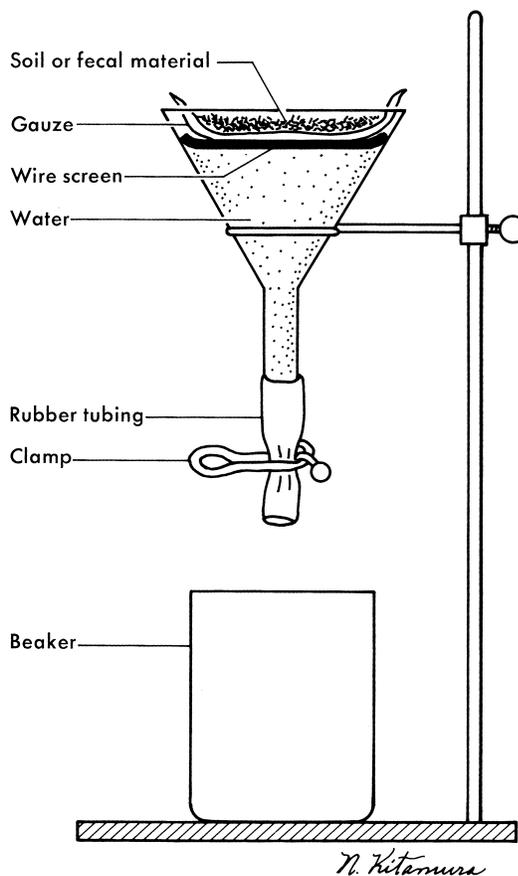

Figure 9.5.1–1 Diagram of the Baermann apparatus used for recovery of larval-stage nematodes (from reference 2).

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report your findings as “No larvae detected” if no larvae could be detected at the end of incubation.
- B. Report larvae detected by fecal culture.
Example: *Strongyloides stercoralis* larvae detected by fecal culture.

VIII. PROCEDURE NOTES

- A. It is often difficult to observe details in rapidly moving larvae. If desired, use slight heating or a drop of iodine or formalin to kill the larvae.
- B. Preserved fecal specimens or specimens obtained after a barium meal are not suitable for processing by this method.
- C. *Wear gloves when you perform this procedure.*
- D. When you release the pinch clamp, do it slowly to prevent splashing.
- E. For the same reason, hold the end of the tubing toward the bottom of the beaker.
- F. Infective larvae may be found any time after the fourth day and occasionally after the first day in heavy infections. *Caution must be exercised in handling the fluid, gauze pad, and beaker to prevent accidental infection. Always remember to wear gloves.*

IX. LIMITATIONS OF THE PROCEDURE

- A.** This technique allows both parasitic and free-living forms of nematodes to develop. If specimens have been contaminated with soil or water containing these forms, it may be necessary to distinguish parasitic from free-living forms. This distinction is possible, since parasitic forms are more resistant to slight acidity than are free-living forms. Proceed as follows (2–4). Add 0.3 ml of concentrated hydrochloric acid per 10 ml of water containing the larvae (adjust the volume to achieve a 1:30 dilution of acid). Free-living nematodes are killed, while parasitic species live for about 24 h.
- B.** Specimens that have been refrigerated are not suitable for culture. Larvae of certain species are susceptible to cold.

9.5.2

“Culture” of Larval-Stage Nematodes: Harada-Mori Technique

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

This filter paper test tube culture technique was initially introduced by Harada and Mori in 1955 (2) and was later modified by others (3, 5). The technique employs a filter paper to which fecal material is added and a test tube into which the filter

paper is inserted. Moisture is provided by adding water to the tube. The water continuously soaks the filter paper by capillary action. Incubation under suitable conditions favors hatching of ova and/or

development of larvae. Fecal specimens to be cultured should not be refrigerated, since some parasites (especially *Necator americanus*) are susceptible to cold and may fail to develop after refrigeration.

II. SPECIMEN

Observe standard precautions.

The specimen must be fresh stool that has not been refrigerated.

III. MATERIALS

A. Reagents

None

B. Supplies

1. Disposable glass or plastic pipettes
2. Glass slides (1 by 3 in. or larger)
3. Coverslips (22 by 22 mm; no. 1 or larger)
4. Filter paper (40 or 42 is fine; weight is not critical)
5. Wooden applicator sticks (nonsterile)
6. 15-ml-capacity conical tube
7. Forceps

C. Equipment

1. Binocular microscope with 10 \times , 40 \times , and 100 \times objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
2. Oculars should be 10 \times . Some workers prefer 5 \times ; however, overall smaller magnification may make final organism identifications more difficult.

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. To ensure reliable results, follow routine procedures for optimal collection and handling of specimens for parasitologic examination.
- B. If available, examine known positive and negative samples of stools (from laboratory animals) to make sure that the procedure is precise.
- C. Review larval diagrams (any parasitology text) for confirmation of larval identification.
- D. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (see procedures 9.1 and 9.3.2). Although there is not universal agreement, the

IV. QUALITY CONTROL

(continued)

microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.

- E. Record all QC results.

V. PROCEDURE

Figure 9.5.2-1 Diagram of Harada-Mori culture system (from reference 1).

- A. *Wear gloves when performing this procedure.*
- B. Cut a narrow (3/8 by 5 in.) strip of filter paper, and taper it slightly at one end. Smear 0.5 to 1 g of feces in the center of the strip.
- C. Add 3 to 4 ml of distilled water to a 15-ml conical centrifuge tube.
- D. Insert the filter paper strip into the tube so that the tapered end is near the bottom of the tube. The water level should be slightly (0.5 in.) below the fecal spot. It is not necessary to cap the tube. However, a cork stopper or a cotton plug may be used (*see* Fig. 9.5.2-1).
- E. Allow the tube to stand upright in a rack at 25 to 28°C. Add distilled water to maintain the original level (usually evaporation takes place over the first 2 days, but then the culture becomes stabilized).
- F. Keep the tube for 10 days, and check daily by withdrawing a small amount of fluid from the bottom of the tube. Prepare a smear on a glass slide, cover with a coverslip, and examine with the 10× objective.
- G. Examine the larvae for motility and typical morphological features to reveal whether hookworm, *Strongyloides*, or *Trichostrongylus* larvae are present.

VI. RESULTS

- A. Larval nematodes (hookworm, *Strongyloides* spp., or *Trichostrongylus* spp.) may be recovered.
- B. If *Strongyloides* organisms are present, free-living stages and larvae may be found after several days in culture.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report your findings as “No larvae detected” if no larvae could be detected at the end of incubation.
- B. Report larvae detected by fecal culture.
Example: *Strongyloides stercoralis* larvae detected by fecal culture.

VIII. PROCEDURE NOTES

- A. It is often difficult to observe details in rapidly moving larvae. If desired, use slight heating or a drop of iodine or formalin to kill the larvae.
- B. Infective larvae may be found anytime after day 4 or even on day 1 in a heavy infection. Since infective larvae may migrate upward as well as downward on the filter paper strip, be careful when handling the fluid and the paper strip itself to prevent infection. Handle the filter paper with forceps.
- C. It is important to maintain the original water level to keep optimum humidity.
- D. Preserved fecal specimens or specimens obtained after a barium meal are not suitable for processing by this method.
- E. *Wear gloves when you perform this procedure.*

IX. LIMITATIONS OF THE PROCEDURE

- A. This technique allows both parasitic and free-living forms of nematodes to develop. If specimens have been contaminated with soil or water containing these forms, it may be necessary to distinguish parasitic from free-living forms. This distinction is possible since parasitic forms are more resistant to slight acidity than are free-living forms. Proceed as follows (4, 6). Add 0.3 ml of concentrated hydrochloric acid per 10 ml of water containing the larvae (adjust the volume to achieve a 1:30 dilution of acid). Free-living nematodes are killed, while parasitic species live for about 24 h.
- B. Specimens that have been refrigerated are not suitable for culture. Larvae of certain species are susceptible to cold.
- C. This method requires too much time to be clinically useful, but it can be used for field or survey studies where rapid results are not that important. Due to the time factor, this method, as well as the petri dish-filter paper slant method (procedure 9.5.3), may be replaced by the agar plate method (procedure 9.5.4), which is not only more rapid but also more sensitive.

9.5.3

“Culture” of Larval-Stage Nematodes: Petri Dish-Filter Paper Slant

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

This alternative culture technique for recovery of nematode larvae was originally described by Little (1, 2). As in previously described techniques (procedure 9.5.2), sufficient moisture is provided by continuous soaking of filter paper in water. Stool material is placed on filter paper that has

been cut to fit the dimensions of a standard (1 by 3 in.) microscope slide. The filter paper is then placed on a slanted glass slide in a glass or plastic petri dish containing water. This technique has the added advantage of allowing the micro-

biologist to look for nematode larvae and free-living stages of *Strongyloides stercoralis* in the fecal mass or the surrounding water by direct examination of the preparation with a dissecting microscope without having to sample the preparation.

II. SPECIMEN

Observe standard precautions.

The specimen must be fresh stool that has not been refrigerated.

III. MATERIALS

A. Reagents

None

B. Supplies

1. Disposable glass or plastic pipettes
2. Glass slides (1 by 3 in., or larger if you prefer)
3. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)
4. Filter paper (40 or 42 is fine; weight is not critical)
5. Wooden applicator sticks (nonsterile)
6. Glass or plastic petri dish (100 by 15 mm)
7. Piece of glass rod or glass tubing cut to fit a petri dish (100 by 15 mm)

C. Equipment

1. Binocular microscope with 10 \times , 40 \times , and 100 \times objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
2. Oculars should be 10 \times . Some workers prefer 5 \times ; however, overall smaller magnification may make final organism identifications more difficult.
3. Dissecting microscope with at least two different magnifications

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. To ensure reliable results, follow routine procedures for optimal collection and handling of specimens for parasitologic examination.
- B. If available, examine known positive and negative samples of stools (from laboratory animals) to make sure that the procedure is precise.

IV. QUALITY CONTROL (continued)

- C. Review larval diagrams (any parasitology text) for confirmation of larval identification.
- D. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (see procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- E. Record all QC results.

V. PROCEDURE

- A. Wear gloves when performing this procedure.
- B. Cut a filter paper strip (1 by 3 in.), and smear a film of 1 to 2 g of fecal material in the center of the strip.
- C. Place the strip on a glass slide (1 by 3 in.). Place the slide at an incline (about 10°) at one end of the petri dish by resting the slide on a piece of glass rod or glass tubing.
- D. Add water to the petri dish so that the bottom one-fourth of the slide is immersed in water. Cover the dish, and keep at 25 to 28°C. As needed, add water to maintain the original level (see Fig. 9.5.3–1).
- E. Keep the dish for 10 days. Examine daily either by using the dissecting microscope or by withdrawing a small amount of fluid and placing it on a microscope slide. Add a coverslip, and examine microscopically with the 10× and 40× objectives.
- F. Examine any larvae recovered for typical morphological features.

VI. RESULTS

- A. Larval nematodes (hookworm, *Strongyloides* spp., or *Trichostrongylus* spp.)
- B. If *Strongyloides* organisms are present, free-living stages and larvae may be found after several days of culture.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report your findings as “No larvae detected” if no larvae could be detected at the end of incubation.
- B. Report larvae detected by fecal culture.
Example: *Strongyloides stercoralis* larvae detected by fecal culture.

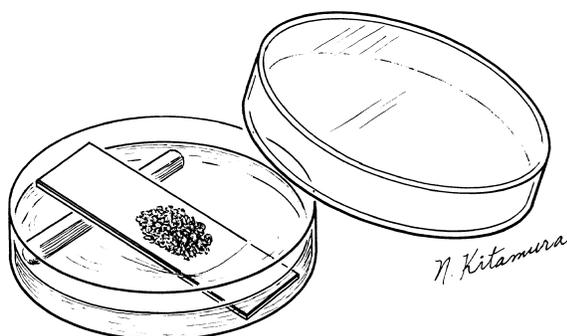

Figure 9.5.3–1 Diagram of petri dish-filter paper slant (from reference 1).

VIII. PROCEDURE NOTES

- A. It is often difficult to observe details in rapidly moving larvae. If desired, use slight heating or a drop of iodine or formalin to kill the larvae.
- B. Infective larvae may be found anytime after day 4. Since infective larvae may migrate upward as well as downward on the filter paper strip, be careful when handling the fluid and the paper strip itself to prevent infection.
- C. *Wear gloves when handling the cultures.*
- D. It is important to maintain the original water level to keep optimum humidity.
- E. Preserved fecal specimens or specimens obtained after a barium meal are not suitable for processing by this method.

IX. LIMITATIONS OF THE PROCEDURE

- A. This technique allows both parasitic and free-living forms of nematodes to develop. If specimens have been contaminated with soil or water containing these forms, it may be necessary to distinguish parasitic from free-living forms. The method for doing so depends on the fact that parasitic forms are more resistant to slight acidity than are free-living forms. Proceed as follows (3, 4). Add 0.3 ml of concentrated hydrochloric acid per 10 ml of water containing the larvae (adjust the volume to achieve a 1:30 dilution of acid). Free-living nematodes are killed, while parasitic species live for about 24 h.
- B. Specimens that have been refrigerated are not suitable for culture. Larvae of certain species (*Necator americanus*) are susceptible to cold.
- C. This method requires too much time to be clinically useful, but can be used for field or survey studies where rapid results are not that important. Due to the time factor, this method, as well as the Hara-Mori filter paper slant method (procedure 9.5.2), may be replaced by the agar plate method (procedure 9.5.4), which is not only more rapid but also more sensitive.

9.5.4

“Culture” of Larval-Stage Nematodes: Agar Plate Culture for *Strongyloides stercoralis*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Agar plate cultures are recommended for the recovery of *Strongyloides stercoralis* larvae and tend to be more sensitive than some of the other diagnostic methods (1, 3, 4, 9). Stool is placed onto agar plates, and the plates are sealed to prevent accidental infections and held for 2 days at room temperature. As the larvae crawl over the agar, they carry bacteria with them, thus creating visible tracks over the agar. The plates are examined under the microscope for confirmation of larvae, the surface of the agar is then washed with 10% formalin, and final confirmation of larval identification is made via wet examination of the sediment from the formalin washings (Fig. 9.5.4–1).

In a study looking at the prevalence of *S. stercoralis* in three areas of Brazil, the diagnostic efficacy of the agar plate culture method (included in this procedure)

was as high as 93.9%, compared to only 28.5 and 26.5% for the Harada-Mori filter paper culture and fecal concentration methods, when fecal specimens were processed using all three methods (8). Among the 49 positive samples, about 60% were confirmed as positive using only the agar plate method. These results indicate that the agar plate approach is probably a much more sensitive diagnostic method, and it is recommended for the diagnosis of strongyloidiasis.

It is important to remember that more than half of *S. stercoralis*-infected individuals tend to have low-level infections (10). The agar plate method continues to be documented as a more sensitive method than the usual direct smear or fecal concentration methods (6, 7). Daily search for furrows on agar plates for up to six consecutive days results in increased sensitiv-

ity for diagnosis of both *S. stercoralis* and hookworm infections. Also, a careful search for *S. stercoralis* should be made in all patients with comparable clinical findings before deciding on a diagnosis of idiopathic eosinophilic colitis, because consequent steroid treatment may have a fatal outcome by inducing widespread dissemination of the parasite (2).

Human T-cell leukemia virus 1 (HTLV-1) infection is endemic in a number of Latin American countries. HTLV-1-associated myelopathy/tropical spastic paraparesis and adult T-cell leukemia lymphoma are emerging diseases in the region. *S. stercoralis* hyperinfection syndrome and therapeutic failure in apparently healthy patients with nondisseminated strongyloidiasis may be markers of HTLV-1 infection (5).

II. SPECIMEN

Observe standard precautions.

The specimen must be fresh stool that has not been refrigerated.

III. MATERIALS

A. Reagents (see Appendix 9.5.4–1)

B. Supplies

1. Disposable glass or plastic pipettes
2. Glass slides (1 by 3 in., or larger if you prefer)
3. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)
4. Plastic petri dish (100 by 15 mm)
5. Wooden applicator sticks (nonsterile)
6. Glass or plastic centrifuge tube (15 ml)
7. Plastic bags (large enough to hold several petri plates)
8. Metal forceps (no shorter than 3 to 4 in.)
9. Cellulose tape

C. Equipment

1. Binocular microscope with 10×, 40×, and 100× objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
2. Oculars should be 10×. Some workers prefer 5×; however, overall smaller magnification may make final organism identifications more difficult.
3. Dissecting microscope with at least two different magnifications

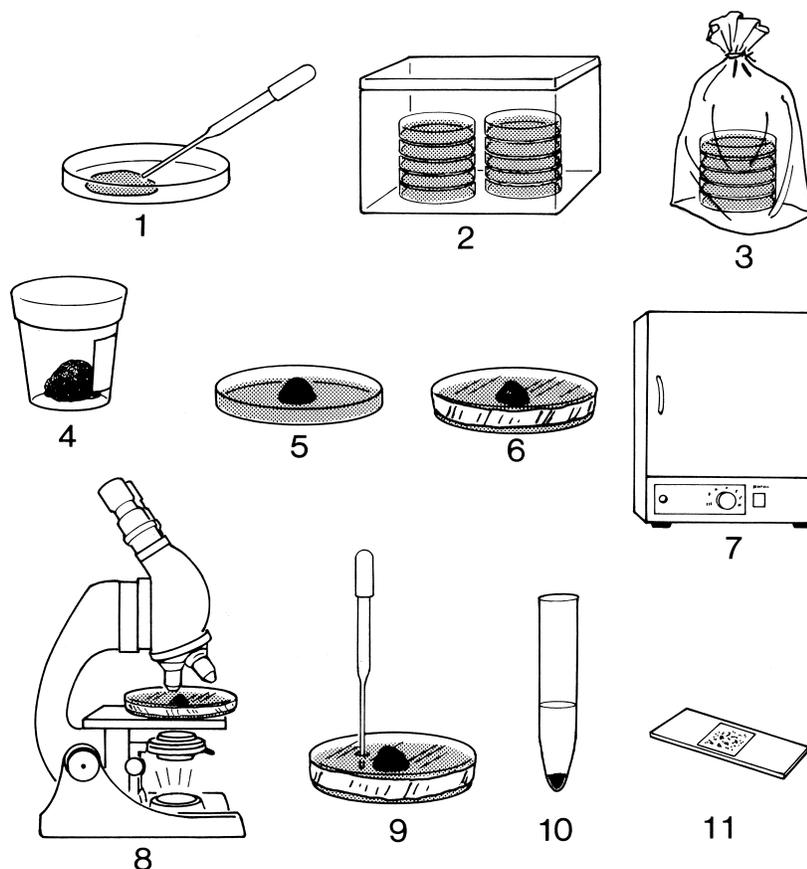

Figure 9.5.4-1 Agar culture method for *S. stercoralis*. (1) Agar plates are prepared; (2) agar is dried for 4 to 5 days on the bench top; (3) plates are stored in plastic bags; (4) fresh stool is submitted to the laboratory; (5) approximately 2 g of stool is placed onto an agar plate; (6) the plate is sealed with tape; (7) the culture plate is incubated at 26 to 33°C for 2 days; (8) the plate is examined microscopically for the presence of tracks (bacteria carried over agar by migrating larvae); (9) 10% formalin is placed onto agar through a hole made in the plastic with hot forceps; and (10) material from the agar plate is centrifuged and (11) examined as a wet preparation for rhabditiform or filariform larvae (high dry power; magnification, $\times 400$). (Illustration by Sharon Belkin; from reference 3).

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. To ensure reliable results, follow routine procedures for optimal collection and handling of specimens for parasitologic examination.
- B. Examine agar plates to ensure that there is no cracking and the agar pour is sufficient to prevent drying. Also, make sure there is no excess water on the surfaces of the plates.
- C. Review larval diagrams and descriptions (any parasitology text) for confirmation of larval identification.
- D. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope). Although there is not universal agreement, the microscope should

IV. QUALITY CONTROL*(continued)*

probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.

- E. Record all QC results (condition of agar plates).

V. PROCEDURE

- A. Place approximately 2 g of fresh stool in the center of the agar plate (area of approximately 1 in. in diameter).
- B. Replace the lid and seal the plate with cellulose tape or shrink seal.
- C. Maintain the agar plate (right side up) at room temperature for 2 days.
- D. After 2 days, examine the sealed plates through the plastic lid under the microscope for microscopic colonies that develop as random tracks on the agar and evidence of larvae at the ends of the tracks away from the stool.
- ▣ **NOTE:** It has been documented that daily search for furrows on agar plates for up to six consecutive days results in increased sensitivity for diagnosis of both *S. stercoralis* and hookworm infections (7). When trying to rule out strongyloidiasis in immunocompromised patients or in those who may receive immunosuppressives, it is recommended that two plates be set up, one that can be examined after 2 days and one that can be examined after the full 6 days.
- E. With the end of hot forceps (heat the end of the forceps until able to melt plastic), make a hole in the top of the plastic petri dish.
- F. Gently add 10 ml of 10% formalin through the hole onto the agar surface, swirl to cover the surface, and rinse the agar plate. Allow to stand for 30 min.
- G. Remove the tape and lid of the agar plate. Pour the 10% formalin through a funnel into a centrifuge tube. Do not try and pour the formalin off directly into the centrifuge tube; the size of the tube opening is too small, and formalin will be spilled onto the counter.
- H. Centrifuge formalin rinse fluid for 5 min at $500 \times g$.
- I. Prepare wet-smear preparation from sediment, and examine using the $10\times$ objective (low power) for the presence of larvae. If larvae are found, confirm identification using the $40\times$ objective (high dry power).

VI. RESULTS

- A. Larval nematodes (hookworm, *Strongyloides* spp., or *Trichostrongylus* spp.)
- B. If *Strongyloides* organisms are present, free-living stages and larvae may be found after several days on the agar plates.

POSTANALYTICAL CONSIDERATIONS**VII. REPORTING RESULTS**

- A. Report your findings as “No larvae detected” if no larvae could be detected at the end of incubation and rinse procedure.
- B. Report larvae detected by agar plate culture.
Example: *Strongyloides stercoralis* larvae detected by fecal culture.

VIII. PROCEDURE NOTES

- A. It is often difficult to observe details in rapidly moving larvae. If desired, use slight heating or a drop of iodine or formalin to kill the larvae.
- B. Infective larvae may be found anytime after the first or second day or even on the first day in a heavy infection. *Since infective larvae may be present on the agar, caution must be exercised in handling the plates once the cellulose tape is removed. Wear gloves when handling the cultures.*
- C. It is important to maintain the plates upright at room temperature. Do not incubate or refrigerate at any time; this also applies to the fresh stool specimen.

VIII. PROCEDURE NOTES*(continued)*

- D. Fresh stool is required for this procedure; preserved fecal specimens or specimens obtained after a barium meal are not suitable for processing by this method.

IX. LIMITATIONS OF THE PROCEDURE

- A. This technique is successful if any larvae present are viable. If the fresh stool specimen is too old, larvae may not survive and a negative result will be reported.
- B. Specimens that have been refrigerated or preserved are not suitable for culture. Larvae of certain species (*Necator americanus*) are susceptible to cold environments.

APPENDIX 9.5.4–1

Agar: 1.5% agar
 0.5% meat extract
 1.0% peptone
 0.5% NaCl

■ **NOTE:** Positive tracking on agar plates has been seen with a number of different types of agar. However, the most appropriate agar formula is that seen above.

9.5.5

Determination of Egg Viability: Schistosomal Egg Hatching

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The diagnosis of schistosomal infections can be aided by this method. When eggs of *Schistosoma mansoni* or *Schistosoma japonicum* are scarce, their presence may be detected by allowing them to hatch. Upon dilution of a specimen with spring (nonchlorinated) water, eggs hatch within a few hours, after which the preparation is examined for free-swimming miracidia

(1–4). Miracidia are phototropic; that is, they have a tendency to swim toward light. This procedure takes advantage of the organisms' phototropism. This is a very sensitive test for indirectly demonstrating small numbers of viable eggs in fecal specimens. This technique also allows one to determine the viability of the eggs. This is not a concentration technique; therefore,

unless tests for egg viability are desired, there is seldom any point in using this technique to look for schistosome eggs in urine, in which they are readily concentrated by centrifugation. McMullen and Beaver (3) recommended the use of a side-arm flask, but an Erlenmeyer flask may be an acceptable substitute.

II. SPECIMENS

Observe standard precautions.

- A. Fresh stool that has not been refrigerated
- B. Urine (24 h) collected with no preservatives
- C. Urine (random) collected with no preservatives

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Reagents

- Indicate the expiration date on the label and in the work record or on the manufacturer's label.
- 1. 0.85% NaCl
- 2. Spring water (nonchlorinated)

B. Supplies

- 1. Gauze
- 2. Funnel
- 3. Centrifuge tubes (50 ml)
- 4. 250-ml beaker
- 5. 500-ml sidearm flask or Erlenmeyer flask
- 6. Magnifying lens (hand lens)
- 7. Aluminum foil or brown paper

C. Equipment

- 1. Lamp (desk, gooseneck, or comparable)
- 2. Binocular microscope with 10×, 40×, and 100× objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
- 3. Oculars should be 10×. Some workers prefer 5×; however, overall smaller magnification may make final organism identifications more difficult.

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Make sure that water used in this procedure is chlorine free. Chlorine will affect the viability of miracidia.
- B. Check saline solution for the presence of any free-living organisms (flagellates or ciliates).

IV. QUALITY CONTROL (continued)

- C. If available, known positive and negative samples should be examined to make sure that the procedure is acceptable. Since this is not usually practical, review drawings and size measurements of schistosomal eggs and/or miracidia (any parasitology text).
- D. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- E. Record all QC results.

V. PROCEDURE

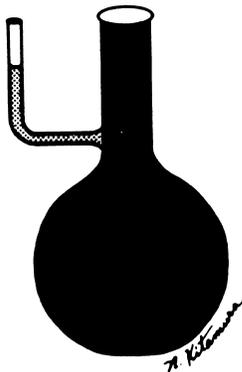

Figure 9.5.5-1 Diagram of a sidearm hatching flask (from reference 2).

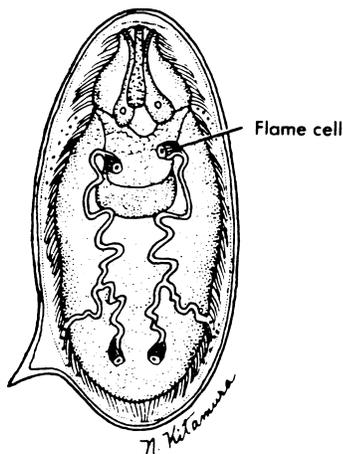

Figure 9.5.5-2 Diagram of a schistosomal miracidium within the egg shell (from reference 2).

- A. Homogenize a stool specimen (40 to 50 g) in 50 to 100 ml of 0.85% NaCl.
- B. Strain specimen through two layers of gauze placed on a funnel. Collect material in a centrifuge tube.
- C. Allow the suspension to settle for 1 h. Pour off and discard the supernatant fluid, and repeat this process (steps V.B and V.C) at least twice.
- D. Decant and discard the saline solution, suspend the sediment in a small quantity of chlorine-free (spring) water, and pour the suspension into a 500-ml sidearm flask or an Erlenmeyer flask (Fig. 9.5.5-1).
- E. Add chlorine-free water to the flask so that the fluid level rises to 2 to 3 cm in the sidearm flask or to the top 2 cm of the Erlenmeyer flask. Cover the flask with aluminum foil or black paper, leaving the side arm of the flask exposed to light. If an Erlenmeyer flask is used, cover to 1 cm below the level of fluid in the neck of the flask.
- F. Allow the flask to stand at room temperature for several hours or overnight in subdued light.
- G. When ready for examination, place a bright light at the side of the flask opposite the surface of exposed water. Do not place the light against the glass to avoid generation of excess heat. As the eggs hatch, the liberated miracidia will swim to the upper layers and collect in the side arm (or neck region of an Erlenmeyer flask) (Fig. 9.5.5-2).
- H. Examine the illuminated area with a magnifying lens (hand lens) to look for minute white organisms swimming rapidly in a straight line (placing a piece of dark cardboard behind the flask will help you see the white miracidia against the dark background).

VI. RESULTS

- A. Living miracidia may be seen.
- B. Failure to see living miracidia does not rule out schistosomiasis.

POSTANALYTICAL CONSIDERATIONS**VII. REPORTING RESULTS**

- A. Report as “Miracidia of schistosomes detected, indicating presence of viable eggs.”
- B. Report as “No miracidia of schistosomes detected; presence of eggs is not ruled out by this procedure.”

VIII. PROCEDURE NOTES

- A. Both urine and stool specimens must be collected without preservatives and should not be refrigerated prior to processing.
- B. Hatching will not occur until the saline is removed and nonchlorinated water is added.
- C. If a stool concentration is performed, use saline throughout the procedure to prevent premature hatching.
- D. Make sure the light is not too close to the side arm or top layer of water in the Erlenmeyer flask. Excess heat will kill the miracidia.

IX. LIMITATIONS OF THE PROCEDURE

- A. Absence of swimming miracidia does not rule out the presence of eggs. Non-viable eggs or eggs that did not hatch will not be detected by this method. Use microscopic examination of direct or concentrated specimens to demonstrate the presence or absence of eggs.
- B. Egg viability can be determined by placing some stool or urine sediment (same material as that used for the hatching flask) on a microscope slide.
 1. Examine under 100× to locate eggs.
 2. Examine individual eggs under 400×, and look for moving cilia on the flame cells (primitive excretory system) (Fig. 9.5.5–2).
 3. Presence of moving cilia is proof of egg viability.
- C. Coprozoic, free-living ciliates may be present in soil-contaminated water. Therefore, it may be necessary to perform the following steps to differentiate those forms from the parasitic miracidia (4).
 1. Transfer a few drops of the suspension containing the organisms to a slide (3 by 2 in.), and examine under the microscope.
 2. Add a drop of weak iodine solution (pale-tea color) or dilute methylene blue (pale blue).
 3. Parasitic miracidia will stop moving, but free-living forms will continue to move.

9.5.6

Recovery of Scolices and Proglottids of Cestodes

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Occasionally, stool specimens have to be examined for the presence of scolices and gravid proglottids of cestodes for proper species identification. This procedure requires mixing a small amount of feces with water and straining the mixture through a wire screen to look for scolices and proglottids (1). The same procedure may be used to look for small adult nem-

atodes and trematodes (2). Appearance of scolices after therapy is an indication of successful treatment. *If scolices have not been passed, they may be attached to the mucosa. The parasite is capable of producing more segments from the neck region of the scolex, and the infection continues.*

II. SPECIMEN

Observe standard precautions.

- A. Fresh feces obtained prior to or after therapy
- B. For posttherapy specimen, the patient must receive a saline purge immediately after taking niclosamide or praziquantel.
- C. Stool specimen (24 h) collected in 10% formalin

III. MATERIALS

Include QC information on reagent container and in QC records.

- A. **Reagent**
 - ☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.
- B. **Supplies**
 1. Small-mesh (30/50 mesh) sieve or screen
 2. Glass slides (1 by 3 in. or larger)
 3. Wooden applicator sticks (nonsterile)
- C. **Equipment**
 4. 500-ml beaker
 5. Magnifying lens (hand lens)
 6. Glass dish
 7. Rubber bands (small)
 8. Shallow pan
 1. Wood's lamp (optional)
 2. Stereoscope (dissecting microscope)

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. To ensure reliable results, follow routine procedures for optimal collection and handling of specimens for parasitologic examination.
- B. Review diagrams and sizes (any parasitology text) of proglottids and scolices of tapeworms.

V. PROCEDURE

- A. Mix a 24-h stool specimen (fresh or preserved in 10% formalin) with water, and thoroughly break up the specimen to make a watery suspension.
- B. Slowly strain small portions of the suspension (or the purged stool) through a double layer of screen wire or a sieve (one coarse-mesh screen placed over a fine-mesh screen).
- C. Wash off the sediment remaining from each portion by running a slow current of water over it.
- D. Examine the cleansed debris with a hand lens to look for scolices and proglottids (*Taenia* scolex is 0.5 to 1 cm long and 1 to 2 mm wide).
- E. Repeat steps V.C and V.D for each portion of the suspension strained.
- F. Collect the strained sediment in a glass dish, and place over a black surface to increase the contrast of organisms against the background.
- G. Observe with a magnifying hand lens, and pick out pieces of worms with an applicator stick.
- H. Rinse gravid proglottids and/or scolices with tap water, and place between two microscope slides separated at the edges by thin pieces of cardboard.
- I. Fasten the preparation by placing rubber bands at each end of the slides so that the segments become somewhat flattened.
- J. Use the low power of a dissecting microscope for determining the number of uterine branches and genital pores in the segments and the presence or absence of a rostellum of hooks on the scolex.
- K. India ink injection of proglottid
 1. Using a syringe (1 ml or less) and a 25-gauge needle, inject India ink into the central uterine stem of the proglottid, thus filling the uterine branches with ink, or inject ink into the uterine pore.
 2. Rinse the proglottid in water or saline.
 3. Blot the proglottid dry on paper towels, and press it between two slides.
 4. Use the low power of a dissecting microscope for determining the number of uterine branches.

VI. RESULTS

- A. Tapeworm proglottids may be recovered (either singly or with several attached together).
- B. A scolex may or may not be seen.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report as "A search for adult worms reveals presence/absence of . . . [finding]." **Example:** *Taenia saginata* scolex present.
- B. Indicate species of gravid proglottid. **Example:** *Taenia solium* proglottid

VIII. PROCEDURE NOTES

- A. Remember that *T. solium* eggs are infective (cysticercosis), as are the eggs of *Hymenolepis nana*.
- B. Wear gloves when performing this procedure.
- C. Specimens preserved in 70% alcohol are recommended.
- D. After the identification has been made, leave the proglottid between the two slides (place a rubber band around the slides), dehydrate through several changes of ethyl alcohol (50, 70, 90, and 100%), clear in two changes of xylene, and mount with Permount for a permanent record. After xylene treatment, the proglottid will be stuck to one of the two slides. Do not try to remove it (will crack; very brittle), but merely put the Permount onto the proglottid and add the cover slip.

VIII. PROCEDURE NOTES

(continued)

- E. The proglottid of *T. solium* must be gravid, containing the fully developed uterine branches. If the proglottid is not fully developed (gravid), the branches may not be visible; when the uterine branches cannot be seen and/or counted, the proglottid cannot be accurately identified to the species level.
- F. If the patient has received niclosamide or praziquantel, a purged specimen is required, and it should be immediately preserved in 10% formalin.
- G. Wood's lamp may be used to search for scolices if the patient has been given quinacrine dyes. The worms, having absorbed the dye, will fluoresce at a wavelength of 360 nm. Also, after the use of guinacrine, tapeworm proglottids will appear yellow.

IX. LIMITATIONS OF THE PROCEDURE

- A. Niclosamide or praziquantel therapy leads to dissolution of the tapeworm. Therefore, the scolex and other parts may be difficult to recover unless the patient receives a saline purge soon after taking the medication.
- B. It may often be difficult to identify proglottids without staining. This may be achieved by staining with India ink (*see* item V.K above).
- C. If the proglottid is not gravid or has started to disintegrate, it will be difficult to see the uterine branches, even after India ink injection.

9.6.1

Examination for Pinworm:
Cellulose Tape Preparation

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The clear-cellulose-tape preparation is the most widely used procedure for the detection of human pinworm infections (2, 4). Adult *Enterobius vermicularis* worms inhabit the large intestine and rectum; however, the eggs are not normally found in

fecal material. The adult female migrates out the anal opening and deposits the eggs on the perianal skin, usually during the night. The eggs, and occasionally the adult female worms, stick to the sticky surface of the cellulose tape. These cellulose tape

preparations are submitted to the laboratory, where they are examined under the microscope. Commercial collection systems are also available (pinworm collection kit; Evergreen Scientific, Los Angeles, Calif.) (1).

II. SPECIMEN

Observe standard precautions.

The specimen is collected from the skin of the perianal area first thing in the morning, before the patient has bathed or used the toilet. Preparations should be taken for at least 4 to 6 consecutive days with negative results before a patient is considered free of the infection.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Reagent

- Indicate the expiration date on the label and in the work record or on the manufacturer's label.
- Xylene (or xylene substitute [ethyl acetate]) or toluene

B. Supplies

1. Clear cellulose tape (not Magic mend tape)
2. Tongue depressors
3. Glass slides (1 by 3 in., or larger if you prefer)

C. Equipment

1. Binocular microscope with 10×, 40×, and 100× objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
2. Oculars should be 10×. Some workers prefer 5×; however, overall smaller magnification may make final organism identifications more difficult.

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (see procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.

IV. QUALITY CONTROL (continued)

- B. Pictures of *Enterobius* eggs (with measurements) should be available for comparison with the clinical specimen.
- C. Record all QC results.

V. PROCEDURE

- A. Place a strip of clear cellulose tape (adhesive side down) on a microscope slide as follows: starting ca. 1.5 cm from one end, run the tape toward the same end, and wrap the tape around the slide to the opposite end. Tear the tape even with the end of the slide. Attach a label to the tape at the end torn flush with the slide.
- B. To obtain a sample from the perianal area, peel back the tape by gripping the labeled end, and, with the tape looped (adhesive side outward) over a wooden tongue depressor that is held firmly against the slide and extended about 2.5 cm beyond it, press the tape firmly several times against the right and left perianal folds (see Fig. 9.6.1–1).
- C. Smooth the tape back on the slide, adhesive side down.
- D. Label with patient name and date.
- E. Submit the tapes and slides to the laboratory in a plastic bag.
- F. Examine the slide directly under the low-power objective (10×) of the microscope. To make the eggs more visible, lift the tape from the slide and add a drop of xylene or toluene to the slide. Press the tape back down on the slide. Examine with low light intensity on low power.

VI. RESULTS

- A. Typical pinworm eggs are thick shelled and football shaped, with one flattened side, and may contain a partially or fully developed larva.
- B. Adult female worms are occasionally seen on the tape preparation. The worms are approximately 1 cm in length, are white or cream colored, and have a pointed tail.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the organism and stage. Do not use abbreviations.
Example: *Enterobius vermicularis* eggs present.
- B. Report adult worms.
Example: *Enterobius vermicularis* adult worm present.

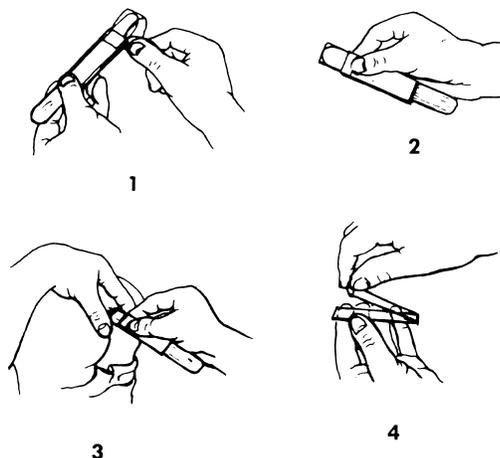

Figure 9.6.1–1 Collection of *E. vermicularis* eggs by the cellulose tape method (from reference 1).

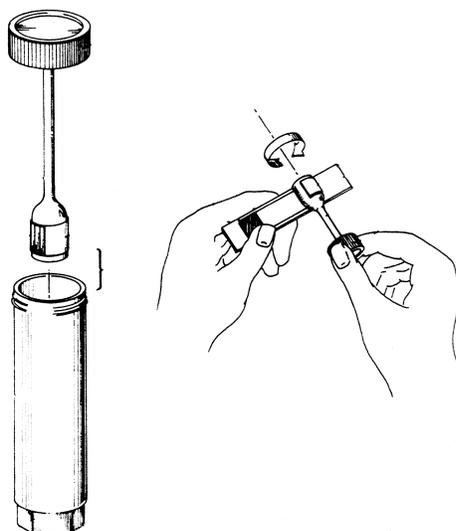

Figure 9.6.1–2 Diagram of a commercial kit (Evergreen Scientific) for use in sampling the perianal area for the presence of pinworm (*E. vermicularis*) eggs. On the left is the vial containing the sampler, which has sticky tape around the end. Once this is applied to the perianal area and eggs are picked up on the tape, the label area is placed at one end of the slide. The sticky tape is rolled down the slide and attaches to the glass. This device is easy to use and provides an area sufficient for adequate sampling. A minimum of four to six consecutive negative tapes are required to rule out a pinworm infection; most laboratories are accepting four rather than requesting the full six. (From reference 1.)

VII. REPORTING RESULTS (continued)

C. Report negatives.

Example: No *Enterobius vermicularis* eggs or adults seen.

VIII. PROCEDURE NOTES

- A. Pinworm eggs are usually infectious. The use of glass slides and tapes may expose laboratory personnel to these eggs.
- B. Some recommend the use of the Swube (paddle with sticky adhesive coat; Becton Dickinson) as a safer alternative. The petrolatum swab is another alternative (3). Another option is the collection system available from Evergreen Scientific (Fig. 9.6.1–2).
- C. If opaque tape is submitted by mistake, a drop of immersion oil on the top of the tape will clear it enough to proceed with the microscopic examination.

IX. LIMITATIONS OF THE PROCEDURE

- A. The female pinworm deposits eggs on the perianal skin only sporadically.
- B. Without multiple tapes (taken consecutively, one each morning), it is not possible to determine if the patient is positive or negative for the infection.
- C. Occasionally, a parent will bring in an adult worm collected from the perianal skin or from the surface of the stool. The identification of the adult worm (almost always the female) confirms the infection.

9.6.2

Sigmoidoscopy Specimen: Direct Wet Smear

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The direct smear (1, 2) is primarily used to detect motile parasites that are found in the colon (the organism in question is usually *Entamoeba histolytica* or *Entamoeba histolytica/E. dispar*). Specific ulcerated areas should always be sampled; in the absence of specific lesions, the mucosa is

randomly sampled. On low-power ($\times 100$) examination of the smear, motility of trophozoites and/or human cells might be detected. At high dry power ($\times 430$), organisms might be tentatively identified on the basis of size, nucleus/cytoplasm ratio, appearance of the cyto-

plasm, and motility (saline only). The direct smear can be prepared either with 0.85% NaCl or with iodine (Lugol's or D'Antoni's). Presumptive findings using this procedure must be confirmed by some type of permanent stained smear.

II. SPECIMEN

Observe standard precautions.

- A. The specimen may consist of mucosal lining, mucus, stool, and/or a combination of the three. The specimen will be taken by the physician and either prepared at bedside for immediate review or submitted to the laboratory for subsequent examination.
- B. Prepare direct wet mounts on clean, new glass slides (1 by 3 in.). Depending on the specimen type, the following amounts should be used.
 1. For mounts of mucus or similar material, place approximately 1 or 2 drops on the slide.
 2. For mounts of stool, place approximately 1 or 2 drops on the slide.
 3. If the material is very wet (watery), place 1 or 2 drops on the slide.
- C. If the specimen must be transported to the laboratory, the material can be placed in a small amount of 0.85% NaCl (0.5 to 1.0 ml) to keep the specimen from drying out. These specimens should be transported to the laboratory within no more than 30 min from collection time and should be examined immediately. If this is not possible, then the material can be preserved and processed as a permanent stained smear (*see* procedure 9.6.3).

III. MATERIALS

- A. **Reagents** (*see* Appendix 9.6.2-1)
- B. **Supplies**
 1. Disposable glass or plastic pipettes
 2. Glass slides (1 by 3 in., or larger if you prefer)
 3. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)
 4. Small tubes containing 0.5 to 1.0 ml of 0.85% NaCl
- C. **Equipment**
 1. Binocular microscope with 10 \times , 40 \times , and 100 \times objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
 2. Oculars should be 10 \times . Some workers prefer 5 \times ; however, overall smaller magnification may make final organism identifications more difficult.
 3. Tabletop centrifuge (for tubes containing specimen and 0.85% NaCl if the specimen is submitted in saline)

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Check the direct-mount reagents each time they are used.
 - 1. The saline should be clear, with no visible contamination.
 - 2. The iodine should be a strong-tea color, and there should be crystals in the bottom of the bottle. Small aliquots of the stock solution should always be strong-tea color. If not, then discard and aliquot some stock solution into your dropper bottle.
- B. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- C. Record all QC results.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. To the drop or two of patient material on the slide, add 1 or 2 drops of 0.85% NaCl, mix with the corner of the coverslip or an applicator stick, and mount with a no. 1 coverslip (22 by 22 mm). The amount of saline will be determined by the specimen (less saline if the material is very liquid).
- C. Examine the smear with the low-power (10 ×) objective with low light. View each field for a few seconds, looking for any organism motility. Any suspicious objects can be examined with the high dry (40×) power objective with low light.
- D. Prepare a wet mount with Lugol's or D'Antoni's iodine (working solution) rather than saline. Another option would be to add a small drop of iodine at the side of the coverslip on the saline wet preparation. The iodine will diffuse into the saline suspension under the coverslip. However, if the specimen is thick or contains mucus, then capillary action pulling the iodine under the coverslip and into the saline may not occur, and a separate iodine mount may be required. The addition of iodine will give the material some color (organisms may be easier to see), but motility will be lost.

VI. RESULTS

- A. Protozoan trophozoites may be confused with human cells (macrophages), so report any identification as presumptive until the permanent stained smears have been examined.
- B. Also, the presumptive identification and quantitation of the human cells (macrophages, PMNs, eosinophils, RBCs) could be obtained from the wet preparations. Consider this information presumptive also until the permanent stained smears have been examined.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the organism and stage (trophozoite, cyst, oocyst, etc.; do not use abbreviations); however, confirmation of species may require some type of permanent stained smear.
Example: *Cryptosporidium parvum* oocysts
- B. Note and quantitate the presence of human cells.
Examples: Moderate WBCs, many RBCs, few macrophages
- C. Call the physician if pathogenic organisms are identified.
- D. Report negative results as a presumptive report (based on wet examination only) prior to the examination of the permanent stained smear.
- E. See Table 9.6.2–1 for correct method of quantitation.

VIII. PROCEDURE NOTES

- A. Remember that the iodine working solution should be a strong-tea color; if it is not, discard and prepare new working solution.
- B. Final identification of some of the intestinal protozoa may be difficult (small size, confusion between organisms and human cells), and a permanent stained smear must be used as a confirmatory method and examined at $\times 1,000$ to see morphological details.
- C. In saline, human cells and/or protozoan trophozoites may exhibit some motility.
- D. In iodine, human cells and/or protozoan trophozoites may be seen (no motility).
- E. Confirm presumptive findings (either positive or negative) with a permanent stained smear.

IX. LIMITATIONS OF THE PROCEDURE

- A. Multiple areas of the mucosa should be examined (six smears are often recommended), and this technique should not take the place of the routine ova and parasite examination.
- B. Wet preparations are normally not examined with oil immersion power ($100\times$). Consequently, use permanent stained smears to confirm morphology and organism (or human cell) identification.
- C. If the specimen amount is limited, then do not do the wet preparation, but process the specimen that is available by using the permanent-stained-smear protocol (*see* procedure 9.6.3) to maximize the amount and clinical relevance of the information obtained.
- D. Morphologic differentiation between the *Entamoeba histolytica*/*E. dispar* group and *Entamoeba coli* can be difficult, in addition to the problem of differentiating human cells from protozoa. Also, unless RBCs are seen, it will be impossible

Table 9.6.2–1 Quantitation of parasites, human cells, yeast cells, and artifacts in specimens from the intestinal tract^a

Quantity	No. of protozoa, human cells, yeast cells, artifacts		No. of helminths/coverlip ^b
	Per 10 oil immersion fields ($\times 1,000$) ^c	Per 10 $40\times$ fields ($\times 400$) ^d	
Few	≤ 2	≤ 2	≤ 2
Moderate	3–9	3–9	3–9
Many	≥ 10	≥ 10	≥ 10

^a In general, protozoa are not quantitated on the laboratory slip (exception: *Blastocystis hominis*), but human cells, yeast cells, and artifacts like Charcot-Leyden crystals are normally reported and quantitated.

^b Wet preparation. Coverslips were 22 by 22 mm.

^c Polyvinyl alcohol smear.

^d Wet preparation.

IX. LIMITATIONS OF THE PROCEDURE (continued)

to differentiate organisms in the *E. histolytica*/*E. dispar* group from the actual pathogen, *E. histolytica*.

REFERENCES

1. **Garcia, L. S.** 2001. *Diagnostic Medical Parasitology*, 4th ed., p. 805. ASM Press, Washington, D.C.
2. **Melvin, D. M., and M. M. Brooke,** 1985. *Laboratory Procedures for the Diagnosis of Intestinal Parasites*. U.S. Department of Health and Human Services publication no. (CDC) 85-8282. U.S. Government Printing Office, Washington, D.C.

APPENDIX 9.6.2-1

Include QC information on reagent container and in QC records.

Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. 0.85% NaCl

1. Dissolve in distilled water in an appropriate glass flask by using a magnetic stirrer.

sodium chloride (NaCl) 850 mg
distilled water 100 ml

2. Store in a glass bottle.
3. Label as 0.85% NaCl with the preparation date and an expiration date of 6 months. Store at room temperature.

B. Modified D'Antoni's stock iodine

1. Dissolve in distilled water in an appropriate glass flask, using a magnetic stirrer.

potassium iodide (KI) 1.0 g
powdered iodine crystals 1.5 g
distilled water 100 ml

2. The D'Antoni's solution should be saturated with iodine, with some excess crystals left in the bottle. Store in a brown bottle at room temperature. The stock solution remains good as long as an excess of iodine crystals remains on the bottom of the bottle.
3. Label as D'Antoni's stock iodine with the preparation date and an expiration date of 1 year.
4. Small amounts of stock iodine solution can be aliquoted into brown dropper bottles for routine daily use. The expiration date will be from 30 to 60 days, depending on the amount of fading of the solution from the normal strong-tea color (smaller dropper bottles and use of clear glass result in a shorter expiration time). The use of a brown bottle will lengthen the expiration time.

C. Lugol's iodine solution

1. Dissolve in distilled water in an appropriate glass flask by using a magnetic stirrer.

potassium iodide (KI) 10.0 g
iodine crystals 5.0 g
distilled water 100 ml

2. The Lugol's solution should be saturated with iodine, with some excess crystals left in the bottle. Store in a brown bottle at room temperature. The stock solution remains good as long as an excess of iodine crystals remains on the bottom of the bottle.
3. Label as Lugol's stock iodine with the preparation date and an expiration date of 1 year.
4. Small amounts of stock iodine solution can be aliquoted into brown dropper bottles for routine daily use. The expiration date will be from 30 to 60 days, depending on the amount of fading of the solution from the normal strong-tea color (smaller dropper bottles and the use of clear glass result in a shorter expiration time). The use of a brown bottle will lengthen the expiration time.

9.6.3

Sigmoidoscopy Specimen: Permanent Stained Smear

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The permanent stained smear is used primarily to detect parasites in the colon (the primary organism in question is usually *Entamoeba histolytica* or *Entamoeba histolytica/E. dispar*). Specific ulcerated areas are always sampled; in the absence of

specific lesions, the mucosa would be randomly sampled. On oil immersion (magnification of $\times 1,000$) examination of the smear, protozoan trophozoites and/or cysts might be detected. Coccidian oocysts, helminth eggs or larvae, and/or hu-

man cells are also detected with this procedure. The permanent smear can be stained with trichrome or iron hematoxylin stains. Permanent stained smears usually confirm structures seen on wet specimen examinations (1).

II. SPECIMEN

Observe standard precautions.

The specimen may consist of mucosal lining, mucus, stool, and/or a combination of the three.

- A. Prepare smears on clean, new glass slides (1 by 3 in.).
- B. For mounts of mucus or similar material, place approximately 1 or 2 drops of specimen on the slide.
- C. For mounts of stool, place approximately 1 drop on the slide.
- D. If the material is very wet (watery), place 1 or 2 drops on the slide.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

1. Schaudinn's fixative
See Appendix 9.2.2-1, item A, for preparation instructions.
2. Polyvinyl alcohol (PVA) fixative
See Appendix 9.2.2-1, item B, for preparation instructions.

B. Supplies

1. Disposable glass or plastic pipettes
2. Glass slides (1 by 3 in., or larger if you prefer)
3. Coverslips (22 by 22 mm or larger; no. 1 thickness)

C. Equipment

1. Binocular microscope with 10 \times , 40 \times , and 100 \times objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
2. Oculars should be 10 \times . Some workers prefer 5 \times ; however, overall smaller magnification may make final organism identifications more difficult.
3. Tabletop centrifuge

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Check the fixatives weekly or when a new lot number is used (visual inspection). Use either fresh stool containing protozoa or negative stool seeded with human buffy coat cells to evaluate the efficacy of the fixatives after staining (*see* procedures 9.3.6 and 9.3.7). Cultured protozoa can also be used.
- B. The Schaudinn's fixative should appear clear, without floating debris or crystals. Some crystal sediment on the bottom of the Coplin jar or dish is acceptable.
- C. The PVA should be clear (slight milky or smoky color is acceptable). A slight precipitate on the bottom of the container is acceptable. The fluid should easily move in the bottle when it is inverted, and the viscosity of many of the available formulations will actually approach that of water.
- D. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- E. Record all QC results.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. If the specimen does not contain blood and/or mucus or is not "wet," gently smear a drop or two of patient material onto the slide, and immediately immerse the slide into the Schaudinn's fixative. There should be no problem with adherence to the slide. The fixation and staining times are identical to those for routine fecal smears (*see* procedures 9.2.2, V, 9.3.6, and 9.3.7 for specific directions).
- C. If the material is bloody, contains a lot of mucus, or is a wet specimen, gently mix 1 or 2 drops of patient material with 3 or 4 drops of PVA fixative directly on the slide. Allow the smear to air dry for at least 2 h prior to staining. The fixation and staining times are identical to those for routine fecal smears (*see* procedures 9.2.2.V, 9.3.6, and 9.3.7 for specific directions).
- D. Examine the stained smear with the oil immersion lens (100×) with maximum light. Examine at least 300 oil immersion fields of the smear.

VI. RESULTS

- A. With either the trichrome or iron hematoxylin stain, the protozoan trophozoites and cysts will be easily seen. Oocysts will not be clearly delineated; if you see suspect organisms, then use additional procedures for confirmation (*see* procedures 9.4.1 and 9.4.2).
- B. Helminth eggs or larvae may not be easily identified on the permanent stained smear, and you may need to do wet-mount examinations.
- C. Human cells are readily identified (macrophages, PMNs, RBCs, etc.). Yeast cells (single cells, budding, presence of pseudohyphae) can also be easily seen.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the organism and stage. Do not use abbreviations.
Example: *Entamoeba histolytica* trophozoites (contain ingested RBCs)
- B. Note and quantitate the presence of human cells.
Examples: Moderate WBCs, many RBCs, few macrophages, etc.
- C. Report and quantitate yeast cells.
Example: Moderate budding yeast cells and few pseudohyphae
- D. Call the physician if pathogenic organisms are identified.
- E. See Table 9.6.3–1 for correct method of quantitation.

VIII. PROCEDURE NOTES

- A. Sigmoidoscopy specimens are submitted in order to help differentiate between inflammatory bowel disease and amebiasis. It is critical that the specimens be preserved immediately after being taken. Any delay could result in the disintegration of amebic trophozoites or distortion of human cells.
- B. It is critical that permanent stained smears of this material be carefully examined with the oil immersion lens (100×).

IX. LIMITATIONS OF THE PROCEDURE

- A. The more areas of the mucosa sampled, the more likely the organisms will be found. If only one or two smears are submitted for examination, the physician must be informed (recommendation is six smears from representative areas of the mucosa).
- B. The examination of smears prepared at sigmoidoscopy does not take the place of routine ova and parasite examinations but serves as a supplemental procedure. Stools for routine examinations should also be submitted (a minimum of three specimens collected every other day or within no more than 10 days).
- C. Morphologic differentiation between the *Entamoeba histolytica*/*E. dispar* group and *Entamoeba coli* can be difficult, in addition to the problem of differentiating human cells from protozoa. Also, unless RBCs are seen, it will be impossible to differentiate organisms in the *E. histolytica*/*E. dispar* group from the actual pathogen, *E. histolytica*.

9.6.4

Duodenal Contents: String Test (Entero-Test Capsule)

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The Entero-Test capsule is usually administered and the string is retrieved by a physician. This test is used to procure specimens from the duodenum that are then examined for the presence of parasites. The Entero-Test is a gelatin capsule lined with silicone rubber that contains a spool of nylon string and a weight (Fig. 9.6.4–1). The end of the string is taped to the back of the patient's neck or the patient's

cheek just before the capsule is swallowed with water. After swallowing the capsule, the patient is allowed to relax for 4 h. The patient is not allowed to eat during this time but is allowed to drink a small amount of water. As the capsule dissolves, the string unwinds and is carried by peristalsis to the duodenum, and the duodenal mucus adheres to the string. Any *Strongyloides* larvae (2), *Giardia* trophozoites

(1–6), or *Cryptosporidium* (1, 5, 6) or *Isospora* (1, 5, 6) oocysts that are present will also adhere to the string and will be pulled up with the string when it is removed. The specimen can be examined as a wet preparation or as a permanent stained smear. In rare instances, *Clonorchis sinensis* eggs may be recovered (1–3). This test is a less invasive substitute for duodenal aspiration (1–6).

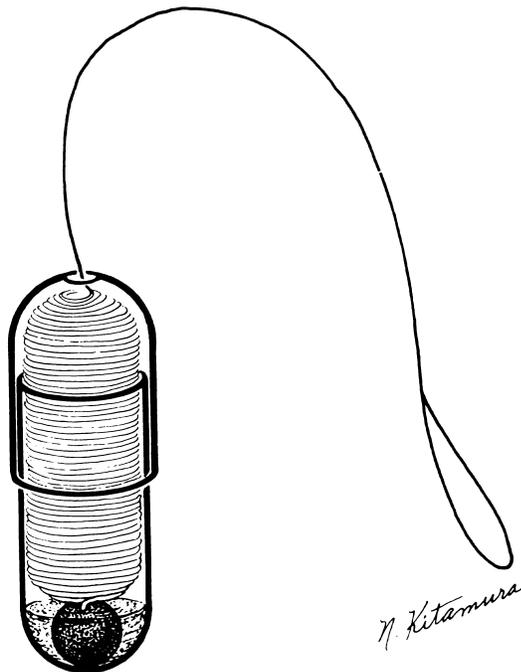

Figure 9.6.4–1 Diagram of Entero-Test capsule (from reference 2).

II. SPECIMEN

Observe standard precautions.

- A. The physician must notify the laboratory when a capsule is swallowed so that a parasitologist is available to read the test 4 h later, when the string is removed.
- B. The string is placed in a small, securely covered container that is transported in a plastic bag. Unless the specimen container is hand delivered to the microbiology unit, a petri dish should not be used because the top cannot be securely attached. A urine container with a screw-cap top is practical for this purpose.
- C. The specimen must be transported immediately and read within 1 h (2).
- D. If there is *any* delay anticipated in transport to the laboratory, a small amount of saline (~1 ml) can be added to keep the string moist.

III. MATERIALS

Include QC information on reagent container and in QC records.

- A. **Reagents**
 - ☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.
 - 1. Schaudinn's fixative.
See Appendix 9.2.2-1, item A, for preparation instructions.
 - 2. Polyvinyl alcohol (PVA) fixative
See Appendix 9.2.2-1, item B, for preparation instructions.
 - 3. 10% Formalin
See Appendix 9.2.2-1, item G, for preparation instructions.
- B. **Supplies**
 1. Disposable glass or plastic pipettes
 2. Glass slides (1 by 3 in., or larger if you prefer)
 3. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)
4. Gloves
5. Urine container
6. Entero-Test capsule (adult or pediatric size) (*see* Appendix 9.10.6-1 at the end of this section for supplier)
7. Test tube (16 by 125 mm)
- C. **Equipment**
 1. Binocular microscope with 10×, 40×, and 100× objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
 2. Oculars should be 10×. Some workers prefer 5×; however, overall smaller magnification may make final organism identifications more difficult.

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Check the fixatives weekly or when a new lot number is used (visual inspection). Use either fresh stool containing protozoa or negative stool seeded with human buffy coat cells to evaluate the efficacy of the fixatives after staining (*see* procedures 9.3.6 and 9.3.7). Cultured protozoa can also be used.
 1. The Schaudinn's fixative should be clear, without floating debris or crystals. Some crystal sediment on the bottom of the Coplin jar or dish is acceptable.
 2. The PVA should be clear (slightly milky or smoky color is acceptable). A slight precipitate on the bottom of the container is acceptable. The fluid should easily move in the bottle when it is inverted. The viscosity of many of the available formulations will actually approach that of water.
 3. The 10% formalin should be clear, with no visible contamination.
- B. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- C. Record all QC results.

V. PROCEDURE

- A.** *Gloves must be worn when handling this specimen.* Infectious *Strongyloides* larvae can penetrate the intact skin.
- B.** Record the color of the string. Yellow bile stain indicates that the string did reach the duodenum.
- C.** Place the specimen under the biosafety cabinet, hold the dry white end in one hand, and strip all the mucus off the string by gripping it between the thumb and index finger of the other hand and squeezing it all the way down to the end, so that the mucus goes into the screw-cap container.
- D.** Place 1 drop of mucus on a clean slide, and cover with a coverslip (22 by 22 mm). If the mucus is very viscous, add a drop of saline before adding the coverslip.
- E.** Store the remaining mucus in a transfer pipette placed in a labeled test tube (16 by 125 mm) so that it will not dehydrate.
- F.** Examine the entire coverslip under low power (100×) for larvae or motile trophozoites, looking especially carefully at the mucus, where *Giardia lamblia* may be entangled.
- G.** Examine the mucus under high dry power (400×), since *G. lamblia* may be detectable only by the flutter of the flagella rather than by motility.
- H.** If there is enough specimen, gently smear a drop or two of patient material on two slides, and immediately immerse the slides in Schaudinn's fixative so that permanent stained slides may be made. If the specimen is not adequate for this, place the wet mount slide in a Coplin jar containing Schaudinn's solution after it has been read. The coverslip will float off and sink to the bottom, allowing the remaining material to be stained. The fixation and staining times are identical with those for routine fecal smears (*see* procedure 9.2.2 for specific directions).
- I.** If the material contains a lot of mucus or is a watery specimen, gently mix 1 or 2 drops of patient material with 3 or 4 drops of PVA fixative directly on the slide. Let the smear air dry for at least 2 h prior to staining. The fixation and staining times are identical to those for routine fecal smears (*see* procedure 9.2.2 for specific directions).
- J.** Place a drop of the mucus on one or more slides to be stained for *Cryptosporidium* and *Isospora* species, and then repeat the wet-mount procedure (steps, V.D through G above) until all the remaining mucus is used.
- K.** Stain the *Cryptosporidium* and *Isospora* slide(s) with modified acid-fast stain, and examine as usual (*see* procedures 9.4.1 and 9.4.2 for specific directions).
- L.** Examine the permanent stained smear with the oil immersion lens (100×) with maximum light. Examine at least 300 oil immersion fields on each smear.
- M.** If *Strongyloides* larvae are found, preserve the rest of the specimen in 10% formalin for teaching purposes.

VI. RESULTS

- A.** With either the trichrome or iron hematoxylin stain, the protozoan trophozoites and cysts will easily be seen. Oocysts will not be clearly delineated; if suspect organisms are seen, use additional procedures for confirmation (*see* procedures 9.4.1 and 9.4.2).
- B.** *Cryptosporidium* and *Isospora* oocysts will be visible on permanent stained smears (modified acid-fast procedures) (*see* procedures 9.4.1 and 9.4.2 for specific directions).
- C.** Helminth eggs or larvae may not be easily identified on the permanent stained smear but will be visible in the wet preparations.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

A. Report the organism and stage (trophozoite, cyst, oocyst, etc.). Do not use abbreviations. Confirmation of species may require some type of permanent stained smear.

Examples: *Giardia lamblia* trophozoites, *Strongyloides stercoralis* larvae

B. Call the physician if pathogenic organisms are identified.

C. Quantitate *C. sinensis* eggs if they are recovered.

D. If the results are negative on the wet smear examination, a preliminary report can be sent (based on wet examination only) prior to the examination of the permanent stained smear.

E. See Table 9.6.4–1 for correct method of quantitation.

VIII. PROCEDURE NOTES

Modified acid-fast methods (or immunoassay detection methods) will have to be used for the identification of *Cryptosporidium parvum*. *Isospora belli* can be identified on the wet examination or from smears stained by modified acid-fast methods.

IX. LIMITATIONS OF THE PROCEDURE

A. Many of the parasites will be caught up in the mucus; therefore, it is very important to examine the specimen carefully under high dry power (400 \times) with low light in order to see the flutter of the *Giardia* flagella.

B. If the duodenal specimens from the Entero-Test capsule are normally examined as wet preparations, remember that some of the organisms (*Cryptosporidium* and *Isospora* species) may be missed without additional permanent stains.

Table 9.6.4–1 Quantitation of parasites, human cells, yeast cells, and artifacts in specimens from the intestinal tract^a

Quantity	No. of protozoa, human cells, yeast cells, artifacts		No. of helminths/cover slip ^b
	Per 10 oil immersion fields ($\times 1,000$) ^c	Per 10 40 \times fields ($\times 400$) ^d	
Few	≤ 2	≤ 2	≤ 2
Moderate	3–9	3–9	3–9
Many	≥ 10	≥ 10	≥ 10

^a In general, protozoa are not quantitated on the laboratory slip (exception: *Blastocystis hominis*); however, human cells, yeast cells, and artifacts like Charcot-Leyden crystals are normally reported and quantitated.

^b Wet preparation. Coverslip was 22 by 22 mm.

^c PVA smear.

^d Wet preparation.

9.6.5

Duodenal Contents: Duodenal Aspirate

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Some organisms may be difficult to recover in the stool, particularly those normally found in the duodenum. An alternative approach to routine stool examinations is to sample the duodenal contents. Samples are obtained through the use of nasogastric intubation or the Entero-Test

capsule (string test). Fluid from the duodenum is examined for the presence of *Strongyloides stercoralis* larvae (1, 2), *Giardia lamblia* trophozoites (1, 2), and *Cryptosporidium parvum* and *Isospora belli* oocysts. The specimen can be examined as a wet preparation or as a per-

manent stained smear. In rare instances, *Clonorchis sinensis* eggs may be recovered (1, 2). Material can also be examined as permanent stained smears (e.g., modified trichrome stain) for the presence of microsporidial spores.

II. SPECIMEN

Observe standard precautions.

Duodenal fluid must be transported immediately in a securely covered container placed in a plastic bag. A screw-cap urine container or plastic centrifuge tube with no preservatives is practical for this purpose.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Reagents

■ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

1. Schaudinn's fixative
See Appendix 9.2.2-1, item A, for preparation instructions.
2. Polyvinyl alcohol (PVA) fixative
See Appendix 9.2.2-1, item B, for preparation instructions.
3. 10% Formalin
See Appendix 9.2.2-1, item G, for preparation instructions.

B. Supplies

1. Disposable glass or plastic pipettes
2. Glass slides (1 by 3 in., or larger if you prefer)

3. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)
4. Gloves
5. Urine container
6. Centrifuge tubes (15 or 50 ml)

C. Equipment

1. Binocular microscope with 10×, 40×, and 100× objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
2. Oculars should be 10×. Some workers prefer 5×; however, overall smaller magnification may make final organism identifications more difficult.
3. Tabletop centrifuge

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

A. Check the fixatives weekly or when a new lot number is used (visual inspection). Use either fresh stool containing protozoa or negative stool seeded with human buffy coat cells to evaluate the efficacy of the fixatives after staining (see procedures 9.3.6 and 9.3.7). Cultured protozoa can also be used.

1. The Schaudinn's fixative should be clear, without floating debris or crystals. Some crystal sediment on the bottom of the Coplin jar or dish is acceptable.

IV. QUALITY CONTROL

(continued)

2. The PVA should be clear (slightly milky or smoky color is acceptable). A slight precipitate on the bottom of the container is acceptable. The fluid should easily move in the bottle when it is inverted. The viscosity of many of the available formulations will actually approach that of water.
 3. The 10% formalin should be clear, with no visible contamination.
- B.** The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- C.** Record all QC results.

V. PROCEDURE

- A.** *Gloves must be worn when handling this specimen.* Infectious *Strongyloides* larvae can penetrate the intact skin.
- B.** Examine the specimen within 1 h after it is taken. Note the amount of yellow color, which indicates bile staining and confirms that the specimen is actually from the duodenum.
- C.** Centrifugation may be necessary to concentrate the mucus and any organisms present ($500 \times g$ for 10 min). Centrifugation should be routinely performed if the volume of fluid is ≥ 2 ml.
- D.** Place 1 drop of fluid on a clean slide, and cover with a coverslip (22 by 22 mm). If the specimen is very viscous, add a drop of saline before adding the coverslip.
- E.** Examine the entire coverslip under low power ($100\times$) for larvae or motile trophozoites, looking especially carefully around the mucus, where *G. lamblia* may be entangled.
- F.** Examine the mucus present under high dry power ($400\times$), since *G. lamblia* may be detectable only by the flutter of the flagella rather than by motility.
- G.** If there is enough specimen, gently smear a drop or two of patient material on two slides, and immediately immerse the slides in Schaudinn's fixative so that permanent stained slides may be made. If the specimen is not adequate for this, place the wet-mount slide in a Coplin jar containing Schaudinn's solution, after it has been read. The coverslip will float off and sink to the bottom, allowing the remaining material to be stained. Fixation and staining times are identical to those for routine fecal smears (*see* procedure 9.2.2 for specific directions).
- H.** If the material contains a lot of mucus or is a watery specimen, gently mix 1 or 2 drops of patient material with 3 or 4 drops of PVA fixative directly on the slide. Let the smear air dry for at least 2 h prior to staining. The fixation and staining times are identical to those for routine fecal smears (*see* procedure 9.2.2 for specific directions).
- I.** Place a drop of the duodenal fluid on one or more slides to be stained for *Cryptosporidium* and *Isospora* species, and then repeat the wet mount procedure (steps V.D through G above) until all the remaining mucus (after centrifugation) or sediment is gone.
- J.** Stain the *Cryptosporidium* and *Isospora* slide(s) with modified acid-fast stain, and examine as usual (*see* procedures 9.4.1 and 9.4.2 for specific directions).
- K.** Examine the permanent stained smear with the oil immersion lens ($100\times$) with maximum light. Examine at least 300 oil immersion fields on each smear.

V. PROCEDURE (continued)

- L. If *Strongyloides* larvae are found, preserve the rest of the specimen in 10% formalin for teaching purposes.

VI. RESULTS

- A. With either the trichrome or iron hematoxylin stain, the protozoan trophozoites and cysts will easily be seen. Oocysts will not be clearly delineated; if suspect organisms are seen, use additional procedures for confirmation (see procedures 9.4.1 and 9.4.2).
- B. *Cryptosporidium* and *Isoospora* oocysts will be visible on permanent stained smears (modified acid-fast procedures) (see procedures 9.4.1 and 9.4.2 for specific directions).
- C. Helminth eggs or larvae may not be easily identified on the permanent stained smear but will be visible in the wet preparations.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the organism and stage (trophozoite, cyst, oocyst, etc.). Do not use abbreviations. Confirmation of species may require some type of permanent stained smear.
Examples: *Giardia lamblia* trophozoites, *Strongyloides stercoralis* larvae
- B. Call the physician if pathogenic organisms are identified.
- C. Quantitate *C. sinensis* eggs if they are recovered.
- D. If the results are negative on the wet smear examination, a preliminary report can be sent (based on wet examination only) prior to the examination of the permanent stained smear.
- E. See Table 9.6.5–1 for the correct method of quantitation.

VIII. PROCEDURE NOTES

- A. If you receive more than 2 ml of specimen, you must centrifuge the specimen (500 × g for 10 min) and examine the mucus or material in the bottom of the tube.
- B. Modified acid-fast methods (or immunoassay detection methods) will have to be used for the identification of *C. parvum*. *I. belli* can be identified by wet examination or from smears stained with the modified acid-fast methods.

Table 9.6.5–1 Quantitation of parasites, human cells, yeast cells, and artifacts in specimens from the intestinal tract^a

Quantity	No. of protozoa, human cells, yeast cells, artifacts		No. of helminths/coverlip ^b
	Per 10 oil immersion fields (×1,000) ^c	Per 10 40× fields (×400) ^d	
Few	≤2	≤2	≤2
Moderate	3–9	3–9	3–9
Many	≥10	≥10	≥10

^a In general, protozoa are not quantitated on the laboratory slip (exception: *Blastocystis hominis*), but human cells, yeast cells, and artifacts like Charcot-Leyden crystals are normally reported and quantitated.

^b Wet preparation. Coverslips are 22 by 22 mm.

^c PVA smear.

^d Wet preparation.

IX. LIMITATIONS OF THE PROCEDURE

- A. Many of the parasites will be caught up in the mucus; therefore, it is very important to centrifuge the specimen and concentrate this mucous material for examination. Centrifugation is mandatory if the specimen is more than 2 ml in volume.
- B. Although duodenal aspirate specimens are normally examined as wet preparations, remember that some of the organisms may be missed without additional permanent stains (*Cryptosporidium* and *Isospora* species).

9.6.6

Urogenital Specimens: Direct Saline Mount

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Trichomonas vaginalis infections are primarily diagnosed by detecting live motile flagellates from direct saline (wet) mounts. Microscope slides made from patient specimens can be examined under low and high power for the presence of actively moving organisms.

II. SPECIMENS

Observe standard precautions.

- A. Vaginal discharge
- B. Urethral discharge
- C. Penile discharge
- D. Urethral-mucosa scrapings
- E. First-voided urine with or without prostatic massage

Collect specimens with a platinum loop, cotton or Dacron swab, or speculum. Place these specimens in a small amount (<1.0 ml) of 0.85% NaCl in a test tube or on a microscope slide, and dilute them with a drop of 0.85% NaCl. If the specimen cannot be examined immediately, place the swab in Amies transport medium, which will keep the organisms viable for approximately 24 h. Collect urine specimens in a clean-catch urine collection container. Centrifuge the urine at $500 \times g$, and examine the sediment for *T. vaginalis*. Hold all specimens at room temperature, because refrigerator temperatures inhibit motility and have a deleterious effect on the organisms. Returning the specimen to room temperature will not reverse these deleterious morphological changes. Reject any specimens more than 24 h old.

III. MATERIALS

- A. **Reagents** (see Appendix 9.6.6–1)
- B. **Supplies**
 - 1. Disposable glass or plastic pipettes
 - 2. Glass slides (1 by 3 in., or larger if you prefer)
 - 3. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)
 - 4. Small tubes containing 0.5 to 1.0 ml of 0.85% NaCl
- C. **Equipment**
 - 1. Binocular microscope with $10\times$, $40\times$, and $100\times$ objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
 - 2. Oculars should be $10\times$. Some workers prefer $5\times$; however, overall smaller magnification may make final organism identifications more difficult.
 - 3. Tabletop centrifuge
 - 4. Staining rack

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Check the direct-mount reagents each time they are used.
 - 1. The saline should be clear, with no visible contamination.
 - 2. The iodine should be a strong-tea color, and there should be crystals in the bottom of the bottle. Small aliquots of the stock solution should always be strong-tea color. If not, then discard, and aliquot some stock solution into your dropper bottle.
- B. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- C. Record all QC results.

V. PROCEDURE (1)

- A. Apply the patient's specimen to a small area on a clean microscope slide.
- B. Immediately before the specimen dries, add 1 or 2 drops of saline with a pipette. If urine sediment is used, the addition of saline may not be necessary.
- C. Mix the saline and specimen together with the pipette tip or the corner of the coverslip.
- D. Cover the specimen with the no. 1 coverslip.
- E. Examine the wet mount with the low-power (10×) objective and low light.
- F. Examine the entire coverslip for motile flagellates. Suspicious objects can be examined with the high-power (40×) objective.
- G. The organism is usually slightly larger than a PMN, and you should see flagellar movement.

VI. RESULTS

- A. If motile flagellates (axostyle and undulating membrane) are seen, then the trophozoites of *T. vaginalis* are present.
- B. If nonmotile organisms (axostyle) are visible after staining with D'Antoni's iodine, then the trophozoites of *T. vaginalis* are present.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the organism. Do not report the organism stage, since there is no known cyst stage for the trichomonads. The organisms do not need to be quantitated.
Example: *Trichomonas vaginalis* present.
- B. If no flagellated organisms are seen, report the specimen as negative for *T. vaginalis*.
Example: No *Trichomonas vaginalis* seen.

VIII. PROCEDURE NOTES

- A. It is very important that specimens to be examined for *T. vaginalis* be delivered to the laboratory within 1 h after collection.
- B. After 1 h, organisms will lose their motility, particularly when they begin to dry out.

VIII. PROCEDURE NOTES

(continued)

- C. If a dry smear is delivered to the laboratory, salvage it by fixing the dry smear as you would a thin blood film (absolute methanol) and stain it with Giemsa at a 1:20 dilution for at least 20 min (*see* procedure 9.8.5). The stained organisms may be difficult to see, but if you can actually see and identify the organisms as *T. vaginalis*, that information may be clinically relevant.
- D. Calgiswabs are not recommended (tight adherence of specimen to swab). Reject the specimen if submitted on this type of swab.
- E. When the specimen is examined microscopically, always confirm that no fecal contamination (artifacts, vegetable debris, etc.) is present. This type of contamination is rare and would probably be limited to a urine specimen. However, if a urine or other urogenital specimen was contaminated with fecal material, it is possible that *Pentatrichomonas hominis* (nonpathogen found in the intestinal tract) could be misidentified as *T. vaginalis*, an identification that implies sexual transmission.

IX. LIMITATIONS OF THE PROCEDURE

- A. If the specimen is left at room temperature or held at refrigerator temperature for a prolonged period (usually >1 h), the organisms will round up, lose their motility, and eventually die. Motility may occasionally be enhanced by warming the specimen to 37°C, but this will not revive dying organisms.
- B. Wet mounts have been reported to detect *T. vaginalis* in 75 to 85% of infected patients. *Alternative diagnostic methods may include culture, use of monoclonal antigen detection kits, use of permanent stained slides, and collection of a second sample for examination.*
- C. If the patient has a *P. hominis* intestinal infection and the urogenital specimen becomes contaminated with fecal material, a false-positive *T. vaginalis* result may be reported, because *P. hominis* and *T. vaginalis* are similar in shape.

REFERENCE

APPENDIX 9.6.6-1

Include QC information on reagent container and in QC records.

Reagents

- ☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. 0.85% NaCl

1. Dissolve in distilled water in an appropriate glass flask by using a magnetic stirrer.

sodium chloride (NaCl)	850 mg
distilled water	100 ml
2. Store in a glass bottle.
3. Label as 0.85% NaCl with a preparation date and an expiration date of 6 months. Store at room temperature.

APPENDIX 9.6.6–1 (continued)

B. Modified D'Antoni's stock iodine

1. Dissolve in distilled water with an appropriate glass flask by using a magnetic stirrer.

potassium iodide (KI) 1.0 g
powdered iodine crystals 1.5 g
distilled water 100 ml

2. The D'Antoni's solution should be saturated with iodine, with some excess crystals left in the bottle. Store in a brown bottle at room temperature. The stock solution remains good as long as an excess of iodine crystals remains on the bottom of the bottle.
3. Label as D'Antoni's stock iodine with the preparation date and an expiration date of 1 year.
4. Small amounts of stock iodine solution can be aliquoted into brown dropper bottles for routine daily use. The expiration date will be from 30 to 60 days, depending on the amount of fading of the solution from the normal strong-tea color (small dropper bottles and the use of clear glass will result in a shorter expiration time). The use of a brown bottle will lengthen the expiration time.

9.6.7

Urogenital Specimens: Permanent Stained Smear (Giemsa)

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Trichomonas vaginalis infections are primarily diagnosed from direct saline (wet) mounts by detecting live motile flagellates. Permanently stained smears can be made from patient specimens for specific

identification of the organism. Although a number of stains can be used, Giemsa and Papanicolaou stains are the ones most frequently used to diagnose *T. vaginalis* infections.

II. SPECIMEN

Observe standard precautions.

- A. Vaginal discharge
- B. Urethral discharge
- C. Penile discharge
- D. Urethral-mucosa scrapings
- E. First-voided urine with or without prostatic massage

Collect specimens with a platinum loop, cotton-Dacron swab, or speculum. Place these specimens in a small amount (<1.0 ml) of 0.85% NaCl in a test tube, or smear them directly onto a microscope slide. Use a drop of 0.85% NaCl to dilute the direct smear when it is placed on the slide. Air dry slides prepared in this manner before transporting them to the laboratory. Place specimens collected with a cotton-Dacron swab in Amies transport medium if the specimen cannot be processed immediately. Organisms will remain viable for approximately 24 h in Amies transport medium. Collect urine specimens in a clean-catch urine collection container. Centrifuge the urine at $500 \times g$ for 5 min, and examine the sediment for *T. vaginalis*. Hold all specimens at room temperature, because refrigerator temperatures have a deleterious effect on the organisms. Returning the specimen to room temperature will not reverse these deleterious morphological changes. Reject any specimens more than 24 h old.

III. MATERIALS

A. Reagents (see Appendix 9.6.7–1)

B. Supplies

1. Disposable glass or plastic pipettes
2. Glass slides (1 by 3 in., or larger if you prefer)
3. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)
4. Small tubes containing 0.5 to 1.0 ml of 0.85% NaCl
5. 2 Coplin jars

C. Equipment

1. Binocular microscope with $10\times$, $40\times$, and $100\times$ objectives (or the

approximate magnifications for low-power, high dry power, and oil immersion examination)

2. Oculars should be $10\times$. Some workers prefer $5\times$; however, overall smaller magnification may make final organism identifications more difficult.
3. Tabletop centrifuge (for tubes containing specimen and 0.85% NaCl if the specimen is submitted in saline)

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Check the direct-mount reagents each time they are used.
 1. The saline should be clear, with no visible contamination.
 2. Giemsa stain

A peripheral blood film may be used to quality control the Giemsa stain. For staining characteristics, see procedure 9.8.5.
 3. Phosphate buffer

Check the buffer each time you use it. The buffer should be clear, with no signs of visible contamination or precipitates. The pH should be between 6.8 and 7.2.
 4. Review the Giemsa-stained control slide before searching the patient's specimen for the organism. If there was potential fecal contamination of the specimen, you may have to differentiate *T. vaginalis* from *Pentatrichomonas hominis*.
- B. The microscope should have been calibrated within the last 12 months, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- C. Record all QC results.

V. PROCEDURE (1)

- A. Apply patient's specimen to a small area of a clean microscope slide.
- B. Immediately before the specimen dries, add 1 or 2 drops of saline with a pipette. If urine sediment is used, the addition of saline may not be necessary.
- C. Mix the saline and specimen together with the pipette tip.
- D. Air dry the slide.
- E. Fix in absolute methanol for 1 min (Coplin jar or slide staining rack).
- F. Place the slide in the Giemsa solution, and stain for the desired time, depending on the stain dilution used (20 min at 1:20 dilution).
- G. Rinse the slide with tap water (gently running or in a Coplin jar) to remove excess stain solution.
- H. Air dry the slide. Do not apply a coverslip.
- I. Examine the slide with the oil (100×) objective.
- J. Examine the entire smear for flagellates.
- K. The organism is usually slightly larger than a PMN. The organism is 7 to 23 μm long and 5 to 15 μm wide. Differential characteristics to be observed include anterior flagella, undulating membrane, axostyle, and nucleus.

VI. RESULTS

- A. If motile flagellates (axostyle and undulating membrane) are seen, then the trophozoites of *T. vaginalis* are present.
- B. If organisms (axostyle) are visible after staining with Giemsa stain, then the trophozoites of *T. vaginalis* are present.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the organism. Do not report the organism stage, since there is no known cyst stage for the trichomonads. The organisms do not need to be quantitated.
Example: *Trichomonas vaginalis* present.
- B. If no flagellated organisms (axostyle and undulating membrane) are seen, report the specimen as negative for *T. vaginalis*.
Example: No *Trichomonas vaginalis* seen.

VIII. PROCEDURE NOTES

- A. It is very important that specimens to be examined for *T. vaginalis* be delivered to the laboratory within 1 h after collection.
- B. After 1 h, organisms will lose their motility, particularly when they begin to dry out, and the morphology on the permanent stained smear will be difficult to see.
- C. If a dry smear is delivered to the laboratory, salvage it by fixing the dry smear as you would a thin blood film (absolute methanol) and staining it with Giemsa at a 1:20 dilution for at least 20 min (*see* procedure 9.8.5). The stained organisms may be difficult to see, but if you can actually see and identify the organisms as *T. vaginalis*, that information may be clinically relevant.
- D. Calgiswabs are not recommended (tight adherence of specimen to swab). Reject the specimen if submitted on this type of swab.
- E. When the specimen is examined microscopically, always confirm that no fecal contamination (artifacts, vegetable debris, etc.) is present. This type of contamination is rare and would probably be limited to a urine specimen. However, if a urine or other urogenital specimen was contaminated with fecal material, it is possible that *P. hominis* (nonpathogen found in the intestinal tract) could be misidentified as *T. vaginalis*, an identification that implies sexual transmission.

IX. LIMITATIONS OF THE PROCEDURE

- A. If the specimen is left at room temperature or held at a refrigerator temperature for a prolonged period (usually >1 h), the organisms will round up and eventually die.
- B. If the patient has a *P. hominis* intestinal infection and the urogenital specimen becomes contaminated with fecal material, a false-positive *T. vaginalis* result may be reported, because *P. hominis* and *T. vaginalis* are similar in shape. The position of the undulating membrane will allow differentiation between *T. vaginalis* and *P. hominis*.

APPENDIX 9.6.7-1

Include QC information on reagent container and in QC records.

Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. 0.85% NaCl

1. Dissolve in distilled water in an appropriate glass flask by using a magnetic stirrer.

sodium chloride (NaCl) 850 mg
distilled water 100 ml

2. Store in a glass bottle.

3. Label as 0.85% NaCl with a preparation date and an expiration date of 6 months. Store at room temperature.

B. Giemsa stain

For preparation of Giemsa stain and phosphate buffer solutions, see procedure 9.8.5.

C. Absolute methanol

APPENDIX 9.6.7-2

Diagnostic differential characteristics

Characteristic	<i>T. vaginalis</i>	<i>P. hominis</i>
Size	7–23 µm long 5–15 µm wide	5–15 µm long 7–10 µm wide
Shape	Pear	Pear
Flagella	4 anterior	3–5 anterior
Undulating membrane	Extends half of organism length	Extends entire length with free trailing flagella
Axostyle	Present	Present
Nucleus	Anterior end, oval	Anterior end, oval

9.6.8

Urine Concentration: Centrifugation

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Helminthic larval stages and eggs and some protozoa infecting humans may be found in the urine whether or not they cause pathologic sequelae in the urinary tract. Filariasis can be diagnosed from

urine samples, and *Trichomonas vaginalis* and *Schistosoma haematobium* eggs can be detected in the urine. Microfilariae may be detected in the urine of heavily infected patients or of patients recently treated with

diethylcarbamazine. Some of the microsporidia, such as *Encephalitozoon (Septata) intestinalis*, can be found in the urine, particularly that of immunosuppressed patients, including those with AIDS.

II. SPECIMENS

Observe standard precautions.

Urine

A. *T. vaginalis*

Collection of first-voided urine, particularly after prostatic massage in male patients, is useful for the diagnosis of this infection.

B. *S. haematobium*

Collection of a midday urine specimen or a 24-h collection in a container without preservatives is recommended. Peak egg excretion occurs between noon and 3 p.m. In patients with hematuria, eggs may be found trapped in the blood and mucus in the terminal portion (last-voided portion) of the urine specimen.

C. Filariasis

Microfilariae may be detected in urine of patients with chyluria, of patients with very heavy filarial infections, and of patients treated with diethylcarbamazine.

D. Microsporidia

Microsporidial spores may be detected in concentrated urine of patients who are immunosuppressed, including those with AIDS. A number of different stains can be used, such as modified trichrome and optical brightening agents.

III. MATERIALS

A. Reagent (see Appendix 9.6.8–1)

B. Supplies

1. Disposable glass or plastic pipettes
2. Glass slides (1 by 3 in., or larger if you prefer)
3. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)
4. Small tubes containing 0.5 to 1.0 ml of 0.85% NaCl
5. Conical centrifuge tubes (15 ml)
6. Erlenmeyer flask (1,000 ml)

C. Equipment

1. Binocular microscope with 10 \times , 40 \times , and 100 \times objectives (or the

approximate magnifications for low-power, high dry power, and oil immersion examination)

2. Oculars should be 10 \times . Some workers prefer 5 \times ; however, overall smaller magnification may make final organism identifications more difficult.
3. Tabletop centrifuge (for tubes containing specimen and 0.85% NaCl if the specimen is submitted in saline)

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Check the direct-mount reagent each time it is used. The saline should be clear, with no visible contamination.
- B. The microscope should have been calibrated within the last 12 months, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- C. Record all QC results.

V. PROCEDURE

- A. If a 24-h urine sample was collected, allow the specimen to sediment for 2 h, and decant the major portion of the supernatant. There may be 100 to 200 ml of sediment left. If a first-voided urine specimen is received, use the entire specimen.
- B. Place the remaining urine specimen (sediment) in centrifuge tubes.
- C. Centrifuge the specimen at $500 \times g$ for 5 min.
- D. Decant the supernatant fluid.
- E. With a pipette, mix and aspirate the sediment.
- F. Place 1 drop of the sediment on a microscope slide.
- G. Place a coverslip on top of the sediment.
- H. Observe the specimen under the coverslip at magnifications of $\times 100$ and $\times 400$. Examine the entire coverslip at $\times 100$ and at least half the coverslip at $\times 400$.

VI. RESULTS

- A. If motile flagellates are seen (axostyle and undulating membrane), then the trophozoites of *T. vaginalis* are present.
- B. If live microfilariae are seen, then confirm or accomplish species identification by using permanent stains (1) (*see* procedures 9.8.5, 9.8.6, and 9.8.8).
- C. If eggs of *S. haematobium* are seen, observe the eggs for live miracidia. If flame cell activity (motile cilia) is detected inside the miracidium larva, the miracidium is viable. A hatching test may also be used to determine if the eggs are viable (1) (*see* procedure 9.5.5).

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. *T. vaginalis*
Report the organism. Do not report the stage, since there is no known cyst stage for the trichomonads. The organisms do not need to be quantitated.
Example: *Trichomonas vaginalis* present.
- B. **Filariae**
Report the presence of microfilariae. Genus and species should be reported if possible. The organisms do not need to be quantitated.
Example: *Wuchereria bancrofti* microfilariae present.

VII. REPORTING RESULTS

(continued)

C. *S. haematobium*

If eggs are present, report the genus and species and whether the eggs are viable or nonviable.

Examples: *Schistosoma haematobium* eggs present (viable eggs seen).

Schistosoma haematobium eggs present (nonviable, eggshells only).

VIII. PROCEDURE NOTES

- A. Specimens to be examined for *T. vaginalis* should be delivered to the laboratory as soon as possible after collection. Hold all specimens at room temperature because refrigerator temperatures will have a deleterious effect on *T. vaginalis*.
- B. Species identification of the microfilariae from unstained preparations (urine sediment) may not be possible, and permanent stains may be necessary for further identification (1).
- C. It is very important that all urine specimens (24-h and single-voided specimens) be collected with no preservatives. It is clinically important to determine whether the eggs are viable. This can be accomplished by examining eggs in the wet preparations at $\times 400$.
- D. It is possible, although much less likely, that *Schistosoma mansoni* or *Schistosoma japonicum* eggs could also be recovered in urine. Therefore, the egg morphology must be carefully examined for accurate identification to species.
- E. For the detection of *T. vaginalis*, filariae, and schistosomes, reject specimens, including midday urine samples, that are more than 24 h old.
- F. Reject all 24-h urine specimens that are more than 48 h old.
- G. When the specimen is examined microscopically, always confirm that no fecal contamination (artifacts, vegetable debris, etc.) is present. This type of contamination is rare and would probably be limited to a urine specimen. However, if a urine or other urogenital specimen was contaminated with fecal material, it is possible that *Pentatrichomonas hominis* (nonpathogen found in the intestinal tract) could be misidentified as *T. vaginalis*, an identification that implies sexual transmission.

IX. LIMITATIONS OF THE PROCEDURE

- A. If the urine specimen is left at room temperature or held at a low temperature for a prolonged period, *T. vaginalis* may round up, become nonmotile, and eventually die.
- B. If the patient has a *P. hominis* intestinal infection and the urogenital specimen becomes contaminated with fecal material, a false-positive *T. vaginalis* result may be reported because *P. hominis* and *T. vaginalis* are similar in shape.
- C. Microfilariae can be identified to the species level only by making a permanent stained slide from the specimen.

APPENDIX 9.6.8–1

Include QC information on reagent container and in QC records.

Reagent

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

0.85% NaCl

A. Dissolve in distilled water in an appropriate glass flask by using a magnetic stirrer.

sodium chloride (NaCl) 850 mg

distilled water 100 ml

B. Store in a glass bottle.

C. Label as 0.85% NaCl with a preparation date and an expiration date of 6 months. Store at room temperature.

9.6.9

Urine Concentration: Membrane Filter (Nuclepore)

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Microfilariae may be detected in the urine of heavily infected patients or of patients recently treated with diethylcarbamazine. Eggs of *Schistosoma haematobium* can also be recovered in urine specimens (2).

Microfilariae and *S. haematobium* eggs can be easily concentrated by passing the specimen through a membrane filter. The filter can then be observed through a microscope.

II. SPECIMENS

Observe standard precautions.

Urine

A. Filariasis

Microfilariae may be detected in urine of patients with chyluria, of patients with very heavy filarial infections, and of patients treated with diethylcarbamazine. Collect specimens as first-voided specimens or as a 24-h collection in a container without preservatives.

B. *S. haematobium*

Collection of a midday urine specimen or a 24-h collection in a container without preservatives is recommended. Peak egg excretion occurs between noon and 3 p.m. In patients with hematuria, eggs may be found trapped in the blood and mucus in the terminal portion (last-voided portion) of the urine specimen.

III. MATERIALS

A. **Reagent** (see Appendix 9.6.9–1)

B. Supplies

1. Disposable glass or plastic pipettes
2. Glass slides (1 by 3 in., or larger if you prefer)
3. Coverslips (22 by 22 mm; no. 1, or larger if you prefer)
4. Small tubes containing 0.5 to 1.0 ml of 0.85% NaCl
5. Nuclepore membrane filters (25 mm) of 3-, 5-, and 8- μ m pore sizes
6. Filter holder (25 mm) that attaches to syringe

7. Syringe (10 ml)

8. Forceps

C. Equipment

1. Binocular microscope with 10 \times , 40 \times , and 100 \times objectives (or the approximate magnifications for low-power, high dry power, and oil immersion examination)
2. Oculars should be 10 \times . Some workers prefer 5 \times ; however, overall smaller magnification may make final organism identifications more difficult.

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Check the direct-mount reagent each time it is used. The saline should be clear, with no visible contamination.
- B. The microscope should have been calibrated within the last 12 months, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- C. Record all QC results.

V. PROCEDURE

- A. If a midday urine sample is used, proceed to step V.B; if a 24-h urine sample was collected for *S. haematobium* diagnosis, allow the specimen to sediment for 2 h, and decant the major portion of the supernatant. There may be 100 to 200 ml of sediment left.
- B. Thoroughly mix the urine specimen.
- C. Draw 10 ml of urine into the syringe. If the urine is excessively cloudy or turbid, <10 ml may have to be used.
- D. Attach the filter holder containing the filter to the syringe. For *S. haematobium*, use 8- μ m-pore-size filters; for *Wuchereria bancrofti*, *Brugia malayi*, and *Loa loa*, use 5- μ m-pore-size filters; and for *Mansonella* species, use 3- μ m-pore-size filters.
- E. Express the urine through the filter.
- F. Wash the membrane with physiological saline by removing the filter holder, drawing 10 ml of saline into the syringe, reattaching the filter holder, and expressing the saline through the filter.
- G. Repeat step V.F, but fill the syringe with air instead of saline, and express the air through the filter.
- H. Remove the filter holder from the syringe.
 - I. Disassemble the filter holder to expose the filter.
 - J. Remove the filter from the holder with forceps.
 - K. Place the filter upside down on a microscope slide.
 - L. With a Pasteur pipette, add 1 drop of saline to moisten the filter.
- M. Examine the filter for microfilariae and eggs at a magnification of $\times 100$.

VI. RESULTS

- A. If live microfilariae are seen, then confirm or accomplish species identification by using permanent stains (1) (*see* procedures 9.8.5, 9.8.6, and 9.8.8).
- B. If eggs of *S. haematobium* are seen, observe the eggs for live miracidia. If flame cell activity (motile cilia) is detected inside the miracidium larva, the miracidium is viable. A hatching test may also be used to determine if the eggs are viable (1).

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS**A. Filariae**

Report the presence of microfilariae. Genus and species should be reported if possible. The organisms do not need to be quantitated.

Example: *Wuchereria bancrofti* microfilariae present.

B. *S. haematobium*

If eggs are present, report the genus and species and whether the eggs are viable or nonviable.

Examples: *Schistosoma haematobium* eggs present (viable eggs seen).

Schistosoma haematobium eggs present (nonviable, egg shells only).

VIII. PROCEDURE NOTES

A. Species identification of the microfilariae may not be possible from unstained preparations (urine sediment), and permanent stains may be necessary for further identification (1). Microfilariae will measure 3 to 10 μm in width by 160 to 330 μm in length. Depending on the species, a sheath may or may not be present.

B. It is very important that all urine specimens (24-h and single-voided specimens) be collected with no preservatives. It is clinically important to determine whether the eggs are viable. This can be accomplished by examining eggs in the wet preparations at $\times 400$.

C. For the detection of filariae and schistosomes, reject specimens, including mid-day urine samples, that are more than 24 h old.

D. Reject all 24-h urine specimens that are more than 48 h old.

E. If you accidentally put the filter right side up, don't add more than 1 drop of saline (the organisms may accidentally float off the filter and onto the glass slide).

IX. LIMITATIONS OF THE PROCEDURE

A. Microfilariae can be identified to the species level only by making a permanent stained slide from the specimen. For a method that uses the membrane filter, refer to page 807 in Garcia (1).

B. A hatching test may also be used to determine if the eggs are viable. For a hatching method, refer to procedure 9.5.5.

C. Infrequently, eggs of other *Schistosoma* species may be recovered in the urine.

Characterization of schistosome eggs

Species	Egg	
	Size	Shape
<i>Schistosoma haematobium</i>	112–170 by 40–70 μm	Elongate, terminal spine
<i>Schistosoma japonicum</i>	55–85 by 40–60 μm	Oval, minute lateral spine
<i>Schistosoma mansoni</i>	114–180 by 45–73 μm	Elongate, prominent lateral spine

9.7.1

Expectorated Sputum: Direct-Mount and Stained Preparations

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

- A. A direct smear can be used to detect large or motile organisms from the lung. Parasites which can be detected and may cause pneumonia, pneumonitis, or Loeffler's syndrome include *Entamoeba histolytica*, *Paragonimus* spp., *Strongyloides stercoralis*, *Ascaris lumbricoides*, and hookworm. The smears can be examined with and without the addition of D'Antoni's or Lugol's iodine (see procedure 9.3.3).
- B. Trichrome stains of material may aid in differentiating *E. histolytica* from *Entamoeba gingivalis*, and Giemsa stain may better define larvae and juvenile worms. Prepare a stain of material if organisms are found in examination of direct mounts which require additional differentiation.
- C. Although *Cryptosporidium parvum* will be difficult to see in a direct mount, examination of smears stained with modified acid-fast stains (hot or cold method) may provide confirmation of pulmonary cryptosporidiosis.
- D. In order to see microsporidial spores, centrifuged specimens stained with modified trichrome stains or optical brightening agents will be required ($500 \times g$ for 10 min).

II. SPECIMEN

Observe standard precautions.

- A. Expectorated sputum specimens are collected after patient instruction in the appropriate measures to take to ensure quality specimens, including mouth wash before expectorating and exclusion of saliva from specimens.
- B. Transport specimens to the laboratory in clean, closed containers. Select any blood-tinged, viscous areas for sampling.
- C. If the specimen is uniformly mucoid, do the following.
 1. Remove a 1.0-ml portion to a 15-ml conical tube.
 2. Add 1.0 ml of mucolytic agent such as Sputolysin that has been prepared according to the manufacturer's instructions.
 3. Incubate at room temperature for 15 min.
 4. Add 2.0 ml of phosphate buffer (pH 6.8, 0.067 M).
 5. Centrifuge the material at $1,000 \times g$ for 5 min.
 6. Decant supernatant, and use pelleted material to prepare wet mounts and smears.

III. MATERIALS

- | | |
|---|---|
| <p>A. Reagents (<i>see</i> Appendix 9.7.1–1)</p> <p>B. Supplies</p> <ol style="list-style-type: none"> 1. Pasteur pipettes 2. 1- and 10-ml pipettes 3. Glass slides (2 by 3 in.) 4. Glass slides (1 by 3 in.) 5. 22- by 22-mm coverslips; no. 1 thickness 6. 15-ml conical centrifuge tubes 7. Coplin jars with lids 8. Protective gloves <p>C. Equipment</p> <ol style="list-style-type: none"> 1. Centrifuge with carriers for 15-ml tubes with safety caps | <ol style="list-style-type: none"> 2. Binocular microscope with 10×, 40×, and 100× (oil immersion) objectives; 50× oil objective optional but very helpful 3. Oculars should be 10×. Some may prefer 5×; however, overall smaller magnification may make final organism identifications more difficult. |
|---|---|

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Saline (0.85% NaCl), clear and free of particulate material. If cloudy, discard.
- B. Mucolytic agent free of contamination as determined by clear appearance. If cloudy, discard, and make new working solution.
- C. Do a control trichrome stain for each new set of reagents with a specimen containing blood to see that WBCs stain with purple nuclei and blue-green cytoplasm (*see* procedure 9.3.6). If cells do not stain appropriately, change reagents.
- D. With each new lot of Giemsa stain or new buffer, check stain with a specimen containing blood to see that RBCs stain grayish, WBC nuclei stain red-purple, and WBC cytoplasm stains bluish. If cells do not stain appropriately, check stock stain and buffer to find cause.
- E. The microscope(s) should be calibrated, and the original optics used for the calibration should be in place on the microscope(s). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- F. Clean and check centrifuge for speed, and clean brushes once a year.
- G. Maintain temperature of refrigerator where mucolytic-agent working solution is stored at 4°C (range, 2 to 8°C).
- H. Store stock stain solutions in the dark. Store Giemsa stain tightly stoppered. Make fresh working solution each day. Use a clean, dry pipette to remove stain from stock stain container.
- I. Record all QC results.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. Expecterated sputum (untreated with mucolytic agent)
 1. With a Pasteur pipette, place 1 or 2 drops (50 µl) on one side of a glass slide (2 by 3 in.), and cover with a no. 1 coverslip (22 by 22 mm).
 2. Place a second drop on the slide, add 1 drop of saline, and cover with a coverslip.
- C. Material that has been treated with a mucolytic agent can be suspended in 100 µl of saline. Place 1 drop of the mixture on a slide (2 by 3 in.), and cover with a coverslip.
- D. Reserve the specimen and remaining treated specimen for preparation of smears for staining should stains be required.

V. PROCEDURE (*continued*)

- E. Examine the wet preparations field by field with low light and the 10× objective to detect eggs, larvae, oocysts, or amebic trophozoites.
- F. If inconclusive, prepare smears of material for staining.
 1. Place 1 drop of sediment in the center of each of three glass slides (1 by 3 in.), and spread the material with the tip of the pipette.
 2. Place one slide in Schaudinn's fixative while wet, and dry the other two thoroughly.
 3. Trichrome stain the slide fixed in Schaudinn's fixative (*see* procedure 9.3.6).
 4. Fix the air-dried smears in methanol. Stain one with Giemsa (*see* procedure 9.8.5) and the other with a modified acid-fast stain (*see* procedures 9.4.1 and 9.4.2).
 5. Put immersion oil on stained smears, and examine Giemsa-stained smear with the 10× objective and trichrome-stained smear with the 50× oil objective if available. Otherwise, use the 100× oil objective.

VI. RESULTS

- A. Helminth larvae (rare) are more likely to be seen in the wet preparation with and/or without iodine (*see* procedures 9.3.3 and 9.3.4).
- B. Protozoan trophozoites will generally be visible in the trichrome-stained smears.
- C. Oocysts will be seen on the modified acid-fast preparation.

POSTANALYTICAL CONSIDERATIONS**VII. REPORTING RESULTS**

Record any amebae, oocysts, larvae, or eggs detected by wet mounts.

- A. Give genus and species of amebae after confirmation with permanent stain.
- B. "No parasites found" in expectorated sputum are considered "normal flora"; therefore, call the physician if any organisms are detected.

VIII. PROCEDURE NOTES

In the United States, detection of parasites in expectorated sputum is rare. If characteristics of suspected parasites are not "classic," request another specimen for confirmation.

IX. LIMITATIONS OF THE PROCEDURE

- A. Although there are rare reports of detection of *Pneumocystis carinii* in expectorated sputum, this method cannot be recommended for detection of this organism (1).
- B. If *C. parvum* is suspected, remember to centrifuge the sputum specimen for 10 min at 500 × *g*. Otherwise, the oocysts may not be found in the sediment used to prepare smears for modified acid-fast stains.

APPENDIX 9.7.1–1

Include QC information on reagent container and in QC records.

Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. Mucolytic agent such as Sputolysin Stat-Pack dithiothreitol solution (Behring Diagnostics, Inc.)

1. Store unopened at room temperature until expiration date published on package.
2. Store working solution at 4°C. Include the date made and the expiration date. Discard working solution after 48 h. Prepare working solution by removing 1.0 ml from the 10-ml bottle and diluting with 9.0 ml of sterile water.

B. Iodine reagents

1. D'Antoni's iodine (*see* procedure 9.3.3)
2. Lugol's iodine (*see* procedure 9.3.3)

C. Trichrome stain reagents

1. Schaudinn's fixative (*see* procedure 9.2.2)
2. Trichrome stain (*see* procedure 9.3.6)

D. Giemsa stain reagents

1. Giemsa stain (*see* procedure 9.8.5)
2. Phosphate buffer, pH 7.0 to 7.2 (*see* procedure 9.8.5)
3. Phosphate buffer plus Triton X-100 at 0.01% (*see* procedure 9.8.5)

Phosphate buffer solutions

pH	Na ₂ HPO ₄ (9.5 g/liter) (anhydrous) (ml)	NaH ₂ PO ₄ ·H ₂ O (9.2 g/liter) (ml)	Distilled water (ml)
6.6	37.5	62.5	900
6.8	49.6	50.4	900
7.0	61.1	38.9	900
7.2	72.0	28.0	900

9.7.2

Induced Sputum: Stained Preparations for Detection of *Pneumocystis carinii*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Use concentrated stained preparations of induced sputa to detect *Pneumocystis carinii* and differentiate trophozoite and cyst forms from other possible causes of pneumonia. Organisms must be differentiated from fungi such as *Candida* spp. and *His-*

toplasma capsulatum. (For detection of other organisms in sputum specimens, see procedure 9.7.1. Other organisms detected may be reported if control materials for their identification are included.)

II. SPECIMEN

Observe standard precautions.

- A. Induced sputa are collected by pulmonary or respiration therapy staff after patients have used appropriate cleansing procedures to reduce oral contamination.
- B. Nebulizing procedures are determined by the staff collecting specimens. The induction protocol is critical for the success of the procedure. Patients with *Pneumocystis* sp. pneumonia usually have dry, nonproductive coughs. Organisms are rarely detected in expectorated sputa.
- C. The laboratory processing specimens must establish a protocol for this diagnostic procedure in cooperation with the pulmonary staff. Induced sputum specimens are most useful for detection of *P. carinii* in human immunodeficiency virus-infected individuals, as others have fewer, less readily detected organisms (9).

III. MATERIALS

A. Reagents (see Appendix 9.7.2–1)

B. Supplies

1. Pasteur pipettes
2. 15- and 50-ml conical centrifuge tubes
3. 1- and 10-ml pipettes
4. Glass slides (1 by 3 in.)
5. Stain rack
6. Glass Coplin jars
7. 1 plastic Coplin jar with lid for silver stain
8. Graduated cylinder
9. Bleach
10. Protective gloves

C. Equipment

1. Microwave oven or water bath (80°C) and thermometer
2. Centrifuge with carriers for 50- and 15-ml tubes with safety caps
3. Binocular microscope with 40× or 50× oil and 100× oil immersion objectives and 10× oculars
4. Fluorescence microscope with filters to obtain appropriate wavelength of light if immunospecific stains with fluorescent labels are used.

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Incorporate control slides in all stain procedures.
 1. Yeast-containing material may be used as a positive control for silver staining.
 2. Material containing RBCs and WBCs may be used as a control for Giemsa staining (*see* procedure 9.8.5).
 3. Both *P. carinii*-positive and *P. carinii*-negative but yeast-positive material should be used for immunospecific staining (check with suppliers).
 4. Stains cannot be evaluated if controls do not stain appropriately. Stain is not within acceptable results when the following occur.
 - a. *P. carinii* does not stain or stains black without delineation of “parentheses.”
 - b. Fungi and actinomycetes do not stain.
- B. Mucolytic agent must be free of contamination, as determined by clear appearance. Replace working solution after 48 h.
- C. Clean and check centrifuge for speed, and clean brushes once a year.
- D. Maintain temperature of refrigerator where mucolytic agent working solution is stored at 4°C (range, 2 to 8°C).
- E. Keep stock stain solutions in area away from light, buffers, and other reagents; discard (prior to expiration date) if cloudy or apparently contaminated.
- F. Check each new lot of stain for staining quality. Check Giemsa with a specimen containing blood to see that RBCs stain grayish, WBC nuclei stain red-purple, and WBC cytoplasm stains bluish (*see* procedure 9.8.5).
- G. Fluorescence microscope can be evaluated for correct light wavelength for label with commercially available QC slides.
- H. Record all QC results.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. Treat specimens that appear to contain mucus with a mucolytic agent by adding a volume of agent equal to or two-thirds of the volume of the specimen (usually 2 or 3 ml) and incubating at room temperature for 15 min. Large-volume specimens often are thin and watery. For these, larger amounts (up to 20 to 25 ml) may be concentrated by centrifugation prior to the addition of a mucolytic agent.
- C. Centrifuge the specimen at $1,300 \times g$ for 5 min, making sure the safety caps are in place on the centrifuge tube carrier.
- D. Decant supernatants into a disinfectant solution such as a 1:10 dilution of bleach.
- E. If the sediment appears to contain significant blood, a portion (one-half to one-third) should be treated with an RBC lytic agent such as saponin or Lyse at one-half to one-third the volume of the sediment, left at room temperature for 5 min, and recentrifuged to repack sediment.
- F. Decant supernatants from treated specimens.
- G. Use Pasteur pipettes to resuspend sediments in material remaining after decanting.
- H. Prepare smears on glass slides (1 by 3 in.) by placing drops of sediment in centers of slides. For specimens treated to lyse RBCs, prepare two smears: use a drop of sediment before lytic treatment for one smear and a drop of lysed sediment for the other.
- I. Drops may be spread with the pipette so that they are thin and even.

V. PROCEDURE (*continued*)

- J.** Air dry slides, and fix smears for Giemsa or silver staining by dipping in methanol. Slides for immunospecific staining must be fixed according to the package insert directions.
- K.** Rapid Giemsa stain (Diff-Quik or Giemsa Plus)
1. Stain solutions should be kept in dropper bottles. Place 1 or 2 drops of red stain solution 1 on specimen smear and control slide (normal blood film), hold for 10 s, and drain.
 2. Add 1 or 2 drops of blue solution 2, hold for 10 s, drain, and rinse very briefly with deionized water.
 3. Stand slides on end to drain and air dry.
 4. Slides must be examined with oil or mounted with mounting medium.
- L.** Giemsa stain
- Make Giemsa working solution fresh each day. Discard and make new solution after 10 slides have been stained in a Coplin jar.
1. Place 2 ml of Giemsa (azure B) stain in Coplin jar. Remove stain from stock stain in bottle with clean, dry pipette.
 2. Add 40 ml of phosphate buffer, pH 7.0 to 7.2, containing 0.01% Triton X-100.
 3. Place fixed specimen smears and control smears in Giemsa stain for 30 min.
 4. Remove slides, dip in phosphate buffer, stand slides on end, and allow to drain and air dry.
 5. Examine with oil or mount slides.
- M.** Silver stain (3)
1. Place specimen smear slides and control slides on stain rack.
 2. Add 10% chromic acid to cover smears, and let stand for 10 min.
 3. During this period, prepare working methenamine-silver nitrate by placing the following in this order in a plastic Coplin jar: 20 ml of 3% methenamine, 1 ml of 5% silver nitrate, 1.5 ml of 5% sodium borate, and 17 ml of distilled or deionized water.
 4. Wash slides with distilled or deionized water.
 5. Cover with 1% sodium metabisulfate for 1 min.
 6. Wash with water, place slides in plastic Coplin jar containing methenamine-silver nitrate, and cover with cap.
 7. Place in microwave oven at 50% power for approximately 35 s, rotate 90°, heat for another 35 s, and then leave slides in hot liquid for 2 min. Solution should turn brown to black.
 8. If a water bath is used, heat water bath to 80°C. Place plastic Coplin jar containing stain reagents in bath for 6 min prior to placing slides in jar, add slides, and leave jar in bath for an additional 5 min. Solution should turn brown to black.
 9. Remove slides, and wash in distilled, deionized water.
 10. Dip slides up and down in 1% gold chloride, wash in distilled or deionized water, and place on rack again.
 11. Cover slides with 5% sodium thiosulfate for 1 min.
 12. Wash in distilled, deionized water.
 13. Cover with 0.2% fast green in acetic acid counterstain for 1 min.
 14. Wash with distilled, deionized water, and stand slides on end to drain and dry.
 15. Examine with oil immersion or mount slides.
 16. Fill Coplin jar used for staining with bleach (full strength), and let stand for at least 1 h.

V. PROCEDURE (continued)

N. Immunospecific staining

1. Follow package directions (by the manufacturer) exactly.
2. If negative control slide containing yeast cells exhibits fluorescence or if specimen slide is at all equivocal, do not report specimen as positive for *P. carinii* on the basis of this stain.
3. Perform cyst wall and organism stains.

O. For all stains

1. *Examine control slide for each stain prior to examination of specimen stains.* Stain intensity of controls will be a guide to stained appearance of organisms in specimens.
2. Examine stained specimen smears by systematically moving from field to field until the majority of the smear has been covered (*cover total area for silver stain*).
3. In Giemsa stains, clumps of trophozoites of various sizes may be detected. In large clumps, it may be difficult to differentiate individual organisms. *Look at organisms at the edges of clumps, and look for small, more dispersed clumps.*
 - a. Yeastlike fungi will have blue cytoplasm and purple-red nuclei.
 - b. Filamentous fungi stain purple-blue; their nuclei usually do not stain.
 - c. Actinomycetes stain purple-blue.
4. In silver- or other cyst wall-stained smears, look for the various cyst forms, including those that show dark centers, are cup shaped, or show foldlike lines. If dark-staining organisms appear more oval, look carefully for budding forms that indicate that the organisms are yeasts.
 - a. *P. carinii* cysts
For these, 70% should have delicately stained walls, usually brown or grey. They will appear rather transparent, with structures described as “parentheses” staining black.
 - b. Fungi and actinomycetes stain gray to black.
 - c. Glycogen, mucin, and RBCs stain rose taupe to gray.
 - d. Background is pale green.
5. Detecting *P. carinii* in specimen smears of one stain should prompt a careful examination of the other stain to confirm the identification.
6. *Retain all positive-stained specimen slides and the control slides from the procedure for reference.*

VI. RESULTS

P. carinii trophozoites and/or cysts may be recovered with these techniques. Other fungi may also be recovered.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report *P. carinii* from any specimen in which organisms are detected (magnification of $\times 1,000$).
Examples: No *Pneumocystis carinii* seen.
Pneumocystis carinii seen. (No quantitation should be included.)
- B. Report fungi that may be present if positive control specimens contain both yeastlike and filamentous fungi and have been stained appropriately.
 1. Fungi ($\times 400$)
Examples: No mycotic elements seen.
Budding yeast, budding yeast cells and pseudohyphae resembling *Candida* species (quantitated as few, moderate, or many)

VII. REPORTING RESULTS*(continued)*

2. Hyphae are reported with no quantitation.
Examples: Septate hyphae seen.
Nonseptate hyphae seen.
- C. Report actinomycetes (oil immersion, $\times 1,000$) if positive control slides are included and exhibit proper staining characteristics.
Examples: No filamentous branching bacteria seen.
Filamentous branching bacteria seen. (No quantitation.)

VIII. PROCEDURE NOTES

- A. It is advisable to use at least two stains for detection and identification of *P. carinii*. With traditional histochemical stains, a trophozoite stain such as Giemsa and a cyst wall stain such as methenamine-silver nitrate have been described.
- B. There are many cyst wall stains in addition to the ones described here (2, 4, 6, 17), and there are other modifications of the silver stain (7, 10, 12, 15).
- C. Reports of usefulness of stains are variable (14). Other counterstains may be used. A counterstain with Giemsa is useful if one referral slide is to be examined (20).
- D. In selecting a cyst wall stain, consider access to quality stains, stability of reagents, and frequency of testing. Dye lots of toluidine blue O stains vary (21), and stability of sulfation reagents also varies (18). In the modified procedure (6), the sulfation reagent made of glacial acetic acid and concentrated sulfuric acid presents a problem of disposal. Good Gram-Weigert stains depend on decolorization with aniline-xylene reagent, which requires a specific aniline oil.
- E. The rapid silver stain described above is a modification of the stain described by Brinn (3). Heating the chromic acid causes too much nonspecific staining, making the background dark, staining the granules of cells, and slowing examination. With the silver stain described above, it was found that buildup of silver on the stain container interfered with staining. For that reason, bleach should be added to the stain jar after staining. Periodically, jars should be cleaned with a brush.
 1. Residual silver plating on glassware from previous use (not applicable if the plastic Coplin jar is used)
Inspect glassware before use to be sure it is not cracked and does not have residual silver plating.
 2. Always prepare fresh reagents and rinse slides with distilled, deionized water.
 3. If methenamine-silver nitrate is made according to the method described above, the solution will be clear. If it is cloudy or opaque, the glassware may have been dirty or some reagent may have been incorrectly made. Discard the cloudy solution. Check your distilled, deionized water source and prepare fresh working solution. Distilled, deionized water must be used throughout the procedure.
- F. If slides are mounted with mounting medium and coverslips, the stained preparations must be dehydrated in xylene prior to mounting. If mounted slides look opaque, the dehydration and clearing with xylene (or xylene substitute) was not adequate. Soak slides in xylene to remove the coverslips. Repeat dehydration steps with fresh ethanol and xylene.
- G. Occasionally, degenerating PMNs may resemble *P. carinii*.
- H. Monoclonal antibodies specific for human strain *P. carinii* have been described elsewhere (5); immunospecific staining is becoming more widely used in routine laboratory evaluations. The commercial systems vary; some are indirect stains, and some are direct. Reports with all systems have been variable (1, 8, 13, 19).

VIII. PROCEDURE NOTES

(continued)

- I. It is best to select an organism stain and a cyst wall stain or immunospecific stain and gain experience with the stains. Using a pair of stains will help avoid both false-negative and false-positive reporting.
- J. Cyto centrifuge preparations of sputum have been described elsewhere (11), and this procedure is considered helpful by some for determining cell populations for further evaluation of patients. This is a consideration other than detection of organisms.

IX. LIMITATIONS OF THE PROCEDURE

Although induced sputum specimens have been used successfully in diagnosis of *P. carinii* in some institutions (1), they have not been useful at others (16). This may be due, in part, to careful adherence to specimen rejection criteria. If the clinical evaluation of a patient suggests *P. carinii* pneumonia and the induced sputum specimen is negative, a bronchoalveolar lavage specimen should be evaluated by using the stains presented in this protocol.

Nucleic acid amplification of pneumocystis-specific sequences and subsequent oligonucleotide hybridization have been used to detect *P. carinii*. Also, a number of procedures have been developed using PCR or nested PCR; these methods have been very useful, particularly for AIDS patients. Direct-fluorescent-antibody reagents have also been used; these tests are sensitive and specific, and the slides are easy for an experienced reader to review. However, a fluorescent microscope is required.

APPENDIX 9.7.2-1

Include QC information on reagent container and in QC records.

Reagents

■ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

- A. Mucolytic agent such as Sputolysin Stat-Pack dithiothreitol solution (Behring Diagnostics, Inc.) and RBC lytic agent such as saponin (Aldrich, Milwaukee, Wis.; ICN Biochemicals, Costa Mesa, Calif.), Lyse (Curtin Matheson Scientific, Inc.), or Hematall LA-Hgb reagent (Fisher Scientific)
- B. Rapid Giemsa stain such as Diff-Quik (Baxter Scientific Products) or Giemsa Plus (Trend Scientific). Follow manufacturer's instructions or use Giemsa stain.
- C. Giemsa stain, azure B alcoholic stock (Harleco, Philadelphia, Pa.), diluted 1 to 20 with phosphate buffer containing 0.01% Triton X-100 (see procedure 9.8.4).
1. Buffers prepared from stock buffers
 - a. Alkaline buffer (NaHPO₄ solution, 0.067 M) is 9.5 g of Na₂HPO₄ dissolved in 1 liter of distilled water.
 - b. Acid buffer (NaHPO₄, 0.067 M) is 9.2 g of Na₂HPO₄·H₂O dissolved in 1 liter of distilled water.
 2. These buffers can be kept for a long time (12 months).
 3. To prepare buffered water for stain, add 39 ml of acid buffer to 61 ml of alkaline buffer, and add that mixture to 900 ml of water.
- D. Cyst wall stain such as rapid methenamine-silver nitrate (3)
1. Chromic acid (10% solution)

chromic acid (CrO₃) 100.0 g
distilled deionized water 1,000.0 ml

Solution is usable for up to 1 year.

APPENDIX 9.7.2-1 (continued)

2. Methenamine (3% solution)

hexamethylenetetramine, USP [(CH ₂) ₆ N ₄]	12.0 g
distilled deionized water	400.0 ml

Solution is usable for up to 6 months.

3. Silver nitrate (5% solution)

silver nitrate (AgNO ₃)	5.0 g
distilled deionized water	100.0 ml

Solution is usable for up to 1 month at 4°C.

4. Sodium borate (Borax) (5% solution)

sodium borate (Na ₂ B ₄ O ₇ ·10H ₂ O)	5.0 g
distilled deionized water	100.0 ml

Solution is usable for up to 1 year.

5. Sodium bisulfite (1% solution)

sodium bisulfite (NaHSO ₃)	10.0 g
distilled deionized water	100.0 ml

Solution is usable for up to 1 year.

6. Gold chloride (1% solution)

gold chloride	5.0 g
distilled deionized water	500.0 ml

Solution is usable for up to 1 year.

7. Sodium thiosulfate (5% solution)

sodium thiosulfate (Na ₂ S ₂ O ₃ ·5H ₂ O)	50.0 g
distilled deionized water	1,000.0 ml

Solution is usable for up to 1 year.

8. Stock light green

light green, S.F. yellowish C.I. no. 42095	0.2 g
distilled deionized water	100.0 ml
glacial acetic acid (CH ₃ ·COOH)	0.2 ml

Solution is usable for up to 1 year.

9. Working light green

stock light green	10.0 ml
distilled deionized water	40.0 ml

Solution is usable for up to 1 month.

10. Ethanol, 100% (absolute) and 95%

11. Methanol, 100% (absolute)

12. Xylene (or xylene substitute)

All reagents can be stored at 25°C except the silver nitrate, which must be refrigerated. Silver nitrate should be discarded and replaced after storage for 1 month.

E. Immunospecific stain

Commercially available kits (*see* Appendix 9.10.6-1 at the end of this section)

F. Positive control slides are commercially available (Hardy Diagnostics, Santa Maria, Calif.).

9.7.3

Aspirates and Bronchoscopy Specimens

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The examination of aspirated material for the diagnosis of parasitic infections is useful when routine specimens and methods have failed to demonstrate the organisms. Aspirates include liquid specimens collected from a variety of anatomic sites that delineate the types of organisms to be ex-

pected. Aspirates most commonly processed in the parasitology laboratory include fine-needle aspirates and duodenal aspirates. Fluid specimens collected by bronchoscopy include bronchoalveolar lavage (BAL) fluids and bronchial washings.

II. SPECIMENS

Observe standard precautions.

A. Fine-needle aspirates

When specimens are collected and sent to the laboratory for processing, slides must be stained appropriately for suspected organisms and examined microscopically. Suggested stains are Giemsa and methenamine-silver nitrate for *Pneumocystis carinii*, Giemsa for *Toxoplasma gondii*, trichrome for amebae, and modified acid fast for *Cryptosporidium parvum*.

B. Aspirates of cysts and abscesses

Aspirates to be evaluated for amebae may require concentration by centrifugation, digestion (streptokinase; see Appendix 9.7.3–1), microscopic examination for motile organisms in direct preparations, and cultures and microscopic evaluation of stained preparations (12).

C. Duodenal aspirates

Aspirates to be evaluated for *Strongyloides stercoralis*, *Giardia lamblia*, or *Cryptosporidium* may require concentration by centrifugation prior to microscopic examination for motile organisms and permanent stains. In order to see microsporidial spores, centrifuged sediment stained with modified trichrome stains or optical brightening agents will be required.

D. Bone marrow aspirates

Aspirates to be evaluated for *Leishmania* amastigotes, *Trypanosoma cruzi* amastigotes, or *Plasmodium* spp. require Giemsa staining.

E. Fluid specimens collected by bronchoscopy

Specimens may be lavage fluids or washings, with BAL fluids preferred (11). Specimens are usually concentrated by centrifugation prior to microscopic examination of stained preparations (Sputolysin; see Appendix 9.7.3–1). Organisms discussed here which may be detected are *P. carinii*, *T. gondii*, *C. parvum*, and the microsporidia (4, 9).

III. MATERIALS

- | | |
|--|---|
| A. Reagents (<i>see</i> Appendix 9.7.3–1)
B. Supplies <ol style="list-style-type: none"> 1. Pasteur pipettes 2. 1- and 10-ml pipettes 3. Glass slides (2 by 3 in.) 4. Glass slides (1 by 3 in.) 5. Coverslips (22 by 22 mm; no. 1 thickness) 6. Centrifuge tubes, 15 and 50 ml, conical 7. Glass Coplin jars 8. Plastic Coplin jar with lid 9. Stain rack 10. Graduated cylinder 11. Bleach | <ol style="list-style-type: none"> 12. Protective gloves 13. <i>Nocardia asteroides</i> ATCC 19247 C. Equipment <ol style="list-style-type: none"> 1. Centrifuge with carriers for 15- and 50-ml tubes with safety caps 2. Binocular microscope with 10\times, 40\times or 50\times oil, and 100\times oil immersion objectives 3. Fluorescence microscope with filters to obtain appropriate wavelength of light for fluorescent label used if immunostaining 4. Microwave oven or water bath and thermometer |
|--|---|

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Incorporate control slides in all stain procedures.
 1. Yeast-containing material may be used as a positive control for silver staining.
 2. Material containing RBCs and WBCs should be used as a control for Giemsa staining.
 3. Both *P. carinii*-positive and *P. carinii*-negative but yeast-positive material should be used for immunospecific staining.
 4. Stains cannot be evaluated if controls do not stain appropriately.
- B. Material containing RBCs and WBCs should be used as control for Giemsa (*see* procedure 9.8.5) and trichrome (*see* procedure 9.3.6) stains.
- C. Alcohol-fixed slides of *N. asteroides* ATCC 19247 culture serve as a control for modified acid-fast stain.
- D. Use both *P. carinii*-positive and -negative controls for immunospecific staining.
- E. Both Sputolysin and streptokinase working reagents should be stored at 4°C and made fresh after 48 h.
- F. Incubate new lots of media to check for sterility, and inoculate samples with stock amebae to see that medium supports growth (*see* procedures 9.9.1 to 9.9.3 and 9.9.5).
- G. Clean and check centrifuge for speed, and clean brushes once a year.
- H. Maintain temperature of refrigerator where mucolytic agent working solution is stored at 4°C (range, 2 to 8°C).
- I. With each new lot of Giemsa stain or new buffer, check stain with a specimen containing blood to see that RBCs stain grayish, WBC nuclei stain red-purple, and WBC cytoplasm stains bluish. If cells do not stain appropriately, check stock stain and buffer to find cause (*see* procedure 9.8.5).
- J. Fluorescence microscope can be evaluated for correct light wavelength for label with commercially available QC slides.
- K. Check incubator for temperature maintenance at 35 \pm 2°C.
- L. Record all QC results.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. Specimens that contain mucus may be treated with a mucolytic agent by adding a volume of agent equal to or one-half to two-thirds of the volume of specimen and incubating at room temperature for 15 min. Centrifuge at 1,000 \times g for 5 min, and use sediment to prepare wet mounts and smears for staining.

V. PROCEDURE (*continued*)

- C. Specimens that contain cell debris and proteinaceous material and that require digestion should be treated with streptokinase (1 part enzyme solution to 5 parts specimen) for 1 h at 35°C. Shake at intervals (every 15 min). Centrifuge at $1,000 \times g$ for 5 min, and use sediment to prepare wet mounts and smears for staining.
- D. Specimens that include significant amounts of blood require treatment with an agent to lyse RBCs. Add 1 volume of lysing agent per volume of specimen, and incubate at room temperature for 5 min.
- E. Place representative samples of untreated and Lyse-treated specimens in 15-ml conical centrifuge tubes, and centrifuge at $1,000 \times g$ for 5 min. For BAL or bronchial-washing specimens, which usually are 50 ml or more, place 20 to 24 ml of each specimen in a 50-ml conical centrifuge tube, and centrifuge as described above.
- F. Decant supernatants from centrifuged samples into a disposal container containing disinfectant.
- G. With a Pasteur pipette, remove drops of sediment for wet mounts, stain preparations, and culture.
- H. For duodenal aspirates and aspirates from cysts or abscesses, place 1 drop of sediment on a glass slide (2 by 3 in.), add a drop of 0.85% NaCl, and cover with a no. 1 coverslip (22 by 22 mm).
- I. Examine preparation field by field with low light until the entire mount has been examined.
- J. If the wet mount is equivocal for a protozoan, place a drop of sediment on a glass slide (1 by 3 in.), and add a drop of polyvinyl alcohol (PVA) fixative. Mix the drops with a pipette, and spread the mixture into an even film (about 22 by 22 mm). Dry the preparation thoroughly, and stain with trichrome stain.
- K. Trichrome stain (*see* procedure 9.3.6)
- L. For material from cysts or abscesses, prepare cultures by adding 0.5 ml of material to a tube of culture medium for the recovery of amebae in accordance with procedure 9.9.1.
- M. Aspirates of bone marrow may be submitted for diagnosis of leishmaniasis, trypanosomiasis, and occasionally for malaria. Material should be stained with Giemsa stain and examined with the $100\times$ oil immersion objective.
- N. Sediments from BAL or bronchial washings are examined in stained preparations. Three slides should be stained.
 - 1. Use a Pasteur pipette to place drops of sediment from each specimen on at least four slides. With the pipette, spread the sediment into a thin, even film. For specimens treated with an agent to lyse RBCs, use sediment from both treated and untreated samples for smears.
 - 2. Air dry slides, and fix in methanol. If slides are to be stained with immunospecific stains, fix according to package instructions.
 - 3. Stain one slide with rapid Giemsa stain (Diff-Quik or Giemsa Plus).
Rapid Giemsa stain procedure
 - a. Stain solutions should be kept in dropper bottles to avoid bacterial contamination. Place 1 or 2 drops of red stain solution 1 on specimen smear and control slide, hold for 10 s, and drain.
 - b. Add 1 or 2 drops of blue solution 2, hold for 10 s, drain, and rinse very briefly with deionized water.
 - c. Stand slides on end to drain and air dry.
 - d. Slides must be examined with oil or mounted with mounting medium.
 - 4. Stain one slide with modified acid-fast stain (*see* procedure 9.4.1).
 - 5. Stain one slide with methenamine-silver nitrate (4) or other cyst wall stain (3, 8, 14) (*see* procedure 9.7.2).

V. PROCEDURE (*continued*)

6. Staining with immunospecific stain may be desirable (*see* Appendix 9.10.2–1 at the end of this section).
 - a. Follow package directions exactly.
 - b. If negative control slide containing yeast cells exhibits fluorescence or if specimen slide is at all equivocal, do not report specimen as positive for *P. carinii* on the basis of this stain.
 - c. Perform cyst wall and organism stains.
- O. Put oil on stained slides or mount. Examine stained slides with 50× oil immersion objective, if available; otherwise, use 100× oil objective. If any slides are equivocal, stain additional slides.
- P. Slides of fine-needle aspirates from lung are stained as described above (step V.N) for BAL and bronchial washings. Fine-needle aspirates of lesions likely to contain amebae are stained as described above (steps V.H through L) for cysts and abscesses.
- Q. Generally portions of aspirate specimens are shared with bacteriology, and it is always important to consider the importance of a Gram stain in ruling out bacterial etiology.

VI. RESULTS

- A. Helminth larvae (rare) are more likely to be seen in the wet preparation (specimens from bronchoscopy) with and/or without iodine.
- B. Protozoa will be visible in the trichrome- or Giemsa-stained smears; trophozoites and cysts of *P. carinii* can be detected in Giemsa-stained smear.
- C. Cysts of *P. carinii* will be seen on the methenamine-silver-stained smears.
- D. Oocysts will be seen on the modified acid-fast preparation.

POSTANALYTICAL CONSIDERATIONS**VII. REPORTING RESULTS**

- A. Organisms detected should be reported as follows.
 1. From fine-needle aspirates and aspirates of cysts and abscesses, report *P. carinii*, *T. gondii*, and *Entamoeba histolytica* or *Acanthamoeba* spp. if morphology in stained preparations is classic. If ameba cultures are positive, species can be determined. Since the only *Entamoeba* sp. causing disseminated disease is *E. histolytica*, identification to the species level does not require positive culture.
 2. From bone marrow aspirates, report *Leishmania donovani*, *T. cruzi*, or *Plasmodium* spp. if forms demonstrated in stains are classic.
 3. From BAL specimens and bronchial washings, report *P. carinii* if characteristic trophozoite and cysts are detected (cysts alone are sufficient); report *T. gondii* if characteristic tachyzoites are detected in Giemsa stain and *C. parvum* if characteristic oocysts are detected in modified acid-fast or immunospecific stains. Note the quality of the specimen. If only a few alveolar cells are present, failure to find organisms may not rule out infection.
- B. Notify clinician if any organisms described are detected.

VIII. PROCEDURE NOTES

- A. Fine-needle aspirates often vary from stick to stick. Examine Giemsa-stained slides with a low-power (10×) objective to find cellular areas of slides to screen carefully. If one stick has better material than others, use slides of this specimen for other staining.
- B. With aspirates of cysts and abscesses, material may vary from thin, with few cells, to very thick. In thick material, select several samples, including bloody

VIII. PROCEDURE NOTES

(continued)

- areas, for digestion. Organisms will often be found in the bloody material aspirated last.
- C. With duodenal aspirates, if strongyloidiasis is expected, examine all of the specimen sediment in wet mounts with the 10× objective.
 - D. Aspirates of bone marrow are rarely submitted for examination for parasites. In the United States, splenic aspirations are very rarely performed.
 - E. With BAL specimens and bronchial washings, specimens are usually submitted for detection of *P. carinii*, although other organisms may be found. If *C. parvum* oocysts are found, report their detection, although their presence may not be clinically significant. *T. gondii* is being detected more frequently in BAL specimens, particularly those from human immunodeficiency virus-positive individuals (6).

IX. LIMITATIONS OF THE PROCEDURE

Lack of detection of *P. carinii* in BAL samples from patients given prophylaxis with or treated with aerosolized pentamidine has been reported (10). As more individuals are placed on prophylaxis, fluid specimens from bronchoscopy may be less useful.

APPENDIX 9.7.3–1

Include QC information on reagent container and in QC records.

Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. Staining reagents

1. Giemsa stain reagents (see procedure 9.8.5)
 - a. Giemsa stain (see procedure 9.8.5)
 - b. Phosphate buffer, pH 7.0 to 7.2 (see procedure 9.7.2)
 - c. Phosphate buffer plus Triton X-100 at 0.01% (see procedure 9.8.5)
 - d. Rapid Giemsa
 - (1) Diff-Quik (Baxter Scientific)
 - (2) Giemsa Plus (Trend Scientific)
2. Trichrome stain reagents (see procedure 9.3.6)
 - a. Schaudinn's fixative (see procedure 9.2.2)
 - b. PVA fixative (see procedure 9.2.2)
3. Acid-fast stain reagents
 - a. Kinyoun's acid-fast stain (cold) (see procedure 9.4.1)
 - b. Modified acid-fast stain (hot) (see procedure 9.4.2)
4. Methenamine-silver nitrate stain (see procedure 9.7.2)
5. Immunospecific stains

Commercially available kits for staining both *C. parvum* (1) and *P. carinii* use monoclonal antibody (2, 7, 13) for immunospecific staining. Follow the manufacturer's directions exactly, and include appropriate controls.

B. Culture media for *E. histolytica* (see procedure 9.9.1)

C. Materials for digestion

1. Sputolysin Stat-Pack dithiothreitol (Behring Diagnostics)

Prepare (according to package directions) a 1:10 dilution with distilled water (include expiration date). Store no longer than 48 h in refrigeration.
2. Lysing agent (available from most major laboratory suppliers)
3. Streptokinase

Reconstitute streptokinase and streptodornase (Veridase; Lederle Laboratory) as directed by manufacturer.

D. Diluent

0.85% NaCl

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Biopsy specimens are recommended for the diagnosis of tissue parasites. The procedures that may be used for this purpose in addition to standard histological preparations are impression smears and teased and squash preparations of biopsy tissue

from skin, muscle, cornea, intestine, liver, lung, and brain. Tissue to be examined by permanent sections or electron microscopy should be fixed as specified by the laboratories which will process the tissue.

II. SPECIMENS

Observe standard precautions.

Tissue submitted in a sterile container on a sterile sponge dampened with saline may be used for protozoan cultures after mounts for direct examination or impression smears for staining have been prepared. If cultures for parasites will be made, use sterile slides for smear and mount preparation.

- A. To prepare sterile slides for impression smears, lay six to eight glass slides (1 by 3 in.) on a paper towel, fold the towel (containing the slides) accordion fashion, tape, and autoclave using routine temperature and time frames (*see* procedure 9.8.4). An alternative method would be to soak the slides in 95% ethyl alcohol and flame them prior to use.
- B. Use sterile (autoclaved or flamed) forceps for handling tissue.
- C. Place tissue in a sterile petri dish to examine macroscopically and to select sample for microscopic evaluation. Minced tissue can be used if it is kept sterile.
 1. If biopsy tissue is several millimeters to a centimeter in size, select from area differing from normal. For example, select gray consolidated or granulomatous portion of lung or ulcerated area of intestinal tissue.
 2. If tissue is one or several small fragments a few millimeters in size that look alike, use one fragment. If tissue fragments look different, use one of each type for microscopic examination.
- D. Prepare impression smears.
 1. Blot tissue sample on sterile toweling. If the sample is large enough, cut the tissue, and use the cut surface to touch the slide.
 2. Press tissue against slide, lift, and press again. Turn sample over and press against slide to make two more impressions. Keep impressions close together to speed screening. If several tissue samples were selected, make impressions in a row with each sample. For example, place sample 1 on top, sample 2 in the middle, and sample 3 at bottom, making impressions from left to right with each sample rather than from top to bottom. This scheme avoids differences in sample staining related to location.

II. SPECIMENS (*continued*)

3. Air dry smears, and fix in methanol for 1 min for subsequent Giemsa, methenamine-silver nitrate, and modified acid-fast staining. If the amount of tissue is sufficient, prepare multiple smears for each stain selected.

4. Place wet slide in Schaudinn's fixative for subsequent trichrome staining.

5. Fix slide according to manufacturer's directions for immunospecific staining.

E. Teased preparations

1. Place sample in the bottom of a plastic petri dish. Cover with 2 to 4 drops of saline (100 to 200 μ l).

2. Gently tease tissue with needles, or hold tissue with forceps while pulling apart with a scalpel.

3. Put cover on dish, and leave at room temperature for 30 min.

F. Squash preparation

Cut selected tissue portions into very fine fragments with a scalpel. Place a fragment on a slide (1 by 3 in.), add 1 drop of saline, cover with a second slide (1 by 3 in.), and hold together with membrane clips (surgical supply company). If these are not available, use paper clips, but they are not as efficient.

G. Skin scrapings

Request that scrapings be sent between two glass slides or in a small vial.

H. Culture

Prepare cultures to demonstrate the following organisms.

1. *Entamoeba histolytica* (*see* procedure 9.9.1) (18)

2. *Acanthamoeba* spp. and *Naegleria* spp. (*see* procedure 9.9.2)

3. *Leishmania* spp. (*see* procedure 9.9.5)

I. Mouse passage for *Toxoplasma gondii* (15)

1. Grind tissue in 0.85% NaCl until a fine suspension results.

2. Intraperitoneally inject three to five mice of any laboratory strain that weigh \sim 20 g each with 0.2 to 0.4 ml of suspension.

3. House mice in isolation.

4. Check daily for signs of central nervous system (CNS) dysfunction. If CNS symptoms are detected, proceed to animal autopsy (*see* item V.F.4 below).

III. MATERIALS**A. Reagents** (*see* Appendix 9.7.4–1)**B. Supplies**

1. Pasteur pipette
2. Sterile glass slides (1 by 3 in.)
3. Petri dishes
4. Glass Coplin jars with lids
5. Plastic Coplin jars with lids
6. Pipettes, 1 and 10 ml
7. Scalpels
8. Forceps
9. Graduated cylinders
10. Stain rack

11. Protective gloves

12. Tissue grinder

C. Equipment

1. Microwave oven or water bath (80°C) and thermometer
2. Binocular microscope with 10 \times , 40 \times , or 50 \times oil, and 100 \times oil immersion objectives
3. Fluorescence microscope with filters to obtain appropriate wavelength of light for fluorescent label used if immunostaining

ANALYTICAL CONSIDERATIONS**IV. QUALITY CONTROL****A. Incorporate control slides in all stain procedures.**

1. Yeast-containing material may be used as a positive control for silver staining (*see* procedure 9.7.2).

2. Material containing RBCs and WBCs may be used as a control for Giemsa staining (*see* procedure 9.8.5).

3. Both *Pneumocystis carinii*-positive and *P. carinii*-negative but yeast-positive material should be used for immunospecific staining for *P. carinii*.

4. Stains cannot be evaluated if controls do not stain appropriately.

IV. QUALITY CONTROL (continued)

- B. To check for sterility, incubate new lots of media and inoculate stock ameba cultures of *E. histolytica* to see that medium supports growth (see procedure 9.9.1).
- C. In refrigerator where culture medium is stored, maintain temperature at 4°C. Remember, daily temperature recording is required by Clinical Laboratory Improvement Amendments of 1988 regulations.
- D. With each new lot of Giemsa stain or new buffer, check stain with specimen containing blood to see that RBCs stain grayish, WBC nuclei stain red-purple, and WBC cytoplasm stains bluish. If cells do not stain appropriately, check stock stain and buffer to find cause.
- E. Fluorescence microscope can be evaluated for correct light wavelength for label with commercially available QC slides (see Appendix 9.10.6–1).
- F. Check incubator for temperature maintenance at 35°C.
- G. Record all QC results.

V. PROCEDURE

- A. Impression smears
Stain and examine to detect possible organisms according to specimen and clinical history (Table 9.7.4–1).
 1. Giemsa stain (see procedure 9.8.5)
 2. Methenamine-silver nitrate procedure (see procedure 9.7.2) (16)
 3. Modified acid-fast stain (see procedures 9.4.1 and 9.4.2)
 4. Trichrome stain (see procedure 9.3.6)
 5. Staining with immunospecific stain for *P. carinii* may be desirable (see Appendix 9.10.6–1 at the end of this section).
 6. Modified trichrome stain (see procedures 9.4.3, 9.4.4, and 9.4.5). However, many biopsy specimens for the microsporidia are sent for routine histology processing and staining with hematoxylin and eosin (H&E), tissue Gram stains (Brown and Brenn, Brown and Hopps), silver stains (Warthin-Starry), or periodic acid-schiff (PAS).
 - a. Follow package directions exactly.
 - b. If negative control slide containing yeast cells exhibits fluorescence or if specimen slide is at all equivocal, do not report specimen as positive for *P. carinii* on basis of this stain.
 - c. Examine stained slides microscopically for suspected organisms. Send slides to referral laboratory if necessary.
- B. Teased preparation
Skin snips for detection of microfilariae of *Onchocerca volvulus* and *Mansonella streptocerca*
 1. Tease the small bit of tissue apart in a few drops of saline to release the microfilariae.
 2. Remove drops of saline to a glass slide (1 by 3 in.), cover with no. 1 coverslip, and examine with low light for microfilariae.
 3. For a permanent record, run alcohol under coverslip to fix filariae, partially dry, remove coverslip, and stain with Giemsa.
- C. Squash preparation for muscle detection of *Trichinella spiralis*
Examine microscopically with low power (100×) and low light.
- D. Scrapings of skin for scabies
Examine scrapings microscopically at low power (100×) and low light.
- E. Inoculate cultures with ground tissue suspensions (to release organisms from the cells).
 1. Place small tissue sample in sterile tissue grinder (Ten Broeck or Dounce) in 0.5 ml of sterile saline, and grind until tissue is dispersed.

Table 9.7.4–1 Stains for identifying parasites in various tissues^a

Tissue	Possible parasite(s)	Stain(s) ^b
Lung	<i>P. carinii</i>	Giemsa (27), methenamine-silver (4) or other cyst wall (3, 8, 12, 21, 23), immunospecific (2, 11, 17, 19, 26)
Lung	<i>T. gondii</i>	Giemsa, immunospecific (9)
Lung	<i>E. histolytica</i>	Trichrome (28), Giemsa
Liver	<i>T. gondii</i> , <i>Leishmania donovani</i>	Giemsa
Liver	<i>C. parvum</i>	Modified acid fast (14), immunospecific (1, 25)
Liver	<i>P. carinii</i>	Giemsa, silver or other cyst wall, immunospecific
Liver	<i>E. histolytica</i>	Giemsa, trichrome
Brain	<i>Naegleria</i> sp.	Giemsa, trichrome
Brain	<i>E. histolytica</i>	Giemsa, trichrome
Brain	<i>T. gondii</i>	Giemsa, immunospecific
Brain	Microsporidia	Acid fast, Giemsa, Gram (confirm with EM) (24)
Brain	<i>Encephalitozoon cuniculi</i>	Giemsa (confirm with EM)
Skin	<i>Leishmania</i> spp.	Giemsa
Skin	<i>O. volvulus</i>	Giemsa
Skin	<i>M. streptocerca</i>	Giemsa
Intestine		
Small intestine	<i>C. parvum</i>	Modified acid fast (10), immunospecific (1, 25)
Jejunum	<i>Enterocytozoon bieneusi</i>	Giemsa (confirm with EM) (5, 6, 22)
Duodenum	<i>Giardia lamblia</i>	Trichrome
Colon	<i>E. histolytica</i>	Giemsa, trichrome
	<i>C. parvum</i>	Modified acid fast (10), immunospecific (1, 25)
Cornea, conjunctiva	<i>Microsporidium</i> spp., <i>Nosema</i> sp.	Acid fast, Giemsa (confirm with EM) (7)
Cornea, conjunctiva	<i>Acanthamoeba</i> sp.	Giemsa, trichrome, calcofluor for cysts (13)
Muscle	<i>T. spiralis</i>	

^a Note: In disseminated infections with microsporidia, spores and developing stages from a number of different species could be found throughout the body. Routine histology processing and staining (H&E, silver, Gram, PAS) are used, as are Giemsa, modified trichrome stains, and optical brightening agents. However, the modified trichrome stains (chromotrope) are more commonly used and recommended for clinical specimens other than tissues, such as stool, urine, eye specimens, etc.

^b EM, electron microscopy.

V. PROCEDURE (continued)

2. Add several drops of ground tissue to culture medium as follows.
 - a. To NNN medium (see procedure 9.9.5), add drops at bottom of slant, where they will “pool” with condensed moisture on slant. Incubate at room temperature (isolation of *Leishmania* spp.).
 - b. To TYSGM-9 medium (see procedure 9.9.1), add several drops to the liquid medium, add 3 drops of the starch suspension, and incubate at a 45° to 50° angle at 35°C for 48 h (isolation of *E. histolytica*).
 - c. Add drops to center of seeded agar plate, and incubate at 35 to 37°C (isolation of *Acanthamoeba* spp. or *Naegleria* spp.).

V. PROCEDURE (*continued*)

- F. Examine cultures.**
- 1.** TYSGM-9 medium for amebae (*see* procedure 9.9.1)
With a Pasteur pipette, remove 1 or 2 drops of material adhering to sides or bottom of tube, place on glass slide, cover with coverslip, and examine microscopically (100×) with low light.
 - 2.** Agar plate with lawn of *Escherichia coli* or *Enterobacter* for detection of free-living amebae (*see* procedure 9.9.2)
Examine microscopically at low power (100×) for changes in bacterial lawn, particularly patches and “tracks.”
 - 3.** NNN agar for promastigotes of *Leishmania* spp. (20) (*see* procedure 9.9.5)
 - a.** With a Pasteur pipette, remove a drop of fluid from interface of agar slant and condensed moisture.
 - b.** Place on glass slide, and cover with coverslip.
 - c.** Examine microscopically (400×) with low light for motile promastigotes.
 - 4.** Mouse passage for detection of *T. gondii* (15)
 - a.** Wear canvas gloves to handle mice. Gardening gloves work well.
 - b.** Sacrifice mice.
 - c.** Pin mouse to board, spray with 70% ethyl alcohol, and open peritoneal cavity with sterile scissors.
 - d.** Remove fluid from the peritoneal cavity with sterile Pasteur pipette, and place in small tube or make slide directly.
 - e.** Make Giemsa-stained smears of peritoneal exudate, and examine microscopically at 1,000× for *T. gondii* tachyzoites.
 - f.** Place mice and all contaminated disposable materials in bag to be autoclaved and destroyed. Place nondisposable materials (scissors) in bag to be autoclaved prior to washing.
- G.** Correlate all examination results (wet mount, stains, and cultures) to determine presence of organisms.

VI. RESULTS

- A.** The majority of the protozoa will be found on the specimen permanent stained smears (impression smears, touch or squash preparations, teased preparations).
- B.** When culture is used, permanent stained smears of cultural material may also reveal some protozoa (18).
- C.** Although infrequently used, material from animals (at autopsy) can be examined as both wet and permanent stained preparations for confirmation of protozoa.
- D.** Filarial infections may be confirmed by the recovery and identification of microfilariae in skin scrapings and/or biopsies.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

Report organisms detected if identifications are certain. If presumed parasites for which the laboratory has no corresponding reference material are found, confirmation by another laboratory is suggested.

VIII. PROCEDURE NOTES

- A.** Immunospecific staining reagents are rapidly becoming more available. Evaluations of monoclonal antibodies and staining techniques such as indirect fluorescence, direct fluorescence, and enzyme tagging have been variable. In using newly developed tests, closely follow directions, and include all possible control measures. In addition to new tests, there are “new” organisms.
- B.** Daily, more is being learned about the microsporidia. Most individuals working with new pathogens or developing new tests will gladly accept referral material. Check references for workers to whom material might be sent for confirmatory identification.

IX. LIMITATIONS OF THE PROCEDURE

Success in detection of parasites in tissue depends in part on the adequacy of the specimen. It has been reported that patients being treated with aerosolized pentamidine may have localized (peripheral) *P. carinii* (16). Biopsy specimens are often very tiny and may not be representative of the whole infectious process. The availability of more than one tissue sample taken by transbronchial biopsy enhances diagnosis. To optimize the yield from any tissue specimen, examine all areas, and use as many means of organism detection as possible. The tissue sample results from an invasive costly procedure and deserves the most exhaustive examination possible.

APPENDIX 9.7.4–1

Include QC information on reagent container and in QC records.

Reagents

- ☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.
- A. NaCl, 0.85%
- B. Giemsa stain (see procedure 9.8.5)
- C. Rapid Giemsa
1. Diff-Quick (Baxter Scientific)
 2. Giemsa Plus (Trend Scientific)
- D. Giemsa stain buffer with 0.01% Triton X-100 (see procedure 9.8.5)
- E. Giemsa buffer (see procedure 9.8.4)
- F. Methenamine-silver nitrate stain reagents (see procedure 9.7.2)
- G. Trichrome stain reagents (see procedure 9.3.6)
- H. Schaudinn's fixative (see procedure 9.2.2)
- I. Kinyoun's modified acid-fast stain (see procedure 9.4.1)
- J. Bleach
- K. Culture media
1. *E. histolytica* (see procedure 9.9.1)
 2. *Acanthamoeba* spp. and *Naegleria* spp. (see procedure 9.9.2)
 3. *Leishmania* spp. (see procedure 9.9.5)
- L. Modified trichrome stain (see procedures 9.4.3, 9.4.4, and 9.4.5)

9.8.1

Detection of Blood Parasites

I. PRINCIPLE

During some stages in their life cycle, *Plasmodium* spp. (malaria), *Babesia* spp., *Trypanosoma* spp., *Leishmania donovani*, and the filaria are detectable in human blood. *Plasmodium* and *Babesia* species are found within the RBCs; trypanosomes and microfilariae, the larval stage of filariae, are found outside the RBCs; and *Leishmania* amastigotes are occasionally found within monocytes. Trypanosomes and microfilariae, which frequently are present in low numbers, exhibit motility in freshly collected blood films, and this can aid in their detection. However, species identifications of all blood parasites are usually made from either or both of two types of stained blood films: a thin film and a thick film. These films can be made from whole or anticoagulated blood or

from the sediment of a variety of procedures designed to concentrate trypanosomes and microfilariae in the blood. Although the films are clearest when stained with Giemsa stain, many infections are detected and diagnosed by using Wright's stain. Delafield's hematoxylin is used to enhance the morphological features of microfilariae.

Microscopic examination of stained blood films is best accomplished by beginning with a thorough search of both the thin and thick films with low-power magnification for microfilariae. If larvae are found, magnification at a higher power will reveal the finer morphological details necessary to make a definitive identification. Other blood parasites require examination with oil immersion magnification

of both the thin and thick films. Trypanosomes, even those detected in thick films, are more frequently identified in the thicker portion of the thin film. *Plasmodium* and *Babesia* spp., being intracellular parasites, are detected in the thick film but are more readily identified in the thinner portion of the thin film. Depending on the experience of the microscopist, satisfactory examination usually requires 5 to 10 min for the thick film (about 100 fields) and 15 to 20 min for the thin film (about 200 to 300 fields) at $\times 1,000$ (oil immersion) magnification. All species of parasites found in a blood specimen should be reported to the attending physician as soon as possible. Notification of appropriate governmental authorities should be made expeditiously where required by law.

II. THIN AND THICK BLOOD FILMS

A. Purpose

To date, stained blood films are the most reliable and efficient means for definitive diagnosis of nearly all blood parasites. They provide a permanent record and can be sent to a reference laboratory for consultation or verification of diagnosis. Ordinarily, when a laboratorian tests for blood parasites, two types of blood films are prepared: a thin film and a thick film. These can be made on the same microscope slide, that is, with the thin film on one end of the slide and the thick film on the other, or they can be made on separate slides. When malaria is suspected, the recommended procedure is to prepare a thin film on one slide, a thick film on another, and a combination of thin and thick films on a third slide. The thin film can be stained within a few minutes and will afford a quick diagnosis of malaria if the patient has a high degree of parasitemia; the thick film can be stained in a few hours and will afford a diagnosis of lighter infection; and the combination film is stained several hours later when the blood has dried longer, thus resulting in a better differential stain. The combination film is then used to verify the quick diagnosis and is kept as the permanent record. This three-slide procedure can be used for detecting all blood parasites.

II. THIN AND THICK BLOOD FILMS (continued)

B. Thin blood film (see procedure 9.8.2)

The thin film is identical to a differential WBC count film. It provides a good area for examining the morphology of parasites and RBCs and is used to confirm the identity of parasites that cannot be identified in thick films. Most parasitologists concur that a thin film must be used to differentiate *Plasmodium ovale* from *Plasmodium vivax* and *Babesia* species from the ring forms of *Plasmodium falciparum*. The thin film is also better for identifying *Trypanosoma cruzi*, because these organisms become distorted in thick films. The thin film, however, is less sensitive than the thick film in light parasitemias.

C. Thick blood film (see procedure 9.8.3)

The thick film essentially condenses into an area suitable for examination about 20 times more blood than the thin film. In this respect, the thick film is a concentration procedure. Here, the RBCs are lysed during the staining process so that only parasites, platelets, and WBCs remain visible. The thick film, then, has two advantages over the thin film: it saves time in examining the blood and increases the chance of detecting light infections. Therefore, the thick film is recommended for the routine *detection* of all parasites when the diagnostic stages occur in blood, and it can be used, in most instances, for identifying to the species level all microfilariae, the African trypanosomes, and all *Plasmodium* spp. except *P. ovale*.

D. Blood specimen

Blood for detecting parasites is obtained by either finger puncture or venipuncture. These procedures are described in detail in NCCLS publications (1, 2) and procedures 9.8.2 and 9.8.3. *Standard precautions must be used in the collecting, handling, and disposing of these blood samples.* If blood is obtained by finger puncture, care must be taken not to squeeze tissue juice into the sample and risk diluting a possible light parasitemia to below the level of detection.

E. Use of anticoagulants

Blood samples for malaria are preferably collected without anticoagulants, but if anticoagulants must be used for other testing, films for reliable staining of malaria parasites should be made immediately or within 1 h of collection. Trypanosomes and microfilariae are usually not affected by the use of anticoagulants. Although several anticoagulants have been used, EDTA (0.020 g/10 ml of blood) is recommended by most parasitologists for use with malaria parasites. Heparin (0.002 g/10 ml of blood) and sodium citrate (0.050 g/10 ml of blood) are often used for concentration procedures for trypanosomes and microfilariae.

F. Collection guidelines

1. The blood sample must be labeled with the date and time of collection so that findings can be correlated with symptoms and with all other pertinent information. Some parasites appear more frequently in the blood during certain periods than during others. To accommodate this, blood for detection of parasites is usually collected as follows.
 - a. On admission or when first suspected of parasite infection
 - b. If no parasites are found in the first sample, blood is collected every 6 to 12 h until a diagnosis is made or infection is no longer suspected (usually 3 to 5 days). *Infection with a blood parasite cannot be ruled out by a single blood sample.*
 - c. If either trypanosomes or microfilariae are suspected, each sample should be concentrated by an appropriate technique in an effort to detect a low parasitemia.
 - d. *The examination of blood for malaria should be considered a stat request. Preparation and examination of smears and reporting of results should be performed on a stat basis.*

II. THIN AND THICK BLOOD FILMS *(continued)*

2. Blood films for parasites should be made on clean, standard, glass microscope slides (1 by 3 in.). All slides, even new "precleaned" ones, should be dipped in alcohol and polished with a lint-free towel to remove any grease or dirt before the preparations are made.
3. Instrument methods, for either preparing thin films or staining films, have not been reliable for blood parasites. At this time, manual techniques yield better results.

G. Staining of blood films

1. All blood films, regardless of the stain which will be used, should be stained as soon as possible after they are thoroughly dry. Prolonged storage may cause erratic staining.
2. After staining and thorough drying, films may be examined by using oil directly on the film, or a no. 1-thickness coverslip may be applied to the film by using a mounting medium (pH 7.0).

9.8.2

Preparation of Thin Blood Films

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The thin film is prepared like that for a differential WBC count and provides an area for examination where the RBCs are neither overlapping nor distorted. Here the morphologies of parasites and infected RBCs are most typical.

II. SPECIMEN

Observe standard precautions.

The specimen usually consists of fresh whole blood collected by finger puncture or of whole blood containing EDTA (0.020 g/10 ml of blood) that was collected by venipuncture and is less than 1 h old (1). Occasionally a buffy coat (for leishmaniasis) or the sediment from a special concentration procedure (triple centrifugation for trypanosomes) is spread into a thin film.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Reagent

- ☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

Absolute methanol (for Giemsa stain)

B. Supplies

1. Glass microscope slides (1 by 3 in.), alcohol washed
2. Glass marker
3. Blood collection supplies (if applicable)

C. Equipment

None

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Visually, the thin film should be rounded, feathered, and progressively thinner toward the middle of the slide.
- B. There should not be any clear areas or smudges in the film itself (indicating that grease or fingerprints were on the glass).

V. PROCEDURE

- A.** *Wear gloves when performing this procedure.*
- B.** Blood from finger puncture
After wiping off the first drop of blood, touch a clean glass microscope slide (1 by 3 in.) about ½ in. from the end to a small drop of blood (10 to 15 µl) standing on the finger, remove the slide from the finger, turn it blood side up, and place it on a horizontal surface.
Blood from venipuncture
Place a clean glass microscope slide (1 by 3 in.) on a horizontal surface. Place a small drop (10 to 15 µl) of specimen onto the center of the slide about ½ in. from the end.
- C.** Holding a second clean glass slide at a 40° angle, touch the angled end to the midlength area of the specimen slide.
- D.** Pull the angled slide back into the blood, and allow the blood to almost fill the end area of the angled slide.
- E.** Continuing contact with the blood under the lower edge, quickly and steadily move the angled slide toward the opposite end of the specimen slide until the blood is used up.
- F.** The result will be a thin film that is rounded, feathered, and progressively thinner toward the center of the slide.
- G.** Label the slide appropriately, and allow it to air dry while protected from dust for at least 10 min.
- H.** If the film will be stained with Giemsa, then after the film is completely dry, fix it by dipping the slide into absolute methanol, and allow the film to air dry in a vertical position. If the film will be stained with Wright's stain, it does not need to be fixed. Wright's stain contains the fixative and stain in one solution.

POSTANALYTICAL CONSIDERATIONS

VI. PROCEDURE NOTES

- A.** A diamond marking pen is recommended.
- B.** An indelible ink pen can be used.
- C.** Pencil can be used if the information is actually written in the thick part of the smear (where the original drop of blood was placed).
- D.** Do not use wax pencils; the material may fall off during the staining procedure.
- E.** Make sure the films are protected from dust (while drying).

VII. LIMITATIONS OF THE PROCEDURE

- A.** A light infection may be missed in a thin film, whereas the increased volume of blood present on a thick film may allow the detection of the infection, even with a low parasitemia.
- B.** If the smears are prepared from anticoagulated blood which is more than 1 h old, the morphology of both parasites and infected RBCs may not be typical.
- C.** You should be able to identify *Plasmodium vivax* and *Plasmodium ovale*, even in the absence of Schüffner's dots (stippling).

9.8.3

Preparation of Thick Blood Films

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The thick film samples more blood than the thin film and therefore is more likely to demonstrate a low parasitemia. RBCs are lysed during staining, making the preparation more or less transparent and leaving only parasites, platelets, and WBCs for examination (1, 2).

II. SPECIMEN

Observe standard precautions.

The specimen usually consists of fresh whole blood collected by finger puncture or of whole blood containing EDTA (0.020 g/10 ml of blood) that was collected by venipuncture and is less than 1 h old. Heparin (2 mg/10 ml of blood) or sodium citrate (0.050 g/10 ml of blood) may be used as an anticoagulant if trypanosomes or microfilariae are suspected. The sediment from a concentration procedure for trypanosomes or microfilariae is frequently spread into a thick film that is stained, examined, and kept as a permanent record (*see* procedures 9.8.11 and 9.8.12). Although both EDTA and heparin have been mentioned as anticoagulants, it is very important to request EDTA, rather than heparin, for the preparation and staining of blood films for malaria. However, heparin can be used for the concentration methods related to the recovery of trypanosomes and microfilariae. As a general rule, EDTA is the recommended anticoagulant for all parasitology blood work.

III. MATERIALS

- | | |
|---|---|
| A. Reagents
None | 3. Blood collection supplies (if applicable) |
| B. Supplies
1. Glass microscope slides (1 by 3 in.), alcohol washed | 4. Paper with newsprint-size print |
| 2. Glass marker | 5. Applicator sticks |
| | C. Equipment
None |

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A.** Visually, the thick smear should be round to oval and approximately 2.0 cm across.
- B.** You should barely be able to read newsprint through the wet or dry film.
- C.** The film itself should not have any clear areas or smudges (indicating that grease or fingerprints were on the glass).

V. PROCEDURE

A. *Wear gloves when performing this procedure.*

B. Blood from finger puncture

After wiping off the first drop of blood, touch a clean glass microscope slide (1 by 3 in.) to a large drop of blood standing on the finger, and rotate the slide on the finger until the circle of blood is nearly the size of a dime or a nickel (1.8 to 2.0 cm). Without breaking contact with the blood, rotate the slide back to the center of the circle. Remove the slide from the finger, quickly turn it blood side up, and place it on a horizontal surface. The blood should spread out evenly over the surface of the circle and be of a thickness that fine print (newsprint size) can just barely be read through it. If it is thicker than this, take the corner of a second clean slide or an applicator stick, and expand the size of the circle until the print is just readable. The final thickness of the film is important. If too thick, it might flake off while drying or wash off while staining. If too thin, the amount of blood available for examination is insufficient to detect a low parasitemia.

Blood from venipuncture

Place a clean glass microscope slide (1 by 3 in.) on a horizontal surface. Place a drop (30 to 40 μ l) of blood onto the center of the side about $\frac{1}{2}$ in. from the end. Using either the corner of another clean glass slide or an applicator stick, spread the blood into a circle about the size of a dime or a nickel (1.8 to 2.0 cm). Immediately place the thick film over some small print, and be sure that the print can just barely be read through it. If not, expand the size of the film until the print can be read. Three or four small drops of blood may be used in place of the large drop, and the small ones can be pooled into a thick film by using the corner of a clean slide or an applicator stick. Be sure that small print can be read through the film.

C. Allow the film to air dry in a horizontal position protected from dust for several hours (6 to 8 h) or overnight. Do not attempt to speed the drying process by applying any type of heat, because heat will fix the RBCs and they will not lyse in the staining process.

D. *Do not fix the thick film.* If thin and thick films are made on the same slide, do not allow the methanol or its vapors to contact the thick film by slightly tilting the slide when fixing the thin film.

E. Label the slide appropriately.

F. If staining with Giemsa will be delayed for more than 3 days or if the film will be stained with Wright's stain, lyse the RBCs in the thick film by placing the film in buffered water (pH 7.0 to 7.2) (*see* procedure 9.7.1) for 10 min. Then remove it from the water, and place it in a vertical position (thick film down) to air dry.

POSTANALYTICAL CONSIDERATIONS

VI. PROCEDURE NOTES

A. A diamond marking pen is recommended.

B. An indelible ink pen can be used.

C. Do not use wax pencils; the material may fall off during the staining procedure.

D. Make sure the films are protected from dust (while drying).

VII. LIMITATIONS OF THE PROCEDURE

A. If the smears are prepared from anticoagulated blood that is more than 1 h old, morphology of the parasites may not be typical, and the film may wash off the slide during the staining procedure.

VII. LIMITATIONS OF THE PROCEDURE *(continued)*

- B.** Identification to the species level, particularly between *Plasmodium ovale* and *Plasmodium vivax* and between the ring forms of *Plasmodium falciparum* and *Babesia* spp., may be impossible without examining the stained thin blood film. Also, *Trypanosoma cruzi* trypomastigotes are frequently distorted in thick films.
- C.** Excess stain on the film may be confusing and make the detection of organisms difficult.

9.8.4

Combination Thick and Thin Blood Films (Can Be Stained as Either)

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

The combination thick-thin blood film provides both options on one glass slide, and the slide can be stained as either a thick or thin blood film. If fixed prior to staining, then the smear will be read as a thin blood film; if RBCs are lysed during staining, the preparation will be read as a thick blood film (parasites, platelets, WBCs). This combination blood film dries more rapidly than the traditional thick blood film, thus allowing staining and examination to proceed with very little waiting time for the slide(s) to dry (1, 2).

II. SPECIMEN

Observe standard precautions.

The specimen usually consists of fresh whole blood collected by finger puncture or of whole blood containing EDTA (0.020 g/10 ml of blood) that was collected by venipuncture and is less than 1 h old. Heparin (2 mg/10 ml of blood) or sodium citrate (0.050 g/10 ml of blood) may be used as an anticoagulant if trypanosomes or microfilariae are suspected.

III. MATERIALS

- | | |
|--|--|
| A. Reagents
None | 3. Blood collection supplies (if applicable) |
| B. Supplies
1. Glass slides (1 by 3 in., or larger if you prefer), alcohol washed
2. Glass marker | 4. Paper with newsprint-size print
5. Applicator sticks |
| | C. Equipment
None |

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- Visually, the smear should consist of alternating thick and thin portions throughout the length of the glass slide.
- One should be able to barely read newsprint through the wet or dry film.
- The film itself should not have any clear areas or smudges, indicating that grease or fingerprints were on the glass.
- Blood from a finger puncture is not recommended, since the procedure does not lend itself to “stirring” to prevent fibrin strands.

V. PROCEDURE (Fig. 9.8.4–1)

- Wear gloves when performing this procedure.*
- Place a clean 1- by 3-in. glass microscope slide on a horizontal surface.
- Place a drop (30 to 40 μ l) of blood onto one end of the slide about 0.5 in. from the end.

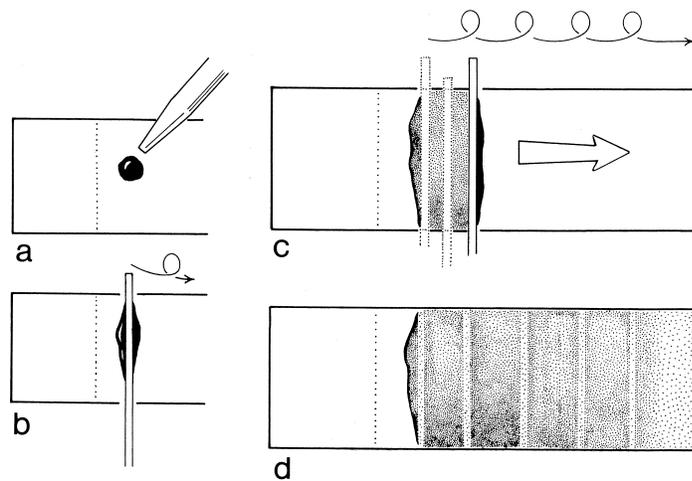

Figure 9.8.4-1 Method of thick-thin combination blood film preparation. (a) Position of drop of EDTA blood; (b) position of applicator stick in contact with blood and glass slide; (c) rotation of applicator stick; (d) completed thick-thin combination blood film prior to staining. (Illustration by Sharon Belkin; from reference 2.)

V. PROCEDURE (continued)

- D.** Using an applicator stick lying across the glass slide and keeping the applicator in contact with the blood and glass, rotate (do not “roll”) the stick in a circular motion while moving the stick down the glass slide to the opposite end.
- E.** The appearance of the blood smear should be alternate thick and thin areas of blood that cover the entire slide.
- F.** Immediately place the film over some small print and be sure that the print is just barely readable.
- G.** Allow the film to air dry horizontally and protected from dust for at least 30 min to 1 h. Do not attempt to speed the drying process by applying any type of heat, because the heat will fix the RBCs and they subsequently will not lyse in the staining process.
- H.** This slide can be stained as either a thick or thin blood film.
- I.** Label the slide appropriately.
- J.** If staining with Giemsa (as a thick film) will be delayed for more than 3 days or if the film will be stained with Wright’s stain, lyse the RBCs on the thick film by placing the slide in buffered water (pH 7.0 to 7.2) for 10 min, remove it from the water, and place it in a vertical position to air dry.
- K.** If staining with Giemsa (as a thin film), after the film is completely dry, fix it by dipping the slide into absolute methanol, and allow the film to air dry in a vertical position. If the film will be stained with Wright’s stain, it does not need to be fixed. Wright’s stain contains the fixative and stain in one solution.

POSTANALYTICAL CONSIDERATIONS

VI. PROCEDURE NOTES

- A.** A diamond marking pen is recommended.
- B.** An indelible ink pen can be used.
- C.** Pencil can be used if the information is actually written in the thickest part of the smear (where the original drop of blood was placed).
- D.** Do not use wax pencils; the material may fall off during the staining procedure.
- E.** Make sure the films are protected from dust (while drying).

VII. LIMITATIONS OF THE PROCEDURE

- A. A light infection may be missed in a thin film, whereas the increased volume of blood present on a thick film may allow the detection of the infection, even with a low parasitemia.
- B. If the smears are prepared from anticoagulated blood which is more than 1 h old, the morphology of both parasites and infected RBCs may not be typical.
- C. If a tube of blood containing EDTA cools to room temperature and the cap has been removed, several parasite changes can occur. The parasites within the RBCs will respond as if they were now in the mosquito after being taken in with a blood meal. The morphology of these changes in the life cycle and within the RBCs can cause confusion when examining blood films prepared from this blood.
 - a. Stippling (Schüffner's dots) may not be visible.
 - b. The male gametocyte (if present) may exflagellate.
 - c. The ookinetes of *Plasmodium* species other than *Plasmodium falciparum* may develop as if they were in the mosquito and may mimic the crescent-shaped gametocytes of *P. falciparum*.
- D. Identification to the species level, particularly between *Plasmodium ovale* and *Plasmodium vivax* and between the ring forms of *P. falciparum* and *Babesia* spp., may be impossible without examining one of the slides stained as a thin blood film. Also, *Trypanosoma cruzi* trypomastigotes are frequently distorted in thick films.
- E. Excess stain deposition on the film may be confusing and make the detection of organisms difficult.

9.8.5

Giemsa Stain

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Giemsa stain is used to differentiate nuclear and/or cytoplasmic morphology of platelets, RBCs, WBCs, and parasites (1–4). The most dependable stain for blood parasites, particularly in thick films, is Giemsa stain containing azure B. Liquid stock is available commercially, or the stock can be made from dry stain powder. Either must be diluted for use with water buffered to pH 6.8 or 7.0 to 7.2, depending on the specific technique used. Either

should be tested for proper staining reaction before use. The stock is stable for years, but it must be protected from moisture because the staining reaction is oxidative. Therefore, the oxygen in water will initiate the reaction and ruin the stock stain. The aqueous working dilution of stain is good only for 1 day.

Although not essential, the addition of Triton X-100, a nonionic surface-active

agent, to the buffered water used to dilute the stain enhances the staining properties of Giemsa (3) and helps to eliminate possible transfer of parasites from one slide to another (1). For routine staining of thin films and combination thin and thick films, a 0.01% (vol/vol) final concentration of Triton X-100 is best. For staining thick films for microfilariae, use a 0.1% (vol/vol) concentration.

II. SPECIMEN

Observe standard precautions.

The specimen may consist of a thin blood film that has been fixed in absolute methanol and allowed to dry, a thick blood film that has been allowed to dry thoroughly and is not fixed, or a combination of a fixed thin film and an adequately dried thick film (not fixed) on the same slide.

III. MATERIALS

A. Reagents (*see* Appendix 9.8.5–1)

B. Supplies (including those for preparing stock stain)

1. 3 or 4 Coplin jars, 50 ml
2. Pipette, 2 ml
3. 3 graduated cylinders, 50 ml
4. Mortar and pestle
5. Flask, Erlenmeyer, 500 ml with cotton plug
6. 2 flasks, volumetric, 1 liter
7. Bottle, brown, 150 to 200 ml
8. Bottles, clear, 100 ml and 3 1-liter
9. Bottle, airtight, 50 ml
10. Filter paper, Whatman no. 1
11. Funnel (glass) to hold filter paper

C. Equipment

1. Microscope, binocular with mechanical stage; low-power (10×), high dry power (40×), and oil immersion (100×) objectives; 10× oculars; calibrated ocular micrometer; light source equivalent to 20-W halogen or 100-W tungsten bulb; blue and white ground-glass diffuser filters
2. Timer, 1 h or more in 1-min increments
3. Water bath, 55 to 60°C
4. pH meter

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. The stock buffer solutions and buffered water should be clear, with no visible contamination.
- B. Check the Giemsa stain reagents, including the pH of the buffered water, before each use. If Triton X-100 has been added to the buffered water, do not use a colorimetric method to determine the pH, because Triton X-100 interferes with the color indicators. Use a pH meter to test buffered water that contains Triton X-100. The buffered water is usable as long as the pH is within the limits listed for the procedure.
- C. Prepare and stain films from “normal” blood, and microscopically evaluate the staining reactions of the RBCs, platelets, and WBCs.
 1. Macroscopically, blood films appear purplish. If blue, the buffered water was too alkaline; if pink to red, the buffered water was too acid.
 2. Microscopically, RBCs appear pinkish gray, platelets appear deep pink, and WBCs have purple-blue nuclei and lighter cytoplasm. Eosinophilic granules are bright purple-red, and neutrophilic granules are purple. Basophilic stippling within uninfected RBCs is blue.
 3. Slight variations may appear in the colors described above depending on the batch of stain used and the character of the blood itself, but if the various morphological structures are distinct, the stain is satisfactory.
- D. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- E. Record all QC results.

V. PROCEDURE

- A. *Wear gloves when performing any of these procedures.*
- B. Thin blood films (only)
 1. Fix air-dried film in absolute methyl alcohol by dipping the film briefly (two dips) in a Coplin jar containing methyl alcohol.
 2. Remove, and let air dry.
 3. Stain with diluted Giemsa stain (1:20, vol/vol) for 20 min. For a 1:20 dilution, add 2 ml of stock Giemsa to 40 ml of buffered water containing 0.01% Triton X-100 in a Coplin jar (Triton X-100 optional).
 4. Wash by briefly dipping the slide in and out of a Coplin jar of buffered water (one or two dips).
 - **NOTE:** Excessive washing will decolorize the film.
 5. Let air dry in a vertical position.
- C. Thick blood films (only)
 1. Allow film to air dry thoroughly for several hours or overnight. Do not dry films in an incubator or by heat, because this will fix the blood and interfere with the lysing of the RBCs.
 - **NOTE:** If a rapid diagnosis of malaria is needed, thick films can be made slightly thinner than usual, allowed to dry for 1 h, and then stained.
 2. *Do not fix.*
 3. Stain with diluted Giemsa stain (1:50, vol/vol) for 50 min. For a 1:50 dilution, add 1 ml of stock Giemsa to 49 ml of buffered water containing 0.01%

V. PROCEDURE (*continued*)

- Triton X-100 (if staining microfilariae, use 0.1% Triton X-100) in a Coplin jar.
4. Wash by placing film in buffered water for 3 to 5 min.
 5. Let air dry in a vertical position.
- D.** Combination thin and thick blood films
1. Allow the thick film to air dry thoroughly.
 2. Fix the thin film by placing only the thin film in methyl alcohol (two dips). Be sure not to get the alcohol or its fumes on the thick film by slightly tilting the slide.
 3. Let air dry in a vertical position with the *thick film up*. Be sure slide is thoroughly dry before staining. Introducing even a minute amount of methyl alcohol into the stain dilution will interfere with the lysing of the RBCs in the thick films.
 4. Stain the entire slide with diluted Giemsa stain (1:50, vol/vol) for 50 min. Place the slide in the stain, *thick film down* to prevent the debris caused by dehemoglobinization from falling onto the thin film. For a 1:50 dilution, add 1 ml of stock Giemsa to 50 ml of buffered water containing 0.01% Triton X-100 in a Coplin jar.
 5. Rinse the thin film by briefly dipping the film in and out of a Coplin jar of buffered water (one or two dips). Wash the thick film for 3 to 5 min. Be sure that the thick film is immersed but *do not allow the water to cover any part of the thin film*.
 6. Let dry in a vertical position with the *thick film down*.

VI. RESULTS

- A. If *Plasmodium* organisms are present, the cytoplasm stains blue and the nuclear material stains red to purple-red.
- B. Schüffner's stippling and other inclusions in the RBCs infected by *Plasmodium* spp. stain red.
- C. Nuclear and cytoplasmic colors that are seen in the malarial parasites will also be seen in the trypanosomes and any intracellular leishmaniae that are present.
- D. The sheath of microfilariae may or may not stain with Giemsa, while the body will usually appear blue to purple.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report any parasite, including the stage(s) seen (do not use abbreviations).
Examples: *Plasmodium falciparum* rings and gametocytes, rings only
Plasmodium vivax rings, trophozoites, schizonts, and gametocytes
Wuchereria bancrofti microfilariae
Trypanosoma brucei gambiense/rhodesiense trypomastigotes
Trypanosoma cruzi trypomastigotes
Leishmania donovani amastigotes
- B. Any laboratory providing malaria diagnoses should be able to identify *Plasmodium vivax* and *Plasmodium ovale*, even in the absence of Schüffner's stippling.

VIII. PROCEDURE NOTES

- A. Blood films prepared from venipuncture blood when an anticoagulant is used must be prepared within 1 h of collection. Otherwise, certain morphological characteristics of both parasites and infected RBCs may be atypical. Also, thick blood films may wash off the slide during the staining procedure.

VIII. PROCEDURE NOTES

(continued)

- B. The correct pH for all buffered-water and staining solutions is also important. Solutions with the incorrect pH will prevent certain morphological characteristics (stippling) from being visible and will not give typical nuclear and cytoplasmic colors on the stained film.
- C. Stain a QC slide each time patient blood films are stained. If several patient specimens are stained on the same day (using the same reagents), only one control slide need be stained and examined. The patient slide can serve as the QC slide; if the WBCs and RBCs exhibit typical colors, any parasites present would also stain correctly.

IX. LIMITATIONS OF THE PROCEDURE

- A. Finding no parasites in one set of blood films does not rule out a parasitic infection.
- B. Examine a minimum of 300 oil immersion ($\times 1,000$) fields before reporting no parasites found.
- C. Examine the entire smear under low power ($100\times$) for the presence of microfilariae. Remember that the sheath may not be visible (*W. bancrofti*).

APPENDIX 9.8.5–1

Include QC information on reagent container and in QC records.

Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. Stock Giemsa stain

Giemsa stain (azure B type) 0.6 g
 glycerin 50.0 ml
 methyl alcohol, absolute (acetone free) .. 50.0 ml

1. Grind 0.6 g of stain powder with 10 to 15 ml of glycerin (freshly opened bottle, neutral) in a clean mortar. Pour the top third into a clean, dry 500-ml flask. Add more glycerin, and grind again. The grinding process should be thorough, to ensure mixing of stain powder and glycerin. Repeat until most of the powder has been mixed with the 50 ml of glycerin and the mixture has been poured into the flask.
2. Stopper or plug the flask, and place and secure it upright in a 55 to 60°C water bath for 2 h. The water in the bath should be above the level of the stain mixture. Shake gently at half-hour intervals.
3. After grinding powder and glycerin together in mortar, measure 50 ml of methyl alcohol (acetone free, neutral), and use it to wash the last bit of stain from the mortar. Pour the washing into a small, airtight bottle.
4. After 2 h, remove glycerin and stain powder mixture from water bath. Allow to come to room temperature, add alcohol washing from the mortar, and shake well.

APPENDIX 9.8.5-1 (continued)

5. Filter before use through Whatman no. 1 paper into a brown bottle. The stain can be used immediately, but it is preferable to let it stand about 2 weeks with intermittent shakings before the initial filtering.
6. Label appropriately, and store protected from light at room temperature. The shelf life is 36 months, providing QC criteria are met (stock solution).

B. Stock solution of Triton X-100 (10%)

Triton X-100	10 ml
distilled water	90 ml

1. Combine above liquids in a bottle.
2. Mix thoroughly, label appropriately, and store at room temperature. This solution will keep indefinitely if tightly stoppered.

C. Stock buffers (for preparing buffered water)

1. Alkaline buffer, 0.067 M solution

Na ₂ HPO ₄ (anhydrous)	9.5 g
distilled water, to make	1.0 liter

In a 1-liter volumetric flask, dissolve Na₂HPO₄ in about three-fourths of the water. Add water to make 1 liter of solution. Store in tightly stoppered bottle, and label appropriately. The shelf life is 24 months.

2. Acid buffer, 0.067 M solution

NaH ₂ PO ₄ ·H ₂ O	9.2 g
distilled water, to make	1.0 liter

In a 1-liter volumetric flask, dissolve NaH₂PO₄·H₂O in about three-fourths of the water. Add water to make 1 liter of solution. Store in tightly stoppered bottle, and label appropriately. The shelf life is 24 months.

D. Buffered water (for diluting stain and washing films), pH 7.0 to 7.2

alkaline buffer (Na ₂ HPO ₄)	61 ml
acid buffer (NaH ₂ PO ₄ ·H ₂ O)	39 ml
distilled water	900 ml

1. Combine above liquids in a 1-liter bottle.
2. Mix thoroughly, and test pH of solution. If pH is not 7.0 to 7.2, discard and remake. The solution can be used as long as the pH remains between 7.0 and 7.2.

E. Buffered water, pH 6.8 (called for by some commercial stains for diluting stain and washing films)

alkaline buffer (Na ₂ HPO ₄)	50 ml
acid buffer (NaH ₂ PO ₄ ·H ₂ O)	50 ml
distilled water	900 ml

1. Combine above liquids in a 1-liter bottle.
2. Mix thoroughly, and test pH of solution. If pH is not 6.8 ± 0.1, discard and remake. The solution can be used as long as the pH is within the limits listed for the procedure.

F. Triton-buffered water solutions (optional)

1. For thin blood films or combination thin and thick blood films
After determining the pH of the buffered water, add 1 ml of the stock 10% aqueous dilution of Triton X-100 to 1 liter of buffered water (pH 7.0 to 7.2, 0.01% final concentration). Label appropriately, and store in tightly stoppered bottle. The solution can be used as long as the pH is within limits listed for the procedure.
2. For thick blood films
After determining the pH of the buffered water, add 10 ml of the stock 10% aqueous dilution of Triton X-100 to 1 liter of buffered water (pH 7.0 to 7.2, 0.1% final concentration). Label appropriately, and store in tightly stoppered bottle. The solution can be used as long as the pH is within limits listed for the procedure.

G. Methyl alcohol, absolute

9.8.6

Wright's Stain

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Wright's stain can be used to stain thin blood films for detecting blood parasites, but it is inferior to Giemsa for staining thick films. The liquid, ready-to-use stain is available commercially, or the stain can be made from dry stain powder and is

ready for use in about a week. The staining reaction is somewhat similar to that of Giemsa and is achieved by using buffered water with a pH of 6.8. The stain contains the fixative and stain in one solution (1, 2).

II. SPECIMEN

Observe standard precautions.

- A. The specimen usually consists of a dry, unfixed thin blood film.
- B. Thick blood films may be stained with Wright's stain if the RBCs are lysed before staining.

III. MATERIALS

- A. **Reagents** (see Appendix 9.8.6-1)
- B. **Supplies**
 - 1. 2 Coplin jars, 50 ml, for dehemoglobinizing thick films
 - 2. Mortar and pestle
 - 3. Flask, volumetric, 1 liter
 - 4. Bottle, brown, 500 ml
 - 5. Bottle, tight stopper, 1 liter
 - 6. Staining rack
 - 7. 3 or 4 pipettes, disposable
 - 8. 3 or 4 pipette bulbs
 - 9. Gauze for wiping slides
 - 10. Filter paper, Whatman no. 1
 - 11. Funnel (glass) to hold filter paper

C. Equipment

- 1. Microscope, binocular with mechanical stage; low-power (10×), high dry power (40×), and oil immersion (100×) objectives; 10× oculars; calibrated ocular micrometer; light source equivalent to 20-W halogen or 100-W tungsten bulb; blue and white ground-glass diffuser filters
- 2. Timer, 1 h or more in 1-min increments
- 3. pH meter

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. The stock buffer solutions and buffered water should be clear, with no visible contamination.
- B. Check the Wright's stain reagents, including the pH of the buffered water, before each use for diagnosis of blood parasites. The buffered water is usable as long as the pH is within the limits listed for the procedure.
- C. Prepare and stain films from "normal" blood, and microscopically evaluate the staining reactions of RBCs, platelets, and WBCs.
 - 1. Macroscopically, blood films appear pinkish purple. If blue, the buffered water was too alkaline; if pink to red, the buffered water was too acid.

IV. QUALITY CONTROL (continued)

2. Microscopically, RBCs appear tan to pinkish red, platelets appear deep pinkish red, and WBCs have bright blue nuclei and lighter cytoplasm.
 3. Slight variations may appear in the colors described above depending on the batch of stain used and the character of the blood itself, but if the various morphological structures are distinct, the stain is satisfactory.
- D. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (see procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- E. Record all QC results.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. Thin blood films (only) (1)
1. Place air-dried films on a level staining rack.
 2. Use a pipette to cover the surface of the slide with stain, adding stain drop by drop. Count the number of drops needed to cover the surface. Let stand 1 to 3 min (optimal staining time [to obtain correct color range and intensity] will vary with each batch of stain).
 3. Add to the slide the same number of drops of buffered water as were used of stain for step V.B.2 and mix the stain and water by blowing on the surface of the fluid.
 4. After 4 to 8 min, flood the stain from the slide with buffered water. Do not pour the stain off before flooding, or a precipitate will be deposited on the slide.
 5. Wipe the underside of the slide to remove excess stain.
 6. Let air dry in a vertical position.
- C. Combination thin and thick blood films
1. Lyse the RBCs in the thick film by immersing it for 10 min in buffered water. *Be sure that the water does not touch the unfixed thin film.*
 2. Remove the slide, and rinse the thick film by dipping in additional buffered water (two or three dips).
 3. Let film air dry thoroughly.
 4. Stain both thin and thick films with Wright's stain as directed for thin films.

VI. RESULTS

- A. If *Plasmodium* organisms are present, the cytoplasm stains pale blue and the nuclear material stains red.
- B. Schüffner's stippling in RBCs infected by malaria species usually does not stain or stains very pale red with Wright's stain.
- C. Nuclear and cytoplasmic colors that are seen in the malarial parasites will also be seen in the trypanosomes and any intracellular leishmaniae that are present.
- D. The sheath of microfilariae may or may not stain with Wright's stain, while the body will usually appear pale to dark blue.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report any parasite, including the stages found (do not use abbreviations).
Examples: *Plasmodium falciparum* rings and gametocytes, rings only
Plasmodium vivax rings, trophozoites, schizonts, and gametocytes
Plasmodium ovale rings and schizonts
Plasmodium malariae rings and developing trophozoites
Babesia sp. rings
Wuchereria bancrofti microfilariae
Trypanosoma brucei gambiense/rhodesiense trypomastigotes
Trypanosoma cruzi trypomastigotes
Leishmania donovani amastigotes
- B. Any laboratory providing malaria diagnoses should be able to identify *Plasmodium vivax* and *Plasmodium ovale*, even in the absence of Schüffner's stippling.

VIII. PROCEDURE NOTES

- A. Blood films prepared from venipuncture blood when an anticoagulant is used must be prepared within 1 h of collection. Otherwise, certain morphological characteristics of both parasites and infected RBCs may be atypical.
- B. The correct pH for all buffered-water and staining solutions is also important. Solutions with the incorrect pH will prevent certain morphological characteristics (stippling) from being visible and will not give typical nuclear and cytoplasmic colors on the stained film.
- C. Stain QC slide each time patient blood films are stained. If several patient specimens are stained on the same day (using the same reagents), only one control slide need be stained and examined.
- D. If at any time the stain appears to contain particulate matter or stain, precipitate, filter prior to use.

IX. LIMITATIONS OF THE PROCEDURE

- A. *Finding no parasites in one set of blood films does not rule out a parasitic infection.*
- B. Examine a minimum of 300 oil immersion ($\times 1,000$) fields before reporting no parasites found.
- C. Examine the entire smear under low power ($100\times$) for the presence of microfilariae. Remember that the sheath may not be visible (*W. bancrofti*).

APPENDIX 9.8.6-1

Include QC information on reagent container and in QC records.

Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label

A. Wright's stain

Wright's stain0.9 g
methyl alcohol, absolute
(acetone free)500.0 ml

1. Grind 0.9 g of stain powder with 10 to 15 ml of methyl alcohol (anhydrous, acetone free) in a clean mortar. Gradually add methyl alcohol while grinding. As the dye is dissolved in the alcohol, pour that solution off and add more alcohol to the mortar. Repeat the process until the 500 ml of alcohol is used up.
2. Store the stain solution in a tightly stoppered glass bottle (1 liter) at room temperature.
3. Shake the bottle several times daily for at least 5 days (aging process).
4. Before use, filter through Whatman no. 1 paper into a brown bottle (stock stain).
5. Label appropriately, and store protected from light at room temperature. The shelf life is 36 months, providing QC criteria are met.

B. Stock buffers (for preparing buffered water)

1. Alkaline buffer, 0.067 M solution

Na_2HPO_4 (anhydrous)9.5 g
distilled water, to make1.0 liter

In a 1-liter volumetric flask, dissolve Na_2HPO_4 in about three-fourths of the water. Add water to make 1 liter of solution. Store in tightly stoppered bottle, and label appropriately. The shelf life is 24 months. Note the date on label and in work record.

2. Acid buffer, sodium dihydrogen phosphate (monobasic), 0.067 M solution

$\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$ 9.2 g
distilled water, to make1.0 liter

In a 1-liter volumetric flask, dissolve $\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$ in about three-fourths of the water. Add water to make 1 liter of solution. Store in tightly stoppered bottle, and label appropriately. The shelf life is 24 months. Note date on label and in work record.

C. Buffered water, pH 6.8 (called for by some commercial stains for diluting stain and washing films)

alkaline buffer (Na_2HPO_4)50 ml
acid buffer ($\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$)50 ml
distilled water900 ml

1. Combine above liquids in a 1-liter bottle.
2. Mix thoroughly, and test pH of solution. If pH is not 6.8 ± 0.1 , discard and remake. The solution can be used as long as the pH is within limits listed for the procedure.

9.8.7

Determination of Parasitemia

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

It is important to report the level of parasitemia when blood films are examined and found to be positive for malaria parasites. Because of the potential for drug resistance in some of the *Plasmodium* species, particularly *Plasmodium falciparum*, it is important that every positive smear be

assessed and the parasitemia reported exactly the same way for follow-up specimens as for the initial specimen (1–6). This allows the parasitemia to be monitored after therapy has been initiated. In cases where the patient is hospitalized,

monitoring should be performed at 24, 48, and 72 h after initiating therapy. Generally the parasitemia will drop very quickly within the first 2 h; however, in cases of drug resistance, the level may not decrease but actually increase over time.

II. SPECIMEN

Observe standard precautions.

The specimen consists of stained thick or thin blood films that have been examined a minimum of 300 oil immersion fields per blood film to determine that the film is positive for malaria parasites.

III. MATERIALS

A. Reagents

None

B. Supplies

None

C. Equipment

Microscope, binocular with mechanical stage; low-power (10×), high dry

power (40×), and oil immersion (100×) objectives; 10× oculars; calibrated ocular micrometer; light source equivalent to a 20-W halogen or 100-W tungsten bulb; blue and white ground-glass diffuser filters

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

A. Prepare and stain films from “normal” blood, and microscopically evaluate the staining reactions of RBCs, platelets, and WBCs (normally done during staining procedure using Giemsa or Wright’s stain).

B. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (see procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.

V. PROCEDURE

- A. Thin blood film: counting several hundred to 1,000 RBCs, report the percentage of infected RBCs per 100 RBCs counted (0.5%, 1.0%, etc.).
- B. Thick or thin blood film: counting 100 WBCs (or more), report the number of parasites per 100 WBCs on the smear.
 1. This figure can be converted to the number of parasites per microliter of blood; divide the number of parasites per 100 WBCs by 100, and multiply that figure by the number of WBCs per microliter of blood.
 2. Depending on the parasitemia, 200 or more WBCs may have to be counted, so the denominator may vary (it may be 200 or even more).
 3. *Using this method, blood for both the peripheral smears and cell counts must be collected at the same time.*

POSTANALYTICAL CONSIDERATIONS

VI. REPORTING RESULTS (Table 9.8.7-1)

- A. Using the thin blood film method, report the percentage of parasite-infected RBCs per 100 RBCs counted.
Example: *Plasmodium falciparum*, parasitemia = 0.5%
- B. Using the thick-thin blood film method, report the number of parasites per microliter of blood.
Example: *Plasmodium falciparum*, parasitemia = 10,000 per μl of blood

Table 9.8.7-1 Parasitemia determined from conventional light microscopy: clinical correlation^a

% Parasitemia	No. of parasites/ μl	Clinical correlation ^b
0.0001–0.0004	5–20	Number of organisms that are required for a positive thick film (sensitivity) <i>Note:</i> Examination of 100 TBF fields (0.25 μl) may miss infections up to 20% (sensitivity of 80–90%); at least 300 TBF fields should be examined before reporting a negative result. <i>Note:</i> Examination of 100 THBF fields (0.005 μl); at least 300 THBF should be examined before reporting a negative result. Both TBF and THBF should be examined for every specimen submitted for a suspected malaria case. <i>One set (TBF + THBF) of negative blood films does not rule out a malaria infection.</i>
0.002	100	Patients may be symptomatic below this level.
0.2	10,000	Level above which immune patients will exhibit symptoms
2	100,000	Maximum parasitemia of <i>P. vivax</i> and <i>Plasmodium ovale</i> (infect young RBCs only)
2–5	100,000–250,000	Hyperparasitemia, severe malaria, ^c increased mortality
10	500,000	Exchange transfusion may be considered, high mortality

^a Adapted from references 2 and 6.

^b TBF, thick blood film; THBF, thin blood film.

^c World Health Organization criteria for severe malaria are parasitemia of $>10,000/\mu\text{l}$ and severe anemia (hemoglobin <5 g/liter). Prognosis is poor if $>20\%$ of parasites are pigment-containing trophozoites and schizonts and/or if $>5\%$ of neutrophils contain visible pigment.

VII. PROCEDURE NOTES

- A. It is critical that the same reporting method be used consistently for every subsequent set of blood films so that the parasitemia can be tracked for decrease or possible increase, indicating resistance.
- B. Remember, drug resistance may not become evident for several days; the parasitemia may even appear to be dropping before it begins to increase again.
- C. It is very important that any patient with *P. falciparum* infection be monitored; drug resistance has also been reported for *Plasmodium vivax* infections.
- D. It is critical to remember that mixed malarial infections occur, many of which will include *P. falciparum*.

VIII. LIMITATIONS OF THE PROCEDURE

- A. A light infection may be missed in a thin film, whereas the increased volume of blood present on a thick film may allow the detection of the infection, even with a low parasitemia.
- B. If the smears are prepared from anticoagulated blood that is more than 1 h old, the morphology of both parasites and infected RBCs may not be typical.
- C. It is important that good-quality blood films be examined and counted according to directions; poorly prepared and/or stained blood films will lead to incorrect assessments of the parasitemia (both too low and too high).
- D. Follow-up counts are critical in monitoring the patient, and it is critical to understand the types of malaria resistance (*see* Table 9.8.7–2).

Table 9.8.7–2 Malaria resistance^a

Resistance definition	Comments
Sensitive	From initiation of therapy, asexual parasites are cleared by day 6; no evidence of recrudescence up to day 28 Peripheral blood films appear to go from positive to negative very quickly (can be a change from one draw to the second draw 6 h later).
Resistance type I	From initiation of therapy, asexual parasites have cleared for at least two consecutive days (the latest day being day 6); recrudescence follows. Parasite count initially drops and blood films appear to be negative; patient should be monitored for a period of days, particularly if drug-resistant <i>P. falciparum</i> is suspected.
Resistance type II	Within 48 h of initiation of therapy, marked reduction of asexual parasitemia to <25% of pretreatment count; however, no subsequent disappearance of parasitemia (smear positive on day 6) Patient appears to be improving; parasite count drops, but blood films always appear positive.
Resistance type III	Modest reduction in parasitemia may be seen; no change or increase in parasitemia seen during first 48 h after treatment; no clearing of asexual parasites In some cases, the parasite count continues to increase with no visible decrease at any time; blood films show overall parasite increase.

9.8.8

Delafield's Hematoxylin Stain

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Microfilariae in an unstained preparation do not show sufficiently definite morphological characteristics to allow positive identification. Although Giemsa stain, used for the routine staining of blood par-

asites, can be used for microfilariae, Delafield's hematoxylin stain is widely used to demonstrate greater structural detail of microfilariae (1, 2). This stain especially enhances the nuclei and the sheath, if pres-

ent. No one type of stain, however, will reveal all the details of morphology, and in some cases, more than one staining procedure may be necessary for species identification.

II. SPECIMEN

Observe standard precautions.

- A. Delafield's hematoxylin stain can be used for thick or thin blood films.
- B. It is most frequently used to stain the sediment of a concentration procedure (see procedures 9.8.10 and 9.8.11) designed to recover more microfilariae from the blood.

III. MATERIALS

A. Reagents (see Appendix 9.8.8-1)

B. Supplies

1. 4 or 5 Coplin jars, 50 ml
2. Glass or plastic Pasteur pipettes
3. Pipette, to deliver 0.05 ml
4. Beakers, 250 ml, 25 ml
5. Flask, Erlenmeyer, 500 ml
6. Graduated cylinders, 3 100 ml, 500 ml, 50 ml
7. Bottles, 2 1,000 ml, 100 ml
8. Funnel (glass) to hold filter paper
9. Filter paper, Whatman no. 1
10. Coverslips, 22 by 22 mm or larger, no. 1 thickness
11. Mounting medium, pH 7.0

C. Equipment

1. Microscope, binocular with mechanical stage; low-power (10 \times), high dry power (40 \times), and oil immersion (100 \times) objectives; 10 \times oculars; calibrated ocular micrometer; light source equivalent to 20-W halogen or 100-W tungsten bulb; blue and white ground-glass diffuser filters
2. Timer, 1 h or more in 1-min increments
3. pH meter (or pH paper) to check ammonia water
4. Hot plate

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. If possible, check the stain procedure before each use for diagnosis of filariasis on blood known to contain microfilariae.
- B. If human blood containing microfilariae is not available, try to obtain canine blood containing *Dirofilaria immitis* from a veterinarian. No sheath is present, but nuclei should be distinct, and the colors should be those described below.

IV. QUALITY CONTROL (continued)

- C. If positive blood is not available, follow the procedure carefully in testing the specimen submitted for diagnosis. Be sure that the morphological features of the microfilariae found are distinct and that the colors are those described below.
 1. Macroscopically, the films appear bluish purple.
 2. Microscopically, the nuclei of the microfilariae are blue or purplish, and the sheath, if present, is a light purple. The cytoplasm is reddish. The R, anal, and excretory cells may or may not be visible, but if they are, they do not differ markedly from the nuclei. The inner body may be seen as a whitish structure.
- D. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (see procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- E. Record all QC results.

V. PROCEDURE (adapted from reference 3)

- A. *Wear gloves when performing this procedure.*
- B. Prepare thick or thin blood films or films from sediments of concentrated blood, and dry thoroughly (see procedures 9.8.10 and 9.8.11).
- C. If thick films are to be stained, lyse the RBCs by placing the film in distilled water for 10 min. Allow to air dry. This step is not necessary for thin blood films or films prepared from sediments.
- D. Fix all films in absolute methanol for 5 min. Allow to air dry.
- E. Stain in undiluted Delafield's hematoxylin for 10 to 15 min.
- F. Destain with acid water (0.05% HCl) for 5 to 10 s.
- G. Wash in water containing sufficient ammonia to yield an alkaline pH (~9.0 to 10.0) until a blue color appears in film.
- H. Air dry.
- I. Mount film with neutral mounting medium and coverslip (no. 1 thickness), or examine unmounted.
- J. Examine the entire film with the low-power (10×) objective. Specific morphological details can be observed with the high dry power (40×) and oil immersion (100×) objectives.

VI. RESULTS

- A. Microfilariae may be present. Based on the positions of the nuclei and the presence or absence of a sheath, they can be identified to the genus and species levels.
- B. If other blood parasites are seen, it is recommended that routine thin and thick films be stained with Giemsa stain.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the genus and species of microfilariae present.
Example: *Wuchereria bancrofti* microfilariae present.
- B. If sufficient morphological detail is not visible to allow generic and/or specific identification, report as follows.
Examples: Sheathed microfilariae present.
Unsheathed microfilariae present.
Microfilariae present.

VIII. PROCEDURE NOTES

- A. It is important that the stock stain age for at least 1 month prior to use. During this time, it should be exposed to sunlight.
- B. If the nuclei do not stain blue and the cytoplasm does not stain red, review proper aging of the stain.
- C. One of the main benefits of this stain is improved visibility of the sheath.
 1. The sheath of *W. bancrofti* will often not be seen using Giemsa stain.
 2. The sheath of *W. bancrofti* is easily seen when Delafield's hematoxylin is used.

IX. LIMITATIONS OF THE PROCEDURE

- A. If the blood specimen is too old or has not been processed properly, the final stain may not reveal clear nuclear and sheath detail.
- B. Regardless of the quality of the stain, a low parasitemia may not be detected.

APPENDIX 9.8.8-1

Include QC information on reagent container and in QC records.

Reagents

Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. Delafield's hematoxylin stain, hematoxylin solution

hematoxylin crystals	4.0 g
ethyl alcohol, 95%	25.0 ml
saturated aluminum ammonium sulfate solution	400.0 ml
methyl alcohol (acetone free)	100.0 ml
glycerin	100.0 ml

1. Dissolve 4.0 g of hematoxylin crystals in 25 ml of 95% ethyl alcohol.
2. Prepare 400 ml of saturated aluminum ammonium sulfate [$\text{AlNH}_4(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$] solution by adding the aluminum ammonium sulfate crystals (~90 g) to 400 ml of very hot distilled water, stirring until no more crystals go into solution, cooling to allow excess alum to crystallize, and decanting the solution.
3. Mix the hematoxylin solution with the 400 ml of saturated aluminum ammonium sulfate solution in a loosely capped or cotton-plugged bottle. Keep in a light, airy location for 2 weeks.
4. After 2 weeks, mix 100 ml of methyl alcohol (acetone free) with 100 ml of glycerin, and add this mixture to the mixture from step A.3.
5. Bottle the complete mixture from step A.4., leave cap loose, and expose to direct sunlight for at least 1 month.
6. Filter before use through Whatman no. 1 paper into a clear glass bottle, stopper tightly, and store at room temperature.
7. Label appropriately. The shelf life is 36 months, providing QC criteria are met.

APPENDIX 9.8.8–1 *(continued)*

B. Acid water destain

HCl 0.05 ml
distilled water99.95 ml

1. Carefully dispense the concentrated hydrochloric acid into the distilled water.
2. Label and store in a tightly stoppered bottle, and label with an expiration date of 12 months.

C. Ammonia water

ammonium hydroxide (NH₄OH) 3 to 5 drops
tap water 50.0 ml

1. Mix the two components in a Coplin jar. Discard remaining solution after use.
2. Check pH (~9.0 to 10.0).

D. Methyl alcohol (acetone free)

E. Glycerin

F. Distilled water

9.8.9

Concentration Procedures: Buffy Coat Concentration

Concentration procedures increase the number of organisms recovered from blood specimens submitted for diagnosis of trypanosomiasis, filariasis, and leishmaniasis. A concentration procedure should be performed routinely on all blood specimens submitted for examination for

trypanosomes or microfilariae when the suspected organisms are not found in thick blood films or when organisms are so few that more are needed to make a positive identification of species (*see* Appendix 9.8.9–1) (1, 2).

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Leishmania donovani amastigotes are difficult to detect in blood specimens but may occasionally be found within monocytes by fractional centrifugation of comparatively large amounts of blood. The procedure may also be used to recover trypanosomes and microfilariae, both of which are found in the plasma.

II. SPECIMEN

Observe standard precautions.

Whole blood collected by using EDTA, heparin, or sodium citrate anticoagulant (regular venipuncture collection tubes are recommended—primarily the lavender/EDTA or green/heparin stoppers)

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Reagents

■ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

1. Methyl alcohol, absolute
2. Giemsa or hematoxylin stain (*see* procedures 9.8.5 and 9.8.8)

B. Supplies

1. 2 centrifuge tubes, glass, 12 ml (plastic tubes can be used, provided they are *clear* plastic)
2. Capillary pipette with bulb
3. Glass microscope slides, 1 by 3 in., alcohol washed
4. Coverslips, 22 by 22 mm or larger, no. 1 thickness
5. Microhematocrit tube(s) (for alternate procedure)

6. Blood collection supplies, if applicable

C. Equipment

1. Centrifuge with sealable carrier cups, speed calibrated
2. Microscope, binocular with mechanical stage; low-power (10×), high dry power (40×), and oil immersion (100×) objectives; 10× oculars; calibrated ocular micrometer; light source equivalent to 20-W halogen or 100-W tungsten bulb; blue and white ground-glass diffuser filters
3. Timer, 1 h or more in 1-min increments

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Check calibration of centrifuge.
- B. Perform the procedure on “normal” blood. The film should be composed almost exclusively of WBCs, which stain characteristically with Giemsa (*see* procedure 9.8.5). If parasites are present, they also should stain characteristically (*see* procedure 9.8.5).
- C. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- D. Record all QC results.

V. PROCEDURE
(adapted from reference 3)

- A. *Wear gloves when performing this procedure.*
- B. Centrifuge the anticoagulated blood specimen in a sealed cup at $100 \times g$ for 15 min.
- C. Remove the thin creamy layer (buffy coat) between the RBCs and plasma with a capillary pipette, or transfer the creamy layer (buffy coat) and plasma to another tube, and centrifuge in a sealed cup at $300 \times g$ for 15 min.
- D. Examine buffy coat directly for motile trypomastigotes and microfilariae.
 - 1. Place one-half drop of saline on a clean microscope slide.
 - 2. Remove a drop of sediment, and mix it in the saline.
 - 3. Add a coverslip, and examine for organism motility with the low-power ($10\times$) and high dry power ($40\times$) objectives.
- E. Prepare thin films, dry, fix, and stain with Giemsa stain (*see* procedure 9.8.5 or, if for microfilariae, procedure 9.8.8).

VI. RESULTS

- A. If present, *L. donovani* amastigotes will be found within the monocytes on a Giemsa-stained film. Nuclear material stains dark purple-red, the cytoplasm is light blue, and the kinetoplast may or may not be visible as a dark bluish purple structure.
- B. Trypomastigotes will be found extracellularly (motile in the wet smear). Morphological detail will be seen in the Giemsa-stained film. The stain reaction is like that of *L. donovani*; the kinetoplast will be visible.
- C. Microfilariae may be found in the wet smear. Morphological detail will be seen in a Giemsa- or hematoxylin-stained film. The stain reaction is typical for each stain (*see* procedures 9.8.5 and 9.8.8).

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the presence of organisms from the wet smear.
Examples: Trypomastigotes present.
Microfilariae present.
- B. Report the genus and species of organisms from the Giemsa-stained film.
Examples: *Trypanosoma cruzi* trypomastigotes present.
Leishmania donovani amastigotes present.

VIII. PROCEDURE NOTES

- A. If you need to add anticoagulant to blood, mix 9 ml of blood and 1 ml of 5% sodium citrate in a glass centrifuge tube. Then proceed with centrifugation.
- B. This procedure can be performed in a microhematocrit tube if the tube is carefully scored and broken at the buffy coat interface and if the WBCs are prepared and stained as for a thin blood film.
- C. Also, the tube can be examined microscopically (high dry magnification) at the buffy coat layer for motile trypomastigotes and microfilariae before the tube is scored and broken.

IX. LIMITATIONS OF THE PROCEDURE

- A. When examined as a wet smear, the intracellular leishmaniae are very difficult to see.
- B. Although trypomastigote and microfilarial motility may be visible on the wet smear, specific identification may be difficult.

APPENDIX 9.8.9-1

QBC Capillary Blood Tube

Recently, a centrifugation procedure which yields a buffy coat has been used to concentrate and detect *Plasmodium* spp. (1-3). The technique uses a commercially available capillary tube (QBC Capillary Blood Tube; Becton Dickinson, Franklin Lakes, N.J.) which is coated with acridine orange stain and fitted with a buoyant plastic insert. The stain causes the malaria organisms to fluoresce, and the plastic insert forces the RBCs containing stained parasites, because they differ in buoyancy from uninfected RBCs, to be concentrated just under the buffy coat. After centrifugation, the tube is examined under the microscope at the plastic insert level for the presence of malaria parasites. Some laboratorians have been able to accurately identify species by using this method. At this time, however, this technique requires more trials, and appropriate thin and/or thick films are recommended for the positive identification of *Plasmodium* spp.

9.8.10

Concentration Procedures: Membrane Filtration Concentration

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Membrane filtration methods for recovering microfilariae from patients with light infections have been developed. These methods have an advantage over simple centrifugation methods in that large samples of blood (20 ml or more) can be used if necessary. The technique described here is one of the most efficient for the clinical laboratory when other procedures used to

recover microfilariae are unsatisfactory (1–3).

Membrane filtration recovers most species of microfilariae; however, because of their smallness, *Mansonella perstans* and *Mansonella ozzardi* may not be recovered. Membranes of smaller pore size (3 μm) have been suggested for recovering these two species.

II. SPECIMEN

Whole blood collected by using EDTA, heparin, or sodium citrate anticoagulant

Observe standard precautions.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

1. Distilled water
2. Methyl alcohol, absolute
3. Giemsa or hematoxylin stain (see procedures 9.8.5 and 9.8.8)
4. Toluene

B. Supplies

1. Glass syringe, 15 ml (clear plastic is acceptable)
2. Nuclepore membrane filter, 25 mm, 5- μm porosity
3. Swinney filter adapter (attaches to syringe, holds filter)

4. Filter paper pad, 25 mm (used to support the membrane filter)

5. Glass microscope slides, 1 by 3 in.

6. Coverslips, 22 by 22 mm or larger, no. 1 thickness

7. Mounting medium

C. Equipment

Microscope, binocular with mechanical stage; low-power (10 \times), high dry power (40 \times), and oil immersion (100 \times) objectives; 10 \times oculars; calibrated ocular micrometer; light source equivalent to 20-W halogen or 100-W tungsten bulb; blue and white ground-glass diffuser filters

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

A. If possible, check the procedure by using human or canine blood containing microfilariae.

B. If positive blood is not available, follow the procedure carefully in testing the specimen submitted for diagnosis. Examine sediment thoroughly with low- and high-power magnification.

IV. QUALITY CONTROL (continued)

- C. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- D. Record all QC results.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. Draw 1 ml of fresh whole blood or anticoagulated blood into a 15-ml syringe containing 10 ml of distilled water.
- C. *Gently* shake the mixture for 2 to 3 min to ensure that all blood cells are lysed.
- D. Place a 25-mm Nuclepore filter (5- μ m porosity) over a moist 25-mm filter paper pad, and place in a Swinney filter adapter (*see* illustration in Appendix 9.6.9–2 of procedure 9.6.9).
- E. Attach the Swinney filter adapter to the syringe containing the lysed blood.
- F. With gentle but steady pressure on the piston, push the lysed blood through the filter.
- G. Without disturbing the filter, remove the Swinney adapter from the syringe, and draw approximately 10 ml of distilled water into the syringe. Replace the adapter, and gently push the water through the filter to wash the debris from the filter.
- H. Remove the adapter again, draw the piston of the syringe to about half the length of the barrel, replace the adapter, and push the air in the barrel through the filter to expel excess water.
- I. To prepare the filter for staining, remove the adapter, draw the piston about half the length of the barrel, and then draw 3 ml of absolute methanol into the syringe. Holding the syringe vertically, replace the adapter, and push the methanol followed by the air through the filter to fix the microfilariae and expel the excess methanol, respectively.
- J. To stain, remove the filter from the adapter, place it on a slide, and allow it to air dry thoroughly. Stain with Giemsa stain as for a thick film (using 0.1% Triton X-100) (*see* procedure 9.8.5) or with Delafield's hematoxylin (*see* procedure 9.8.8).
- K. To cover the stained filter, dip the slide in toluene *before* mounting the filter with neutral mounting medium and a coverslip. This will lessen the formation of bubbles in or under the filter.

VI. RESULTS

- A. If present in the sample, microfilariae are concentrated and will appear on the wet membrane.
- B. After being stained with Giemsa or Delafield's hematoxylin, the microfilariae will stain characteristically. The sheath, if present, may or may not stain with Giemsa.

VII. REPORTING RESULTS

- A. Report the presence of organisms from the wet Nuclepore membrane.
Example: Microfilariae present.
- B. Report the genus and species of organisms from the Giemsa- or hematoxylin-stained membrane.
Example: *Wuchereria bancrofti* microfilariae present.

VIII. PROCEDURE NOTES

- A. Gently shake the water-blood mixture to ensure total lysis of blood cells. Some parasitologists prefer to use an aqueous solution of 10% Teepol (Shell Oil Co.) to lyse the blood cells.
- B. Motile microfilariae may be seen on the membrane filter after washing with water (step V.G); however, low light will be necessary and the filter must be reassembled before fixing with methanol.
- C. The membrane filter must be supported by the moistened filter pad to prevent rupture when the water is expelled through the membrane.
- D. If you need to add anticoagulant to blood, mix 9 ml of blood and 1 ml of 5% sodium citrate in a clear plastic centrifuge tube. Then proceed with centrifugation.

IX. LIMITATIONS OF THE PROCEDURE

- A. Giemsa or hematoxylin staining may be necessary to identify the organisms to the species level.
- B. Identification of microfilariae on filters to the species level may be difficult.

9.8.11

Concentration Procedures: Knott Concentration

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

This technique is used to recover low numbers of microfilariae from blood. A solution is used to lyse the RBCs in a large blood sample, and the organisms are concentrated from the supernatant fluid by centrifugation (1–4). The disadvantage of this technique is that the microfilariae are killed and immobilized and are therefore not readily revealed by any motility.

II. SPECIMEN

Whole blood collected by using EDTA, heparin, or sodium citrate anticoagulant

Observe standard precautions.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Reagent

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

Formalin, aqueous, 2% (vol/vol)
formaldehyde, liquid 2 ml
distilled water 98 ml
Mix thoroughly. Store in stoppered bottle. Label appropriately. Shelf life is 24 months.

B. Supplies

1. Graduated cylinder, 100 ml
2. Pipette, 5 ml
3. Bottle, 100 ml
4. Capillary pipette with bulb
5. Glass microscope slides, 1 by 3 in.
6. Coverslips, 22 by 22 mm or larger, no. 1 thickness

7. Blood collection supplies, if applicable

8. Centrifuge tube, glass, 12 ml

C. Equipment

1. Centrifuge with sealable carrier cups, speed calibrated
2. Microscope, binocular with mechanical stage; low-power (10×), high dry power (40×), and oil immersion (100×) objectives; 10× oculars; calibrated ocular micrometer; light source equivalent to 20-W halogen or 100-W tungsten bulb; blue and white ground-glass diffuser filters
3. Timer, 1 h or more in 1-min increments

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Check calibration of centrifuge.
- B. If possible, check the procedure by using human or canine blood containing microfilariae with or without a sheath.
- C. If positive blood is not available, follow the procedure carefully in testing the specimen submitted for diagnosis. Examine sediment thoroughly with low- and high-power magnification.
- D. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- E. Record all QC results.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. Place 1 ml of fresh whole blood or anticoagulated blood in a centrifuge tube containing 10 ml of 2% formalin. Mix thoroughly.
- C. Centrifuge for 5 min at $300 \times g$.
- D. Pour off the supernatant fluid without disturbing the sediment.
- E. Using a capillary pipette, transfer a portion of the sediment to a slide.
 - 1. Apply a coverslip, and examine microscopically under low-power ($100\times$) and high-power ($400\times$) magnification.
 - 2. If microfilariae are present, prepare a thick film from the remainder of the sediment, air dry, fix in absolute methanol for 5 min, air dry again, and stain with Giemsa or Delafield's hematoxylin (*see* procedures 9.8.5 and 9.8.8).

VI. RESULTS

- A. If present in the sample, microfilariae are concentrated and will appear non-motile in the wet smear.
- B. After being stained with Giemsa or Delafield's hematoxylin, the microfilariae will exhibit diagnostic morphology and typical staining characteristics.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the presence of organisms from the wet smear.
Example: Microfilariae present.
- B. Report the genus and species of organisms from the Giemsa- or hematoxylin-stained film.
Example: *Wuchereria bancrofti* microfilariae present.

VIII. PROCEDURE NOTES

- A. If you need to add anticoagulant to blood, mix 9 ml of blood and 1 ml of 5% sodium citrate in a glass centrifuge tube. Then proceed with centrifugation.
- B. Morphological details may not be visible prior to Giemsa or hematoxylin staining.

IX. LIMITATIONS OF THE PROCEDURE

- A. Motility will not be visible after formalin fixation.
- B. Identification to the species level may be difficult for most laboratorians without additional staining.
- C. The blood-formalin mixture can be sent to a reference laboratory for staining and identification of microfilariae.

9.8.12

Concentration Procedures: Triple Centrifugation Concentration

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

In many instances, the number of trypanomastigotes (trypanosomes) present in peripheral blood is too small to be detected in direct wet mounts or stained films. Fractional centrifugation is an effective method of concentrating the organisms from a relatively large blood sample (1–3).

II. SPECIMEN

Observe standard precautions.

Whole blood collected by using EDTA, heparin, or sodium citrate anticoagulant. Make sure to fill the tube (containing the anticoagulant) completely, thus guaranteeing the correct anticoagulant/blood ratio.

III. MATERIALS

Include QC information on reagent container and in QC records.

A. Reagent

- ☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.
- Giemsa or Wright's stain (*see* procedures 9.8.5 and 9.8.6)

B. Supplies

1. 3 centrifuge tubes, 12 or 15 ml
2. Capillary pipettes with bulb
3. Glass microscope slides, 1 by 3 in.
4. Coverslips, 22 by 22 mm or larger, no. 1 thickness
5. Blood collection supplies, if applicable

C. Equipment

1. Centrifuge with sealable carrier cups, speed calibrated
2. Microscope, binocular with mechanical stage; low-power (10×), high dry power (40×), and oil immersion (100×) objectives; 10× oculars; calibrated ocular micrometer; light source equivalent to 20-W halogen or 100-W tungsten bulb; blue and white ground-glass diffuser filters
3. Timer, 1 h or more in 1-min increments

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Check calibration of centrifuge.
- B. If possible, check the procedure by using blood containing trypanosomes. Positive blood may be available at universities and large research laboratories.
- C. If positive blood is not available, follow the procedure carefully in testing the specimen submitted for diagnosis.
- D. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the micro-

IV. QUALITY CONTROL (continued)

scope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (see procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.

- E. Record all QC results.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
 B. Centrifuge the blood at $300 \times g$ for 10 min.
 C. Transfer the supernatant fluid to a second centrifuge tube, and centrifuge at $500 \times g$ for 10 min.
 D. Again, transfer the supernatant fluid to a clean tube, and centrifuge at $900 \times g$ for 10 min.
 E. Carefully decant the supernatant fluid, and examine about one-half of the sediment directly as a wet preparation for motile trypanosomes. Use the $10\times$ objective for the examination; in order to see greater organism detail, use the $40\times$ objective (do not use the $100\times$ oil immersion objective on wet preparations).
 F. From the remaining sediment, prepare thin films, and stain with Giemsa or Wright's stain.

VI. RESULTS

- A. If present in the sample, trypomastigotes (trypanosomes) are concentrated.
 B. After being stained with Giemsa or Wright's stain, the trypomastigotes will exhibit diagnostic morphology and typical staining characteristics.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. Report the presence of organisms from the wet smear.
Example: Trypomastigotes present.
 B. Report the genus and species of organisms from the Giemsa- or Wright-stained films.
Example: *Trypanosoma cruzi* or *Trypanosoma gambiense/rhodesiense* present.

VIII. PROCEDURE NOTES

- A. Each time, remove the supernatant fluid carefully (do not remove any sediment).
 B. Make sure the centrifuge is calibrated and the timing is begun when the centrifuge reaches the recommended speed.
 C. Leave some sediment for the preparation of thin films for staining with Giemsa or Wright's stain.

IX. LIMITATIONS OF THE PROCEDURE

- A. Although organism motility may be visible, morphological detail may not be.
 B. Unless dividing trypomastigotes are found in the wet preparation, permanent staining with Giemsa or Wright's stain will be necessary to differentiate the species.

9.9.1

Parasite Culture: *Entamoeba histolytica*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Entamoeba histolytica, the agent of intestinal and hepatic amebiasis, can be cultivated in conjunction with the bacteria voided in feces by the infected patient. Although cultures for *E. histolytica* are not routinely offered by most clinical laboratories, this approach may be helpful when routine procedures have failed to provide a diagnosis. Polyxenic cultured organisms can also be used to produce intestinal and hepatic amebiasis in susceptible experi-

mental hosts such as hamsters, guinea pigs, and rats. Axenic cultivation of organisms is invaluable for the following: (i) to study the biochemistry, physiology, and metabolism of the organisms in order to establish nutritional requirements of the parasites; (ii) to produce antigens of and monoclonal and polyclonal antibodies against *E. histolytica* for serological diagnosis as well as other immunologic studies; (iii) to differentiate pathogenic

from nonpathogenic strains by using isoenzyme electrophoresis, monoclonal antibody, and/or DNA probes; (iv) to screen drugs in vitro to identify isolates susceptible and resistant to particular drugs so that advances in chemotherapy can be evaluated; (v) to infect experimental animals to produce the disease so that pathologic processes can be understood; and (vi) to understand the organization of the parasite at the ultrastructural level.

II. SPECIMEN

Observe standard precautions.

- A. The specimen may consist of stool, mucus, or a combination of the two.
- B. The specimen should be as fresh as possible but never more than 24 h old.

III. MATERIALS

- A. Reagents (see Appendix 9.9.1–1)
- B. Supplies
 1. Graduated Erlenmeyer flasks
 2. Graduated cylinders (500 ml)
 3. Volumetric flasks (1,000 and 2,000 ml)
 4. Microscope slides (1 by 3 in. or larger)
 5. Coverslips (no. 1; 22 by 22 mm or larger)
 6. Sterile syringes (10 ml)
 7. Sterile needles (20 gauge)
 8. Sterile screw-cap tubes (16 by 125 mm)
 9. Sterile cryovials or screw-cap vials (to hold 1 ml)
 10. Box for vial storage in freezer
 11. Disposable sterile Pasteur and serological pipettes
 12. Filter paper, Whatman no. 1
 13. Sterile filtration system (Seitz)
 14. Membrane filters (0.22- μ m pore size)
 15. Nutrient agar plates
 16. BHI broth
 17. Thioglycolate broth
 18. Methylene blue solution
 19. Biohazard container of disinfectant for proper disposal of tubes, slides, and pipettes
 20. Biohazard container for proper disposal of patient specimens
 21. ATCC 30925 (*E. histolytica* HU-1: CDC)
 22. ATCC 30015 (*E. histolytica* HK-9)
 23. Laredo strain (*E. histolytica*-like, ATCC 30042) (can be maintained in culture at 25°C)
 24. Any strain of *Entamoeba moshkovskii* (can be maintained in culture at 25°C)

III. MATERIALS (*continued*)**C. Equipment**

1. Binocular microscope with 10×, 40×, and 100× objectives; phase-contrast and/or differential interference contrast optics preferred
2. Binocular inverted microscope with 4×, 10×, and 40× objectives; phase-contrast and/or differential interference contrast optics preferred (this microscope is recommended but not mandatory)
3. Oculars should be 10×. Some may prefer 5×; however, overall smaller magnification may make final organism identifications more difficult.
4. Tabletop centrifuge, preferably refrigerated (for centrifuging tubes containing patient specimens, e.g., watery stools, and for culture tubes)
5. Hot plate
6. Biological safety cabinet, type II
7. Magnetic stirrer and stir bar
8. pH meter
9. Drying oven or dry-heat sterilizer
10. Incubator that can be set at 35 ± 2°C

ANALYTICAL CONSIDERATIONS**IV. QUALITY CONTROL**

- A. Check all reagents and media (PBS solution no. 8, rice starch suspension, Tween 80 solution, TYSGM-9 and TYI-S-33 media) each time they are used or periodically (once a week).
 1. The media should be free of any signs of precipitation and bacterial and/or fungal contamination.
 2. PBS solution no. 8, Tween 80 solution, and rice starch suspension should be clear, with no visible signs of contamination.
- B. Maintain stock cultures of *E. histolytica* at 35°C (ATCC 30925 [strain HU-1: CDC] and ATCC 30015 [strain HK-9]). Maintain *E. histolytica*-like (ATCC 30042) Laredo and *E. moshkovskii* strains in culture at 25°C.
 1. Transfer stock culture (ATCC 30925) every other day with TYSGM-9 medium. Transfer stock cultures held at 25°C once a month.
 2. Transfer stock culture (ATCC 30015) once every 3 days with TYI-S-33 medium.
 3. *E. histolytica* trophozoites are 10 to 60 μm long and demonstrate directional motility by extruding hyaline, fingerlike pseudopodia from the cytoplasm. Cysts are not usually found in cultures.
 4. Trophozoites are uninucleate and the nucleus is characterized by finely granular, uniform, evenly distributed peripheral chromatin. The nucleolus is small and usually centrally located but may be eccentric.
- C. The microscope(s) should be calibrated, and the original optics used for the calibration should be in place on the microscope(s). Post the calibration factors for all objectives on the microscope for easy access (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- D. Record all QC results.

V. PROCEDURE**Xenic and axenic culture**

In Greek, *xenos* means stranger. Culture amebae grown in association with an unknown microbiota are called a xenic culture. If the amebae are grown in association with a single known bacterium, the culture is monoxenic; if the culture contains several identified bacteria, then it is polyxenic. If amebae are grown as pure culture without any bacterial associate, the culture is axenic.

V. PROCEDURE (continued)**A.** Wear gloves when performing this procedure.**B.** Xenic culture

1. Warm several tubes of TYSGM-9 medium in the incubator (35°C for 1 to 2 h).
2. Add 0.1 ml of stock antibiotics to each tube of medium. Final concentrations of antibiotics are 100 U of penicillin and 100 µg of streptomycin per ml.
3. After vortexing or vigorously shaking the tube, use a Pasteur pipette to add 3 drops of the starch suspension to each tube of the medium.
4. Place a pea-sized portion of stool sample into the bottom of the tube, and break up the stool gently with the pipette.
5. Tightly cap the tubes, and incubate at a 45 to 50° angle at 35°C for 48 h.
6. With an inverted microscope and the 10× objective, examine the tubes for the presence of amebae. If present, amebae will usually be seen attached to the underside of the tubes interspersed with the fecal material and rice starch. Sometimes it may be necessary to gently invert the tubes to disperse the stool material and rice starch to uncover the amebae. If you do not have an inverted microscope, proceed to step V.B.13.
7. If amebae are not seen, stand the tubes upright for about 30 min at 35°C.
8. With a Pasteur pipette, remove from the bottom of each tube 0.5 to 0.75 ml of sediment, and inoculate the sediment into fresh tubes containing rice starch and antibiotics. Centrifuge the original tubes at 250 × *g* for 10 min, decant the supernatant, and add 8 ml of fresh medium.
9. Incubate all tubes as described above (step V.B.5) for another 48 h.
10. Examine the tubes as before, and discard the tubes if amebae are still not seen. Report patient results as negative.
11. If amebae are present in small numbers, then chill the tube in ice water for 5 min, and centrifuge the tube for 5 min at 250 × *g*. Aspirate and discard the supernatant, and inoculate the sediment into a fresh tube as before.
12. If amebae are present in large numbers, then let the tube stand upright for 30 min, and remove about 0.5 ml of sediment from the bottom. Inoculate the sediment into fresh tubes as before.
13. If you do not have an inverted microscope, stand the tubes upright for about 30 min at 35°C. With a sterile pipette, remove about 0.5 ml of sediment from the bottom of the tube, and place a couple of drops onto each of two slides. Add 2 drops of methylene blue solution to one of the slides. Cover both slides with coverslips, and examine the slides under the microscope for amebae. Amebae may be rounded or have pseudopodial extrusions. The nucleus may be clearly seen in the methylene blue preparation. Proceed to steps V.B.7 through 12.

C. Axenic culture (used for research)

1. Remove tubes containing TYI-S-33 medium from 4°C and incubate at 35°C for 1 to 2 h.
2. With an inverted microscope, examine stock culture tubes of *E. histolytica* (HK-9 strain) for any signs of bacterial contamination (if present, tubes are no longer acceptable for use). Select one or several tubes showing good growth of amebae. Since the tubes are incubated in a slanted position, usually at an angle of 5° to 10°, a thick button of amebae will be seen at the bottom of the tube. Gently invert the tube once or twice to disperse the amebae uniformly, and examine the tubes again. A majority of the amebae should be attached to the tube walls and show pseudopodial motility. If you do not have an inverted microscope, examine organisms from the bottom of the tube (as a wet smear). If you can see pseudopodial motility, proceed to the next step (step V.C.3).

V. PROCEDURE (*continued*)

3. Immerse the tubes in a bucket of ice-cold water for about 5 to 10 min. This will dislodge the amebae from the tube walls. Invert the tubes several times in order to distribute the amebae.
4. With a Pasteur pipette, remove about 1.0 to 1.5 ml of culture medium; inoculate 0.5 to 1 ml into a fresh tube. Inoculate the rest of the fluid into nutrient agar, BHI broth, and thioglycolate broth for routine monitoring of bacterial contamination. Inoculate several tubes this way, and incubate the cultures slanted at a 5 to 10° angle at 35°C as before.
5. If amebic growth is not good but some amebae are attached to the tube walls, then use a serological pipette to remove about 10 ml of medium from the bottom, and add 10 ml of fresh medium.
6. If amebic growth is not good and only a few amebae are present along with a lot of debris, then centrifuge the tube at 250 × *g* for 10 min, aspirate the supernatant fluid, transfer the sediment to a fresh tube, and incubate the tube as before.

VI. RESULTS

Protozoan trophozoites and/or cysts may be recovered and identified.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

- A. If the tubes containing the fecal material are positive for amebae after 48 h of incubation, then confirm the identification with a permanent stained smear.
- B. To ascertain that the amebae cultured are *E. histolytica*, prepare a permanently stained smear (trichrome or iron hematoxylin), since *Entamoeba coli* may also be isolated in culture.
Example: *Entamoeba histolytica* present.
- C. If the tubes do not show any amebae, then subculture the tubes as described above and incubate for an additional 48 h. If the tubes are still negative for amebae, then report the specimen as negative and discard the tubes.
Example: No *Entamoeba histolytica* isolated.

VIII. PROCEDURE NOTES

- A. When initiating xenic cultures, inoculate stool samples into at least two tubes, one with and the other without antibiotics. In some cases, some component of the natural microbiota may be helpful or even necessary for the amebae to become established and to differentiate (possibly) into cysts.
- B. If the culture tubes become contaminated during routine subculture and maintenance of the axenically grown amebae, try to eliminate the contaminant by adding 1,000 U of penicillin and 1,000 µg of streptomycin or 50 µg of gentamicin per ml. If, however, the contaminant happens to be *Pseudomonas* spp., it is probably better to discard the tube and use an uncontaminated tube for subculture purposes.
- C. Vitamin mixture no. 13 used in the TYI-S-33 medium may be replaced with 10 ml of NCTC-109 medium (any supplier of tissue culture media). Although the final yield of amebae may not be as good as that obtained with medium containing the vitamin mix, the procedure is simpler and saves a lot of time and effort.

IX. LIMITATIONS OF THE PROCEDURE

- A. Culture of *E. histolytica* serves only as a supplemental procedure and never replaces primary diagnosis by microscopic examination. Axenic culture is used for maintaining QC strains and for research purposes. Xenic cultures may be used as a supplemental diagnostic procedure.
- B. Even when the culture system is within QC guidelines, a negative culture is still not definitive in ruling out the presence of *E. histolytica* (1–5).

APPENDIX 9.9.1–1

Include QC information on reagent container and in QC records.

Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. TYSGM-9 medium

1. Nutrient broth

potassium phosphate, dibasic (K ₂ HPO ₄)	...2.8 g
potassium phosphate, monobasic (KH ₂ PO ₄)0.4 g
sodium chloride (NaCl)7.5 g
casein digest peptone (BBL; catalog no. 97023)2.0 g
yeast extract (BBL)1.0 g
glass-distilled water970.0 ml

The nutrient broth may be stored for several months at –20°C (without sterilization), according to L. S. Diamond (1, 2). Note the expiration date on the label and in the work record.

2. 5% Tween 80 solution

- a. With a magnetic stirrer, vigorously stir 95 ml of glass-distilled water in a bottle.
- b. Add 5 g of Tween 80 (very thick solution; must be weighed), and keep stirring for a few minutes. Avoid foam formation.
- c. Filter sterilize with a 0.22-µm-pore-size membrane.
- d. Aseptically dispense into a number of sterile screw-cap test tubes, with 10 ml per tube.
- e. Label as 5% Tween 80 solution with the preparation date and an expiration date of no longer than 1 month.
- f. Store at 4°C.

3. Phosphate-buffered solution (PBS no. 8), pH 7.2

sodium chloride (NaCl)9.5 g
potassium phosphate, dibasic (K ₂ HPO ₄)	...3.7 g
potassium phosphate, monobasic (KH ₂ PO ₄)1.1 g
glass-distilled water to1,000.0 ml

- a. Dissolve the salts in the distilled water by using a magnetic stirrer.
- b. Autoclave for 15 min at 121°C.
- c. When cool, label as PBS no. 8 with the preparation date and an expiration date of 3 months.

APPENDIX 9.9.1–1 (continued)

4. Rice starch

For best results, use rice starch obtained from British Drug Houses Ltd. or Gailard Schlesinger, Inc. (ATCC can also be contacted for information).

- a. Dispense 500 mg of rice starch into each of several screw-cap tubes (16 by 125 mm). Do not tighten the caps.
- b. Place the tubes horizontally in a dry-heat sterilizer or an oven. Make sure that the rice is uniformly distributed loosely over the undersurface of the tubes.
- c. Heat the tubes for 2.5 h at 150°C.
- d. When cool, tighten caps and label as rice starch with the date of preparation and an expiration date of 3 months.

5. Rice starch suspension

- a. Add 9.5 ml of sterile PBS no. 8 to each tube of rice starch.
- b. Shake vigorously or use a vortex mixer to uniformly suspend the rice starch at the time of use.

6. Stock antibiotic solution

- a. Using a sterile 6-ml syringe and 20-gauge needle, add 5 ml of sterile distilled water to a vial of penicillin G sodium (10^6 U).
- b. Using a 6-ml syringe and a 20-gauge needle, add 5 ml of sterile distilled water to a vial of streptomycin sulfate (10^6 µg/ml).
- c. Shake gently, and let stand for 30 min to dissolve the antibiotics completely in the distilled water.
- d. Mix the two antibiotics in a sterile graduated flask or cylinder, and bring the volume to 125 ml with distilled water. Stock concentrations of antibiotics are 8,000 U of penicillin and 8,000 µg of streptomycin per ml.
- e. Filter sterilize the antibiotic solution through a 0.22-µm-pore-size membrane filter, dispense the filtrate into a number of sterile screw-cap vials or sterile cryovials (1 ml per vial), and label as stock antibiotic solution (Pen/Strep) with the preparation date and an expiration date of 1 year.
- f. Store at -20°C in a cryovial box.

7. Buffered methylene blue solution

- a. Solution A, 0.2 M acetic acid

glacial acetic acid 11.55 ml
distilled water 988.45 ml

Add the acetic acid to the water, mix, and store in a glass-stoppered bottle. Label with the date of preparation and an expiration date of 1 year.

- b. Solution B, 0.2 M sodium acetate

sodium acetate ($\text{NaC}_2\text{H}_3\text{O}_2$) 16.4 g
distilled water to 1,000.0 ml

Dissolve the sodium acetate in 400 ml of distilled water in a volumetric flask, bring the volume to 1,000 ml, mix well, and store in a glass-stoppered bottle. Label with the date of preparation and an expiration date of 1 year.

- c. Acetate buffer, pH 3.6

solution A 46.3 ml
solution B 3.7 ml
distilled water to 100.0 ml

Mix solutions A and B in a volumetric flask, and bring the volume to 100.0 ml with distilled water. pH should be 3.6. Store in a glass-stoppered bottle. Label with the date of preparation and an expiration date of 1 year.

- d. Methylene blue stain

methylene blue dye 60.0 mg
acetate buffer (from previous step
[step A.7.c]) 100.0 ml

Dissolve the dye in the buffer, and store in a glass-stoppered bottle. Label with the date of preparation and an expiration date of 1 year.

APPENDIX 9.9.1–1 (continued)

8. Complete medium (TYSGM-9 medium)
 - a. Place 200 mg of gastric mucin (U.S. Biochemical Corp.; catalog no. 16025) in 125-ml screw-cap bottle or Erlenmeyer flask.
 - b. Add 97 ml of nutrient broth (*see* item A.1). Using a magnetic stirrer, stir vigorously for at least 1 h or until the medium becomes clear.
 - c. Autoclave for 15 min at 121°C; cool to room temperature.
 - d. In a biological safety cabinet, aseptically add 5.0 ml of heat-inactivated bovine serum.
 - e. Add 0.1 ml of the 5% Tween 80 solution.
 - f. In a biological safety cabinet, aseptically dispense 8 ml per tube into a number of sterile screw-cap tubes (16 by 125 mm).
 - g. After vigorously shaking the tube, add 0.25 ml of rice starch solution.
 - h. Store the tubes at 4°C for not more than 1 month.
 - i. The final pH of the medium should be 7.2.

B. TYI-S-33 medium

1. Nutrient broth

potassium phosphate, dibasic (K ₂ HPO ₄) ...	1.0 g
potassium phosphate, monobasic (KH ₂ PO ₄)	0.6 g
sodium chloride (NaCl)	2.0 g
casein digest peptone (BBL; catalog no. 97023)	20.0 g
yeast extract (BBL)	10.0 g
glucose	10.0 g
L-cysteine-HCl	1.0 g
ascorbic acid	0.2 g
ferric ammonium citrate	22.8 mg
glass-distilled water to	870.0 ml

- a. Use a magnetic stirrer to dissolve the ingredients listed above in about 700 ml of glass-distilled water.
 - b. Adjust pH to 6.8 with 1 N NaOH.
 - c. Bring the volume to 870 ml with glass-distilled water.
 - d. Filter through a no. 1 Whatman filter paper.
 - e. Autoclave for 15 min at 121°C.
 - f. Cool to room temperature.
 - g. Store at 4°C.
2. Vitamin mixture no. 13

a. Solution 1a

niacin	40 mg
<i>p</i> -aminobenzoic acid	180 mg

Dissolve in glass-distilled water, and bring the volume to 125 ml.

b. Solution 1b

nicotinamide	40 mg
pyridoxal hydrochloride	40 mg
pyridoxine	80 mg
calcium pantothenate	25 mg
choline chloride	830 mg
<i>l</i> -inositol	125 mg
thiamine hydrochloride	25 mg
vitamin B ₁₂	12 mg

Dissolve in about 100 ml of glass-distilled water, and bring the volume to 125 ml.

c. Solution 1c

riboflavin	25 mg
------------------	-------

Using a magnetic stirrer, dissolve in about 100 ml of glass-distilled water with the dropwise addition of 1 N NaOH, and bring the volume to 450 ml with glass-distilled water.

APPENDIX 9.9.1–1 (continued)

d. Solution 1d

folic acid30 mg

Using a magnetic stirrer, dissolve in about 100 ml of glass-distilled water with the dropwise addition of 1 N NaOH, and bring the volume to 450 ml with glass-distilled water.

e. Solution 1e

D-biotin30 mg

Using a magnetic stirrer, dissolve in about 100 ml of glass-distilled water with the dropwise addition of 1 N NaOH, and bring the volume to 450 ml with glass-distilled water.

f. Solution 1

Mix all 5 solutions (a, b, c, d, and e). pH should be 6.5 to 7.0.

g. Solution 2a

DL-6,8-thiolic acid (oxidized form) 100 mg
95% ethanol 50.0 ml

h. Solution 2b

Tween 80 (very thick solution, must be weighed)5.0 g
menadione sodium bisulfite30 mg
 α -tocopherol acetate25 mg

Using a magnetic stirrer, dissolve in about 100 ml of distilled water, and bring the volume to 200 ml.

i. Solution 2c

Mix solutions 2a and 2b, and bring the volume to 300 ml with sterile glass-distilled water.

j. Solution 3

Combine solution 1 and solution 2c, and bring the volume to 2,000 ml with glass-distilled water. Filter sterilize the solution through a 0.22- μ m-pore-size membrane filter.

Dispense in small volumes (e.g., 10 ml), and label as vitamin mix no. 13. Give the date of preparation on the label. Store at -20 or -70°C . The vitamin mix may be stored for several years in this fashion.

3. Complete medium (TYI-S-33 medium)

nutrient broth870.0 ml
bovine serum (inactivated at 56°C for 30 min)100.0 ml
vitamin mix no. 13 20.0 ml

The final medium should have a pH of 6.6.

a. Aseptically dispense 13 to 14 ml per tube into a number of sterile screw-cap glass culture tubes (16 by 125 mm).

b. Label as TYI-S-33 medium with the date of preparation and an expiration date of no longer than 2 weeks.

c. Store at 4°C in a dark place, as the medium is extremely sensitive to light.

▣ **NOTE:** Casein digest peptone varies from lot to lot in its ability to support the growth of *E. histolytica*. Because of the difficulties in obtaining a uniformly good lot that supports good growth of *E. histolytica*, Diamond et al. (3) have formulated a new medium (YI-S), which does not include casein digest peptone. YI-S medium is similar to TYI-S-33 medium. The major difference between the two media, however, is the increase in the concentration of yeast extract to 30 g (in YI-S medium) to compensate for the omission of casein digest peptone in the TYI-S-33 medium.

9.9.2

Parasite Culture: *Acanthamoeba* and *Naegleria* spp.

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Members of the genera *Acanthamoeba* and *Naegleria* are free-living soil and freshwater amebae known to cause human disease. Only one species of *Naegleria*, *Naegleria fowleri*, is known to cause primary amebic meningoencephalitis, which is almost always fatal, whereas several species of *Acanthamoeba* are known to cause fatal granulomatous amebic encephalitis and the nonfatal but vision-threatening *Acanthamoeba* keratitis (1–4). Members of both genera can be easily cultivated in the laboratory either monoxenically (with a single species of bacterium included in the culture medium) or axenically (containing no organisms other than

the amebae). When the etiologic agent in CSF or other body fluids cannot be identified in suspected cases of amebic encephalitis, it is imperative to try to culture the organisms. Culture should be attempted even in those cases for which a presumptive diagnosis has been made on the basis of the morphologic features of the presumed agent, since these organisms can be mistaken for host cells. Axenic cultivation of the organisms is invaluable for the following: (i) studying the biochemistry, physiology, and metabolism of the organisms to determine their nutritional requirements; (ii) producing antigens for

monoclonal and polyclonal antibodies to these amebae for serological diagnosis as well as for other immunologic studies; (iii) differentiating species within the genera by using isoenzyme electrophoresis, monoclonal antibody, and/or DNA probes; (iv) in vitro screening of drugs to identify isolates susceptible and resistant to particular drugs so that advances in chemotherapy can be made; (v) infecting experimental animals so that pathologic processes involved in the disease state can be understood; and (vi) understanding the organization of the parasite at the ultrastructural level.

II. SPECIMENS

Observe standard precautions.

- A. For both *Acanthamoeba* and *Naegleria* spp., the specimens usually consist of CSF, biopsy tissue, or autopsy tissue of the brain, and for *Acanthamoeba*, biopsy or autopsy tissue of the lungs, corneal scrapings or biopsy material, contact lenses and contact lens paraphernalia such as contact lens cases and solutions, skin abscess material, ear discharge, or feces can also be used.
- B. Soil and water samples may also be processed for the isolation of these small free-living amebae.
- C. For best results, process the specimens, especially CSF and tissue samples, for culture within 24 h, preferably sooner if possible.
- D. The samples should never be frozen but may be refrigerated.
- E. If the samples can be processed within 4 to 8 h, keep them at room temperature (24°C) until processed.
- F. Collect all samples aseptically, and place them in sterile containers.
- G. Collect at least 100 ml of water sample for the isolation of the amebae; the container should be large enough to have plenty of air space.

III. MATERIALS

A. Reagents (see Appendix 9.9.2–1)

B. Supplies

1. Nonnutrient agar plates, Nelson's and PYG media
2. Moist chamber
3. Microscope slides (1 by 3 in. or larger)
4. Coverslips (no. 1, 22 by 22 mm or larger)
5. Sterile 1 × ameba saline
6. Sterile distilled water
7. Bacteriological loop
8. Fine spatula made of nichrome wire
9. 18- to 24-h-old culture of *Escherichia coli* or *Enterobacter aerogenes*, *Acanthamoeba castellanii* ATCC 30010, and *Naegleria gruberi* ATCC 30133
10. Sterile Pasteur and serological pipettes (1, 5, and 10 ml)
11. Sterile screw-cap test tubes (13 by 100 or 16 by 125 mm)
12. Volumetric flasks (1,000 ml)
13. Vaspar
14. Parafilm (American Can Co.) or equivalent

C. Equipment

1. Binocular microscope with 10×, 40×, and 100× objectives; phase-contrast and/or differential interference contrast optics preferred
2. Binocular inverted microscope with 4×, 10×, and 40× objectives; phase-contrast and/or differential interference contrast optics preferred (this microscope is recommended but not mandatory)
3. Oculars should be 10×. Some may prefer 5×; however, smaller magnification may make final organism identifications more difficult.
4. Tabletop centrifuge, preferably refrigerated (for centrifuging tubes containing patient specimens, contact lens solutions, and water samples)
5. Hot plate
6. Biological safety cabinet, type II
7. Magnetic stirrer and stir bar
8. pH meter

ANALYTICAL CONSIDERATIONS

IV. QUALITY CONTROL

- A. Check all reagents and media (ameba saline, distilled water, nonnutrient agar plates, Nelson's and PYG media) each time they are used or periodically (once a week).
 1. The media should be free of any signs of precipitation and bacterial and/or fungal contamination.
 2. Page's saline should be clear, with no visible sign of contamination.
 3. Examine the nonnutrient agar plates under the 40× objective of an inverted or binocular microscope, and make sure that no fungal contamination has occurred.
- B. Maintain stock cultures of *A. castellanii* and *N. gruberi* at 25°C.
 1. Transfer stock cultures monthly with nonnutrient agar slants and Page's ameba saline.
 2. *N. fowleri* is 10 to 35 μm long and demonstrates an eruptive locomotion by producing smooth hemispherical bulges. The cyst produces smooth walls (7 to 15 μm thick). The flagellate stage does not have a cytostome.
 3. *Acanthamoeba* is 15 to 45 μm long and produces fine, tapering, hyaline projections called acanthopodia. It has no flagellate stage but produces a double-walled cyst with an outer wrinkled wall (10 to 25 μm thick).
 4. Trophozoites of *Naegleria* and *Acanthamoeba* spp. are uninucleate and have a large, dense, central nucleolus.
 5. Stain
 - a. Run a slide prepared from a stock strain of amebae in parallel with the patient slide.
 - b. Staining results are acceptable when the control amebae stain.
 6. Culture
 - a. Plate both stock cultures onto fresh media, and incubate at 37°C in parallel with patient culture.
 - b. Culture results are acceptable when growth appears by day 7.

IV. QUALITY CONTROL

(continued)

7. Enflagellation
 - a. Run *N. gruberi* in parallel with patient culture being observed for enflagellation.
 - b. Test is acceptable when free-swimming, pear-shaped flagellates with two flagella are observed in 2 to 24 h on the control slide.
- C. The microscope(s) should be calibrated, and the original optics used for the calibration should be in place on the microscope(s). Post the calibration factors for all objectives on the microscope for easy access (see procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- D. Record all QC results.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. Remove the nonnutrient agar plates from the refrigerator, and place them in a 37°C incubator for 30 min.
- C. Add 0.5 ml of ameba saline to a slant culture of *E. coli* or *E. aerogenes*. Gently scrape the surface of the slant (do not break the agar surface). Suspend the bacteria uniformly by gently pipetting with a Pasteur pipette, and add 2 or 3 drops of this suspension to the middle of the warmed agar plate. Spread the bacteria on the surface of the agar with a bacteriological loop.
- D. Inoculate the specimen on the center of the agar plate as follows.
 1. CSF
Centrifuge CSF at $250 \times g$ for 10 min. With a sterile serological pipette, carefully transfer all but 0.5 ml of the supernatant to a sterile tube, and store at 4°C (for possible future use). Mix the sediment in the rest of the fluid, and use a Pasteur pipette to place 2 or 3 drops in the center of the nonnutrient agar plate that has been precoated with bacteria. After the fluid has been absorbed, seal the plates with a 5- to 6-in. length of 1-in.-wide Parafilm. Incubate the plate *upright* at 37°C.
 2. Tissue
Triturate a small piece of the tissue (brain, lung, skin abscess, corneal biopsy, or similar specimens) in a small quantity (ca. 0.5 ml) of ameba saline. Process as described above. Corneal smear, ear discharge material, etc., may be placed directly on the agar surface and incubated as described above (step V.D.1).
 3. Water sample
Water samples (10 to 100 ml) may be processed to isolate amebae. First, filter the water sample through three layers of sterile gauze or cheesecloth to remove leaves, dirt, etc. Next, (i) filter the sample through a sterile 5.0- μm -pore-size cellulose acetate membrane (47-mm diameter), invert the membrane over a nonnutrient agar plate precoated with bacteria, seal, and incubate the plates as described above (step V.D.1); or (ii) centrifuge the water sample for 10 min at $250 \times g$, aspirate the supernatant, suspend the sediment in about 0.5 ml of ameba saline, deposit this suspension in the center of the nonnutrient agar plate precoated with bacteria, seal, and incubate the plate at 37°C as before.
 4. Soil
Mix about 1 g of the soil sample with enough ameba saline (ca. 0.5 to 1 ml) to make a thick slurry. Inoculate this slurry in the center of the nonnutrient agar plate precoated with bacteria, and incubate as described above (step V.D.1).

V. PROCEDURE (*continued*)

5. Contact lens solutions
Small volumes (ca. 1 to 2 ml) may be inoculated directly onto the nonnutrient agar plates precoated with bacteria. Centrifuge larger volumes (2 to 50 ml) as in step V.D.3, inoculate the sediment onto the center of the nonnutrient agar plate, and incubate it as before (step V.D.1).
- E. Examine the plates microscopically for amebae (cysts or trophozoites) every day for 10 days. Thin linear tracks (areas where amebae have ingested bacteria) may be seen. If amebae are seen, circle that area with a wax pencil, carefully remove the Parafilm seal under a biological safety cabinet, open the lid of the petri dish, and carefully cut out the marked area from the agar by using a spatula that has been heated to red hot and cooled before use in order to prevent contamination (a sterile disposable scalpel can also be used). Transfer the piece facedown onto the surface of a fresh agar plate coated with bacteria, seal the plate with Parafilm, and incubate as before (step V.D.1).
- F. Enflagellation experiment
 1. Examine the plates every day for signs of amebae. If present, amebae will feed on bacteria, multiply, and cover the entire surface of the plate within a few days. Once the food supply is exhausted, the amebae will differentiate into cysts.
 2. Mark the area containing a large number of amebic trophozoites with a wax pencil.
 3. Using a bacteriological loop, scrape the surface of the agar at the marked area, and transfer several loopfuls of the scraping to a sterile tube containing about 2 ml of sterile distilled water. Alternatively, flood the surface of the agar plate with about 10 ml of sterile distilled water, gently scrape the agar surface with a loop, transfer the liquid to a sterile tube, and incubate at 37°C.
 4. Periodically examine the tube with an inverted microscope for the presence of flagellates.
 - a. *N. fowleri*, the causal agent of primary amebic meningoencephalitis, undergoes transformation to a pear-shaped flagellate, usually with two flagella but occasionally with three or four flagella. The flagellate stage is a temporary nonfeeding stage and usually reverts to the trophozoite stage. *N. fowleri* trophozoites are typically amebalike and move in a sinuous way. They are characterized by a nucleus with a large, centrally located nucleolus. The trophozoites are also characterized by the presence of a contractile vacuole that appears once every 45 to 50 s and discharges its contents. The contractile vacuole looks like a hole or a dark depression inside the trophozoite and can easily be seen when examining the plate under the 10× or 40× objective. When the food supply is exhausted, *N. fowleri* trophozoites differentiate into spherical, smooth-walled cysts.
 - b. In contrast, *Acanthamoeba* spp., which cause keratitis and granulomatous amebic encephalitis, do not transform into the flagellate stage. *Acanthamoeba* trophozoites are characterized by the presence of fine, thornlike processes that are constantly extended and retracted. The trophozoites produce double-walled cysts characterized by a wrinkled outer wall (ectocyst) and a polygonal, stellate, oval, or even round inner wall (endocyst). The trophozoites are also characterized by the presence of the contractile vacuole, which disappears and reappears at regular intervals (45 to 50 s).
 - c. The cysts of both *Acanthamoeba* and *Naegleria* spp. are uninucleate.

VI. RESULTS

Protozoan trophozoites (amebic, flagellate forms) and/or cysts may be recovered and identified.

POSTANALYTICAL CONSIDERATIONS**VII. REPORTING RESULTS****A. Patient specimens**

If a plate is positive for amebae and the amebae transform into flagellates, then the specimen should be reported as positive for *N. fowleri*. If the amebae do not transform into flagellates even after overnight incubation and if the trophozoites possess the characteristic acanthopodia, show a large centrally placed nucleolus in the nucleus on trichrome stain, and differentiate into the characteristic double-walled cysts, then report the specimen as positive for *Acanthamoeba*.

B. Contact lens solution

If the plates are positive for amebae and the amebae do not transform into flagellates but differentiate into cysts with an outer wrinkled ectocyst and an inner stellate, polygonal, oval, or round endocyst, then report the specimen as positive for *Acanthamoeba*. *Naegleria* spp. have not been isolated from contact lens solutions, but small amebae (e.g., hartmannellid or vahlkampfiid amebae, which produce smooth-walled cysts), probably contaminants, have occasionally been isolated from these solutions.

C. Water samples

Plates inoculated with water samples are usually positive for many genera and species of small free-living amebae (fresh water is their normal habitat). Therefore, report the sample as positive for small free-living amebae.

D. Notify the physician immediately if patient specimens are positive for *Acanthamoeba* or *Naegleria*.**VIII. PROCEDURE NOTES****A. Examine most patient specimens, especially CSF, microscopically as soon as they arrive in the laboratory.**

1. Remove a small drop of the CSF sediment (step V.D.1), place it on a microscope slide, cover it with a no. 1 coverslip, seal the edges of the coverslip with Vaspar, and examine it immediately with a 10× or 40× objective (phase-contrast or differential interference contrast optics are preferred). If bright-field microscopy is used, reduce the illumination by adjusting the iris diaphragm.

a. *N. fowleri* trophozoites are highly motile and can be identified by their sinuous movement. A warmed penny applied to the bottom surface of the slide will activate the trophozoite. Occasionally a flagellate may be seen traversing the field.

b. *Acanthamoeba* trophozoites are rarely seen in the CSF. If present, they may be recognized by their characteristic acanthopodia, which are constantly extending and retracting. Both amebae, especially *Acanthamoeba*, may be recognized by the contractile vacuole.

2. Process and examine lens care solutions (opened) like CSF.

3. If very small amounts of tissue are received, reserve them for culture.

B. An alternative method for the preparation of agar plates would be to prepare agar deeps.

1. Aliquot 20 ml of the nonnutrient agar into screw-cap tubes (20 by 150 mm).

2. Autoclave the tubes at 121°C for 15 min.

3. Store at 4°C with a 12-month expiration date.

4. Prior to use, melt the agar deeps in boiling water.

5. Pour into a petri dish (100 by 15 mm).

6. Cool. Store at 4°C with a 3-month expiration date.

C. ATCC strains of *E. coli* or *E. aerogenes* are not necessary. Any routine clinical isolate or stock organism is acceptable.

VIII. PROCEDURE NOTES

(continued)

- D. Material from the surface of a positive agar plate can be removed, fixed, and stained by trichrome for microscopic examination at a higher magnification ($\times 1,000$).

IX. LIMITATIONS OF THE PROCEDURE

- A. Always confirm results obtained with wet mounts by permanent stained smears (trichrome, iron hematoxylin) for nuclear characteristics in order to differentiate the amebae from host cells.
- B. Organisms may not be recovered if appropriate centrifugation speeds and times are not used.
- C. *Balamuthia mandrillaris* cannot be cultured using the agar plate method.

APPENDIX 9.9.2–1

Include QC information on reagent container and in QC records.

Reagents

- ☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. Page's ameba saline (10 \times)

sodium chloride (NaCl)	1.20 g
magnesium sulfate (MgSO ₄ · 7HOH)	0.04 g
sodium phosphate, dibasic (Na ₂ HPO ₄) ...	1.42 g
potassium phosphate, monobasic (KH ₂ PO ₄)	1.36 g
calcium chloride (CaCl ₂ · 2HOH)	0.04 g
double-distilled water to	1,000 ml

- Using a magnetic stirrer, dissolve the above ingredients in the order listed in distilled water in an appropriate glass flask or bottle.
- Distribute 100 ml into each of 10 glass bottles.
- Label as ameba saline (10 \times) with the preparation date and an expiration date of 3 months.
- Sterilize by autoclaving at 121°C for 15 min.
- Cool and store at 4°C.

APPENDIX 9.9.2-1 (continued)

B. Nonnutrient agar

10× ameba saline (from step A)	100.0 ml
Difco agar	15.0 g
double-distilled water	900.0 ml

1. Mix ameba saline with distilled water by using a magnetic stirrer to make 1× ameba saline. Add 15.0 g of agar to this solution, and dissolve with heat. Autoclave at 121°C for 15 min.
2. Cool to about 60°C, and aseptically pour into sterile plastic petri dishes (20 ml for 100- by 15-mm dish or 5 ml for 60- by 15-mm dish).
3. Label as nonnutrient agar plates with the preparation date and an expiration date of 3 months.
4. After the agar gels, store the agar plates in canisters at 4°C.

C. Nutrient agar, pH 6.8

beef extract	3.0 g
peptone or Gelysate pancreatic digest of gelatin	5.0 g
agar	15.0 g
distilled water	1,000.0 ml

1. Mix well, and autoclave at 121°C for 15 min.
2. Cool to 60°C, and dispense 5 ml per tube; slant to obtain a slant with a thick butt. Nutrient agar slants may be obtained from BBL (catalog no. 20970/20971).

D. Modified Nelson's medium for *N. fowleri*

Panmede (ox liver digest) (Difco)	10.0 g
glucose	10.0 g
10× ameba saline (from step A)	100.0 ml
double-distilled water to	900.0 ml

1. Add ameba saline to distilled water to make 1× ameba saline.
2. Dissolve the ingredients in ameba saline by using a magnetic stirrer.
3. Dispense 10 ml per tube into screw-cap tubes (16 by 125 mm).
4. Autoclave for 15 min at 121°C.
5. Cool, and label as Nelson's medium with the preparation date and an expiration date of 3 months.
6. Store at 4°C.
7. Add 0.2 ml of heat-inactivated fetal calf serum to each tube before inoculating with the amebae.

E. Peptone-yeast extract-glucose (PYG) medium for *Acanthamoeba* spp., pH 6.5 ± 0.2

Proteose Peptone (Difco)	20.0 g
yeast extract (Difco)	2.0 g
magnesium sulfate ($MgSO_4 \cdot 7H_2O$)	0.980 g
calcium chloride ($CaCl_2$)	0.059 g
sodium citrate ($Na_3C_6H_5O_7 \cdot 2H_2O$)	1.0 g
ferric ammonium sulfate [$Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$]	0.02 g
potassium phosphate, monobasic (KH_2PO_4)	0.34 g
sodium phosphate, dibasic ($Na_2HPO_4 \cdot 7H_2O$)	0.355 g
glucose	18.0 g
distilled water to	1,000.0 ml

1. Dissolve all ingredients except $CaCl_2$ in about 900 ml of distilled water in a bottle or flask by using a magnetic stirrer.
2. Add $CaCl_2$ while stirring.
3. Bring the volume to 1,000 ml with distilled water.
4. Dispense 5 ml per tube into screw-cap tubes (16 by 125 mm).

APPENDIX 9.9.2–1 (*continued*)

5. Autoclave at 121°C for 15 min.
6. When tubes have cooled, label the tubes as *Acanthamoeba* medium with the preparation date and an expiration date of 3 months.
7. Store at 4°C.

F. Vaspar

This is a 1:1 mixture of petroleum jelly and paraffin.

1. Melt paraffin in a large (400-ml) beaker, and record the volume, e.g., 100 ml.
2. Gradually add petroleum jelly while stirring with a glass rod until the volume reaches 200 ml.
3. Remove mixture from heat, dispense about 10 to 15 ml into each of several 20-ml flasks or beakers, and cover with a piece of silver foil.
4. Store at room temperature.

9.9.3

Parasite Culture: *Trichomonas vaginalis*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Cultivation is the most sensitive method for the diagnosis of trichomoniasis; however, it may take 3 to 4 days to determine culture results (1–6). Axenic cultivation of the organism is invaluable for diagnosis and for studying the biochemistry, physiology, metabolism, immunology, and ultrastructure of the organism as well as

for screening drugs in vitro so that advances in chemotherapy can be achieved. Axenic cultivation of the parasite also helps us understand the pathologic processes in experimental animals and determine if it is possible to infect suitable experimental animals with organisms grown

in culture and thus simulate the naturally occurring disease process. Along with culture, it is imperative that wet smears and/or stained smears be examined microscopically. If smears are positive, appropriate therapy can be instituted before culture results are available.

II. SPECIMENS

Observe standard precautions.

- A. Specimens from women may consist of vaginal exudate collected from the posterior fornix on cotton-tipped applicator sticks or genital secretions collected on polyester sponges.
- B. Specimens from men can include semen, prostatic fluid, urethral samples collected with polyester sponges, or urine.
- C. Urine samples collected from the patient should be the first-voided specimen in the morning.
- D. It is critical that clinical specimens be inoculated into culture medium as soon as possible after collection. Although collection swabs can be used, there are often problems with specimens drying prior to culture. Many laboratories are currently using the plastic envelope methods simultaneous transport and culture (see procedure 9.9.4).

III. MATERIALS

- A. **Reagents** (see Appendix 9.9.3–1)
 - B. **Supplies**
 1. Disposable sterile Pasteur and serological pipettes
 2. Microscope slides (1 by 3 in. or larger)
 3. Coverslips (no. 1, 22 by 22 mm or larger)
 4. Volumetric flasks (100 ml)
 5. Graduated cylinders (1,000 ml)
 6. Flasks or beakers
 7. Sterile and nonsterile screw-cap tubes (16 by 125 mm)
 8. Büchner or other funnel
 9. Filter paper, Whatman no. 1
 - C. **Equipment**
 10. Culture tube racks
 11. Nutrient agar plates, BHI plates, and thioglycolate broth
 12. Sterile cryovials or screw-cap vials (to hold 1 ml)
 13. Box for vial storage in freezer
 14. ATCC 30001 (*Trichomonas vaginalis*)
1. Binocular microscope with 10×, 40×, and 100× objectives; phase-contrast and or differential interference contrast optics preferred

III. MATERIALS (*continued*)

2. Binocular inverted microscope with 10×, 40×, and 100× objectives; phase-contrast and differential interference contrast optics preferred (this microscope is recommended but not mandatory)
3. Oculars should be 10×. Some may prefer 5×; however, overall smaller magnification may make final organism identifications more difficult.
4. Tabletop centrifuge, preferably refrigerated (for tubes containing patient specimens, e.g., urine, and for culture tubes)
5. Water bath or heating block (range up to 80°C)
6. Freezer, −20°C
7. Magnetic stirrer and stir bar
8. pH meter

ANALYTICAL CONSIDERATIONS**IV. QUALITY CONTROL**

- A. Check all reagents and media (at least once a week). All media, including Ringer's solution, should be free of any signs of precipitation and bacterial and/or fungal contamination.
- B. The microscope(s) should be calibrated, and the original optics used for the calibration should be in place on the microscope(s). Post the calibration factors for all objectives on the microscope for easy access (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.
- C. Maintain stock cultures of *T. vaginalis* (ATCC 30001).
 1. Transfer stock cultures weekly.
 - a. Always culture stock organisms at the same time a patient specimen is inoculated into culture medium.
 - b. If the stock organisms multiply and remain viable during the 96 h, report patient results.
 2. Stain
 - a. Run a slide prepared from a stock strain of *T. vaginalis* in parallel with the patient slide.
 - b. Staining results are acceptable when the control organisms stain well.
- D. Record all QC results.

V. PROCEDURE

- A. *Wear gloves when performing this procedure.*
- B. Inoculation of culture medium
 1. Remove tubes containing culture medium from 4°C, and incubate at 37°C for 1 to 2 h.
 2. Vigorously shake the cotton-tipped portion of the applicator stick containing the patient specimen in the medium, and then break off the tip with sterile forceps and drop it into the medium.
 3. If the material is collected on polyester sponges, then drop the sponges into the medium and shake the tube.
 4. Centrifuge urine samples for 10 min at 250 × *g*, aspirate the supernatant, and inoculate the sediment into the medium.
 5. Examine the tubes daily for several days, and subculture if necessary. To subculture, first shake the tube to disperse the organisms uniformly, remove about 1 to 2 ml, and inoculate into a warmed, fresh tube.
 6. Incubate the tubes in a slanted position (45° angle) at 37°C.

V. PROCEDURE (*continued*)

7. Incubate control tubes and those containing patient material for at least 72 to 96 h.
 8. Examine the entire length of the tube. If the specimen is positive, *T. vaginalis* will be found freely swimming or attached to the tube walls.
 9. Do not report negative results until 96 h.
- C. To maintain stock cultures
1. With an inverted microscope, examine stock culture tubes of *T. vaginalis* for any signs of bacterial contamination. Select one or more tubes showing good growth. Since the tubes are incubated in a slanted position, usually at an angle of 45°, a thick button of organisms will be seen at the bottom of the tube. Gently invert the tube once or twice to disperse the trichomonads uniformly, and examine the tubes again. A large number of the organisms should be freely swimming, and a few of the organisms will be attached to the tube walls.
 2. Immerse the tubes in a bucket of ice-cold water for about 5 to 10 min. This will dislodge the trichomonads from the tube walls. Invert the tubes several times in order to distribute the organisms.
 3. With a sterile Pasteur pipette, remove about 1.0 to 1.5 ml; inoculate 0.5 to 1.0 ml into a fresh tube. Inoculate the rest of the fluid into nutrient agar, BHI, and thioglycolate broth for routine monitoring of bacterial contamination. Inoculate several additional tubes this way, and incubate the cultures slanted at a 45° angle at 37°C as before (step V.B.6).
 4. If growth is poor and only few organisms are present along with a lot of debris, then centrifuge the tube at 250 × *g* for 10 min, aspirate the supernatant, transfer the sediment to a fresh tube, and incubate as before (step V.B.6).

VI. RESULTS

T. vaginalis trophozoites may be recovered and identified.

POSTANALYTICAL CONSIDERATIONS**VII. REPORTING RESULTS**

- A. If organisms are found prior to or at the end of 96 h, report the specimen as positive.
Example: Positive for *Trichomonas vaginalis*
- B. If no trophozoites are seen after 4 days of incubation, then discard the tubes and report as negative.
Example: Negative for *Trichomonas vaginalis*

VIII. PROCEDURE NOTES

- A. Cultivation is the most sensitive method for the diagnosis of trichomoniasis. Every effort, therefore, must be made to inoculate patient materials into culture medium. However, since this method may take 3 to 4 days and the patient materials may occasionally contain nonviable organisms, it is imperative that microscopic examination of wet smears and/or stained smears (Giemsa) also be performed.
- B. Culture control organisms each time a patient specimen is inoculated into the culture medium.
- C. Use the same medium for controls and patient specimen.

IX. LIMITATIONS OF THE PROCEDURE

- A. Even though cultivation is the most sensitive method for the diagnosis of trichomoniasis, it may take 3 to 4 days to arrive at a diagnosis. Every effort, therefore, must be made to microscopically examine wet smears and or stained smears so that appropriate therapy can be instituted without delay in case of positive findings.
- B. Do not report results of patient specimens as positive unless control cultures are positive.

APPENDIX 9.9.3–1

Include QC information on reagent container and in QC records.

Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. Ringer's solution

sodium chloride (NaCl)	0.6 g
sodium bicarbonate (NaHCO ₃)	0.01 g
potassium chloride (KCl)	0.01 g
calcium chloride (CaCl ₂)	0.01 g
double-distilled water to	100.0 ml

Dissolve the ingredients in the order listed, and bring the volume to 100.0 ml with distilled water.

B. Liver infusion

double-distilled water	330.0 ml
Bacto liver infusion powder (Difco)	20.0 g

1. Place the distilled water in a large beaker.
2. Add the liver infusion powder.
3. Infuse for 1 h at 50°C.
4. Raise the temperature to 80°C for 5 min to coagulate the protein.
5. Filter through a Whatman no. 1 filter paper with a Büchner funnel.

C. Methylene blue solution

methylene blue	0.5 g
glass-distilled water	100.0 ml

Mix well until dissolved.

D. Cysteine-peptone-liver-maltose (CPLM) complete medium

Bacto Peptone (Difco)	32.0 g
Bacto Agar (Difco)	1.6 g
cysteine HCl	2.4 g
maltose	1.6 g
Bacto liver infusion (Difco)	320.0 ml
Ringer's solution	960.0 ml

APPENDIX 9.9.3–1 (*continued*)

1. Mix Ringer's solution and liver infusion in a large beaker by using a magnetic stirrer.
2. Add peptone, maltose, cysteine HCl, and agar in that order, and heat the mixture until dissolved.
3. Add 0.7 ml of aqueous methylene blue.
4. Adjust pH to 5.8 to 6.0 with 1 N NaOH or 1 N HCl.
5. Dispense 8-ml volumes into culture tubes.
6. Autoclave at 121°C for 15 min.
7. Aseptically add 2 ml of human serum (heat inactivated at 56°C for 30 min and cooled) per tube. Horse serum is recommended as a replacement for human serum, particularly when considering safety issues such as handling human blood and blood products.
8. Label as CPLM medium with the preparation date.
9. Store at room temperature. Use as long as the amber zone, indicating an anaerobic condition, persists.

E. Diamond's Trypticase-yeast extract-maltose (TYM) complete medium

Trypticase (BBL)	20.0 g
yeast extract (BBL)	10.0 g
maltose	5.0 g
L-cysteine HCl	1.0 g
L-ascorbic acid	0.2 g
potassium phosphate, dibasic (K ₂ HPO ₄) ...	0.8 g
potassium phosphate, monobasic (KH ₂ PO ₄)	0.8 g
Bacto Agar (Difco)	0.5 g
double-distilled water	900.0 ml

1. Dissolve the buffer salts in the distilled water by using a magnetic stirrer.
2. Add the remaining ingredients except the agar in the order given, one at a time, until dissolved.
3. Adjust pH to 6.0 with 1 N HCl.
4. Add agar, and heat to dissolve.
5. Autoclave at 121°C for 15 min.
6. Cool to 45°C and add 100 ml of sterile bovine, sheep, or horse serum that has been heat inactivated for 30 min at 56°C.
7. Aseptically dispense 10-ml volumes into screw-cap tubes (16 by 125 mm).
8. Label as TYM medium with the preparation date and an expiration date of 10 days.
9. Store at 4°C.

F. Diamond's complete medium (modified by Klass)

Trypticase (BBL)	24.0 g
yeast extract (BBL)	12.0 g
maltose	6.0 g
cysteine HCl	1.2 g
ascorbic acid	0.24 g
double-distilled water	900.0 ml

1. Dissolve the ingredients one at a time in the order given.
2. Adjust pH to 6.0 with 1 N HCl or 1 N NaOH.
3. Dispense in 12.5-ml aliquots into screw-cap tubes (16 by 125 mm).
4. Autoclave at 121°C for 15 min.
5. When cool (50°C), add 1 ml of sterile inactivated horse serum and 0.5 ml of antibiotic mixture to each tube.
6. Label as modified TYM medium with the date of preparation and an expiration date of 3 weeks.

APPENDIX 9.9.3–1 (continued)

G. Antibiotics mixture

sodium penicillin G	1,000,000 U
streptomycin sulfate	1,000,000 µg
amphotericin B (Fungizone)	2,000 µg
sterile double-distilled water	50.0 ml

1. Mix thoroughly. Concentration of stock solution is

penicillin	20,000 U/ml
streptomycin	20,000 µg/ml
amphotericin B	40 µg/ml

2. Dispense 1 ml of the antibiotic mixture into sterile screw-cap vials or sterile cryovials.
3. Label as antibiotic solution with the date of preparation and an expiration date of 1 year.
4. Store at -20°C in cryoboxes.

H. Serum substitutions

Bovine, sheep, or horse serum can be substituted in step D.7.

9.9.4

Parasite Culture: InPouch TV System for *Trichomonas vaginalis*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Trichomoniasis is a sexually transmitted infection caused by the flagellated protozoan *Trichomonas vaginalis*. It is recognized as one of the most prevalent forms of sexually transmitted disease (STD) worldwide, with over 180 million cases occurring annually. The CDC estimates that 3 million cases occur in the United States on a yearly basis. *T. vaginalis* can produce premature rupture of membranes in pregnancy and can also cause nongonococcal urethritis in males.

Cultivation is the most sensitive method for the diagnosis of trichomoniasis; however, it may take 3 to 4 days to determine culture results. The InPouch TV system has demonstrated a greater sensitivity than either the saline wet mount or Hollander's, Trichosel, or modified Diamond's media (1–5). The InPouch TV serves first as a specimen transport container and growth chamber during incubation, then as a viewing chamber during microscopy (using a plastic clip that fits

onto the microscope stage). It consists of a clear, gas-impermeable, plastic pouch that is double chambered. The medium contains Trypticase, Proteose Peptone, yeast extract, maltose and other sugars, amino acids, salts, and antifungal and antimicrobial agents in normal saline phosphate buffer. An inoculum containing 1 to 10 organisms is sufficient to cause a positive test if the specimen is inoculated immediately after collection.

II. SPECIMENS

Observe standard precautions.

- A. Specimens from women may consist of vaginal exudate collected from the posterior fornix using sterile cotton or Dacron swabs.
- B. Specimens from men can include semen, prostatic fluid, and urethral samples collected with a cotton swab on a wire handle.
- C. Although urine specimens are not recommended as the most likely to yield positive culture results, urine specimens collected from the patient should be the first-voided specimen in the morning.
- D. Patient specimens that are contaminated with birth control foams or jellies will result in decreased recovery of trichomonads.

III. MATERIALS

A. Reagents

1. InPouch kits [BioMed Diagnostics, Inc.; (800) 964-6466] stored vertically at 15 to 25°C up to 1 year from date of manufacture.
2. *Warning:* This product contains a chemical known to cause cancer, birth defects, or other reproductive harm.

B. Supplies

1. Viewing slide holder (provided in the kit)
2. Disposable protective gloves

C. Equipment

Microscope, binocular with mechanical stage; low-power (10×), high dry power (40×), and oil immersion (100×) objectives; 10× oculars; calibrated ocular micrometer; light source equivalent to a 20-W halogen or 100-W tungsten bulb; blue and white ground-glass diffuser filters

ANALYTICAL CONSIDERATIONS**IV. QUALITY CONTROL**

- A. Inoculate a pouch from each new lot with one drop from a culture of actively growing *T. vaginalis* and incubate at 37°C. Observe for actively motile organisms at 3 days.
- B. An InPouch containing cloudy medium should not be used.
- C. The organism is maintained in subculture medium, purchased separately, where it will remain viable for 7 days.
- D. If product does not meet standards, inform the parasitologist or supervisor, record all QC results.
- E. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. Post the calibration factors for all objectives on the microscope for easy access (multiplication factors can be pasted right on the body of the microscope) (*see* procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.

V. PROCEDURE

- A. Inoculation of InPouch TV: *wear gloves when performing this procedure.*
 1. Remove InPouch TV from box.
 2. Fold pouch back over itself to reduce the folded crease. Make sure that the liquid in the upper chamber is below the closure tape to prevent fluid from leaking upon opening.
 3. Tear open the pouch at the notch just above the white closure. Open the pouch sufficiently to admit the swab, by pulling apart the (white) tape's middle tabs of the closure tape.
 4. Insert swab containing the specimen into the liquid of the pouch's upper chamber (Fig. 9.9.4–1 and 9.9.4–2).
 5. Squeeze the swab to express specimen by gently pressing it between the walls of the upper chamber. Discard swab in a biohazard waste container.

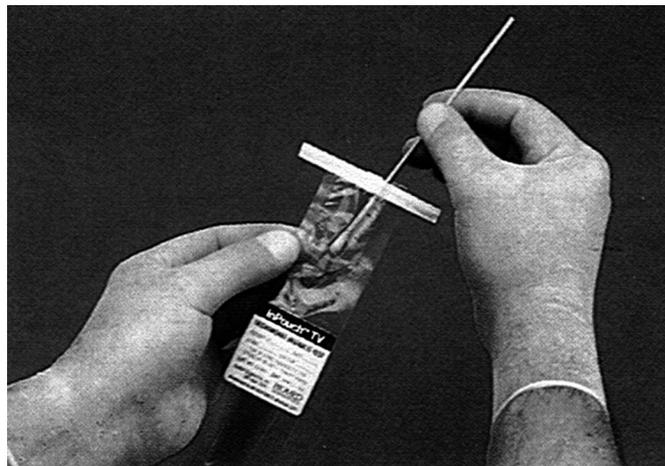

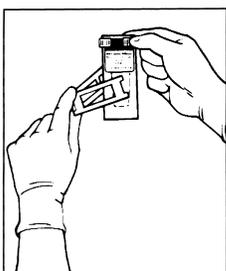

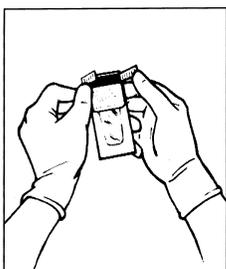

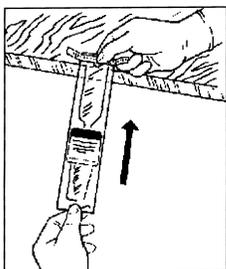

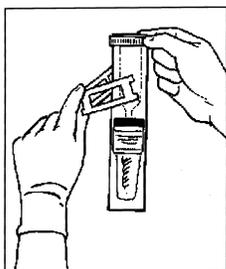

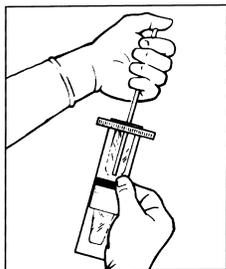

Figure 9.9.4–1 InPouch TV diagnostic system for culturing *Trichomonas vaginalis* (BioMed Diagnostics). The swab containing a specimen from the patient is inserted into the liquid medium within the plastic pouch.

V. PROCEDURE (continued)

6. Squeeze pouch closed, fold the top edge down, and roll three times. Fold the wire tape's end-tabs behind the pouch to lock the roll.
7. Label with patient's name. *Do not obstruct clear plastic with label.*
8. Hold specimen pouch upright at room temperature until prompt delivery to laboratory.

B. Specimen not received in InPouch TV

1. Notify submitter that laboratory procedure requires submission in InPouch TV.
2. If a specimen is received in saline within 30 min of collection, do a wet mount.
3. If a swab is received within 30 min of collection, inoculate an InPouch TV.

C. Microscopic evaluation immediately upon receipt

1. Concentrate the cellular material by standing the pouch vertically for at least 15 min prior to microscopic evaluation. The trichomonads will concentrate at the bottom of the chamber.
2. Place the upper chamber of the pouch on the raised platform of the open plastic microscope clip, positioning the pouch so that the lower portion of the upper chamber is a few millimeters above the lower border of the clip. Close and lock the clip over the pouch.
3. View the pouch from the upper (open window) side of the microscope clip. Observe with a microscope under low power (10×); use high dry power (40×) if necessary for confirmation. Focus on the liquid and not on the textured plastic of the pouch. Clue cells and yeast can also be observed.
4. When no trichomonads can be found in the direct preparation in the upper pouch chamber, the inoculum has fewer than 100 organisms or may be negative. Remove microscope clip after observation.

D. Culture and microscopic evaluation

1. Express the contents of the upper pouch chamber into the lower chamber.
2. Roll down the pouch until the tape is at the top of the label. Fold the wire tape's end tabs to lock the roll. This action helps maintain partial anaerobiosis.
3. Incubate the pouch vertically at 37°C for 18 to 24 h.
4. Prior to reading, distribute the trichomonads by gently rubbing your thumb across the viewing area or pull the pouch upward (five times) across the edge of a table for mixing.
5. Place the bottom of the lower chamber on the raised platform of the open microscope slip, and then close and lock the clip over the pouch.
6. Observe microscopically under low power (10×). The best location in the pouch to find trichomonads is slightly above the bottom edge of the pouch. Focus on the liquid and not on the textured plastic of the pouch.
7. Repeat evaluations daily for the presence of motile trichomonads for up to 5 days. Do not mistake Brownian motion of small debris particles for evidence of *Trichomonas* activity.

Figure 9.9.4–2 Illustration of the InPouch TV culture system for *Trichomonas vaginalis* (BioMed Diagnostics). From top to bottom: (1) introduction of the specimen into the upper chamber containing a small amount of medium; (2) application of a plastic holder for microscope viewing prior to expressing medium into the lower chamber (optional); (3) transfer of a small amount of medium in the upper chamber to the lower chamber; (4) rolling down the upper chamber and sealing it with tape; (5) plastic viewing frame used to immobilize the medium in the pouch for examination under the microscope. (Diagram courtesy of BioMed Diagnostics; reprinted from **L. S. Garcia**, *Diagnostic Medical Parasitology*, 4th ed., 2001, ASM Press, Washington, D.C.)

VI. RESULTS

T. vaginalis trophozoites may be recovered and identified.

POSTANALYTICAL CONSIDERATIONS

VII. REPORTING RESULTS

A. If organisms are found prior to or at the end of 96 h, report the specimen as positive.

Example: Positive for *Trichomonas vaginalis*

B. If no trophozoites are seen after 5 days of incubation, then discard the pouch and report as negative.

Example: Negative for *Trichomonas vaginalis*

VIII. PROCEDURE NOTES

A. Specificity: for cultivation of *T. vaginalis* only. Other *Trichomonas* species will not survive and replicate at the pH and medium composition found in the InPouch TV test kit.

B. Culture: *T. vaginalis* present in low numbers will replicate within 5 h after inoculation into the InPouch system. An inoculum containing 1 to 10 organisms is sufficient to cause a positive test (1, 3).

C. Patient materials may occasionally contain nonviable organisms; it is recommended that if suspicious nonmotile objects are seen, stained smears can be prepared (Giemsa stain).

D. Use the same lot number of medium for controls and patient specimens.

IX. LIMITATIONS OF THE PROCEDURE

A. Even though cultivation is the most sensitive method for the diagnosis of trichomoniasis, it may take up to 5 days to arrive at a diagnosis. Every effort, therefore, must be made to carefully review contents of the pouch on a daily basis.

B. Do not report results of patient specimens as positive unless control cultures are positive.

C. InPouch TV medium suppresses but does not entirely eliminate the growth of yeast.

9.9.5

Parasite Culture: *Leishmania* spp. and *Trypanosoma cruzi*

PREANALYTICAL CONSIDERATIONS

I. PRINCIPLE

Leishmania spp. produce in humans a wide variety of diseases ranging from a mild, self-curing cutaneous form (Oriental sore) to the relatively severe mucocutaneous disease (espundia) to severe, fatal visceral leishmaniasis (kala-azar). *Leishmania* spp. have two stages in their life cycle: the extracellular promastigote, which occurs in the gut of the sand fly vector, and an intracellular amastigote stage, which multiplies in the macrophage of the vertebrate host. The culture form is usually the promastigote stage; however, differentiation of promastigotes into the amastigote form in cell cultures can also be achieved (1–4). In vitro cultivation of

Leishmania greatly facilitates diagnosis in clinical infections and studies of the taxonomy, biochemistry, physiology, metabolism, immunology, and ultrastructure of the organism. Cultivation is also valuable for in vitro screening of drugs that might lead to advances in chemotherapy. Axenic cultivation of the parasite also helps in understanding the pathologic process in experimental animals, which can be infected with organisms grown in culture, thereby inducing disease processes that simulate the naturally occurring disease.

Trypanosoma cruzi, which causes Chagas' disease, is a major public health prob-

lem in Latin America. In addition to the promastigote and amastigote forms, *T. cruzi* also has epimastigote and trypomastigote stages. The culture form is usually the epimastigote stage; however, differentiation of the epimastigotes into metacyclic trypomastigotes in cell-free media and amastigotes in cell cultures can also be achieved. Cultivation of the organisms from patient specimens is an important diagnostic tool. In vitro cultivation of *T. cruzi* also greatly facilitates study of the organism, provides a mechanism for drug screening, and provides a source of organisms for animal studies.

II. SPECIMENS

Observe standard precautions.

Specimens for culturing *Leishmania* spp. may consist of aspirates, scrapings, or biopsy material from skin lesions of patients with cutaneous leishmaniasis; bone marrow aspirates or, more rarely, splenic aspirates from visceral-leishmaniasis patients; or normal skin biopsy specimens, lymph node aspirates, or pieces of liver and spleen from suspected or potential wild- or domestic-animal reservoirs. Specimens for culturing *T. cruzi* may consist of the patient's blood or the gut contents of the triatomid bug.

III. MATERIALS

A. Reagents (see Appendix 9.9.5–1)

B. Supplies

1. Disposable sterile Pasteur and serological pipettes
2. Microscope slides (1 by 3 in. or larger)
3. Coverslips (no. 1, 22 by 22 mm or larger)
4. Volumetric flasks (1,000 ml)
5. Erlenmeyer flasks (500 ml)
6. Graduated cylinders (100 and 500 ml)
7. Sterile and nonsterile screw-cap tubes (16 by 125 mm)
8. Culture tube racks
9. Sterile cryovials or screw-cap vials (to hold 1 ml)
10. Box for vial storage in freezer
11. Büchner funnel
12. Filter paper, Whatman no. 42
13. 0.23- μ m-pore-size membrane filters

III. MATERIALS (*continued*)

14. ATCC 30883 (*Leishmania mexicana*)

15. ATCC 30160 (*T. cruzi*)

C. Equipment

1. Binocular microscope with 10×, 40×, and 100× objectives; phase-contrast and/or differential interference contrast optics preferred

2. Binocular inverted microscope with 10×, 40×, and 100× objectives; phase-contrast and differential interference contrast optics are preferred (this microscope is recommended but not mandatory)

3. Oculars should be 10×. Some may prefer 5×; however, overall smaller magnification may make final organism identifications more difficult.

4. Tabletop centrifuge, preferably refrigerated (for tubes containing patient and animal specimens, e.g., blood and aspirates, or for culture tubes)

5. Water bath (range up to 80°C)

6. Freezer, -20°C

7. Magnetic stirrer and stir bar

8. pH meter

ANALYTICAL CONSIDERATIONS**IV. QUALITY CONTROL**

A. Check all reagents and media at least once a week. The media should be free of any signs of precipitation and bacterial and/or fungal contamination.

B. The microscope(s) should be calibrated, and the original optics used for the calibration should be in place on the microscope(s). Post the calibration factors for all objectives on the microscope for easy access (see procedures 9.1 and 9.3.2). Although there is not universal agreement, the microscope should probably be recalibrated once each year. This recommendation should be considered with heavy use or if the microscope has been bumped or moved multiple times. If the microscope does not receive heavy use, then recalibration is not required on a yearly basis.

C. Maintain stock cultures of *Leishmania* spp.

1. Transfer stock cultures weekly.

a. Always culture stock organisms at the same time a patient specimen is inoculated into culture medium.

b. If the stock organisms multiply and remain viable during the 96 h, then report patient results.

2. Stain

a. Stain a slide prepared from stock culture in parallel with the patient slide.

b. Staining results are acceptable when the control organisms stain well.

D. Record all QC results.

V. PROCEDURE

A. *Wear gloves when performing this procedure.*

B. Inoculation of culture medium

1. Remove tubes containing culture medium (one of NNN medium, modified NNN medium, or Tobie's medium and one of Schneider's medium for leishmaniasis and one of NNN medium or Tobie's medium and one of LIT medium for *T. cruzi*) from 4°C, add fetal bovine serum and antibiotics if required, and incubate at 20 to 23°C for 1 to 2 h.

2. Inoculate the specimen (aspirate, scraping, or biopsy material from skin lesions from cutaneous-leishmaniasis patients; bone marrow aspirates or splenic aspirates from visceral-leishmaniasis patients; or normal skin biopsy specimens, lymph node aspirates, or pieces of liver and spleen from suspected or potential wild- or domestic-animal reservoirs) into the culture tubes. For Chagas' disease, inoculate a few drops of buffy coat into the culture tubes.

3. Add 0.5 ml of overlay (either saline or other overlay, depending on medium).

4. Incubate the tubes at 20 to 24°C.

V. PROCEDURE (*continued*)

5. Once every 2 to 3 days, remove a drop of medium and examine it under the low power ($100\times$) of a microscope, preferably one equipped with phase-contrast optics.
6. If promastigotes are seen, then inoculate a couple of drops of the medium into fresh culture tubes. Add a couple of drops of 0.85% NaCl or the overlay solution (depending on the culture medium used) to the old tube.
7. If visible contamination occurs, add antibiotics to the overlay (to contain 200 U of penicillin and 200 μg of streptomycin per ml).
8. Incubate the tubes containing the patient's specimen for at least 2 weeks.
9. If no organisms are seen even after 2 weeks of incubation, then examine several drops of fluid under the microscope for promastigotes.

VI. RESULTS

- A. *Leishmania* spp. may be recovered and identified.
- B. *T. cruzi* may be recovered and identified.

POSTANALYTICAL CONSIDERATIONS**VII. REPORTING RESULTS**

- A. If organisms are found prior to or at the end of 2 weeks, report as positive.
Examples: Positive for *Leishmania* spp., positive for *Trypanosoma cruzi*
- B. If no organisms are seen even after 2 weeks of incubation, then discard the tubes and report as negative.
Examples: Negative for *Leishmania* spp., negative for *Trypanosoma cruzi*
- C. Identification of the species is generally made on the basis of the clinical symptoms, geographic origin, culture characteristics, isoenzyme profile, and DNA buoyant density.

VIII. PROCEDURE NOTES

- A. Ensure that the skin surrounding the ulcer is thoroughly cleaned and swabbed with 70% alcohol (sterile saline is not acceptable as a cleansing agent) and allowed to dry before the sample is removed. Also ensure that alcohol does not get into the ulcerated area or broken skin.
- B. Patient skin may be simply touched to the wall of the tube to release the amastigotes. If skin from an animal reservoir is used, the specimen must be macerated or triturated.
- C. A punch biopsy taken from the advancing margin of the lesion is often recommended.
- D. It is imperative that only a few drops of bone marrow juice or spleen aspirate be inoculated into tubes. Inoculate several tubes with a few drops each rather than a single tube with a large volume (1 to 2 ml), as the serum in the specimen may contain leishmanicidal or inhibitory factors that will prevent the growth of organisms.
- E. Alternatively, bone marrow juice may be centrifuged for 10 min at $250 \times g$, and the sediment may be washed in 0.85% NaCl by centrifugation and then inoculated into culture tubes.
- F. Buffy coat from the blood sample rather than whole blood should be inoculated.
- G. Because leishmaniae are fastidious organisms and all isolates may not grow in any one medium, it is imperative that at least two media be used; for example, use NNN or modified Tobie's medium and Schneider's *Drosophila* medium.
- H. It is advisable to use two different media such as LIT and NNN media for the initial isolation of *T. cruzi*. Once growth is established, use the medium in which best growth is obtained for subculture. According to James Sullivan, LIT medium used as an overlay on Tobie's slants is excellent for isolation and diagnosis. The major culture form is the epimastigote; occasionally, however, try-

VIII. PROCEDURE NOTES*(continued)*

pomastigotes and amastigotes may also be seen. Make sure that the defibrinated rabbit blood is fresh. In any case, it should not be more than 10 days old. It should be aseptically collected and stored at 4°C until used.

- I.** Although blood collected using EDTA anticoagulant can be used for routine stock culture subcultures, it may not be quite as effective as defibrinated blood in isolating organisms from patient specimens. However, if defibrinated blood is not available, blood collected using EDTA anticoagulant can be used.

IX. LIMITATIONS OF THE PROCEDURE

Cultivating the organism from suspected materials provides a definitive diagnosis, but it may take 3 to 7 days. Every effort, therefore, must be made to microscopically examine wet smears and/or stained smears so that appropriate therapy can be instituted without delay if findings are positive.

APPENDIX 9.9.5–1

Include QC information on reagent container and in QC records.

Reagents

☑ Indicate the expiration date on the label and in the work record or on the manufacturer's label.

A. NNN medium (leishmaniasis or Chagas' disease)

Bacto Agar (Difco) 1.4 g
sodium chloride (NaCl) 0.6 g
double-distilled water 90.0 ml

1. Mix the NaCl and agar in the distilled water in a 500-ml flask.
2. Heat the mixture until the agar melts.
3. Autoclave at 121°C for 15 min.
4. Cool to about 50°C.
5. Add 10 ml of aseptically collected defibrinated rabbit blood.
6. Dispense 4 ml into sterile screw-cap culture tubes (16 by 125 mm).
7. Place the tubes at a 10° angle (shallow slant position) until the agar sets.
8. Immediately transfer the tubes into test tube stands, and let stand in an upright position at 4°C so that the bottom portion of the slants will be covered with the water of condensation. Rapid cooling increases the water of condensation.
9. Label as NNN medium with the preparation date and an expiration date of 3 weeks from the date of preparation.
10. Store at 4°C.

B. NNN medium, Offutt's modification (leishmaniasis)

blood agar base (Difco) 8.0 g
double-distilled water 200.0 ml

1. Heat until the agar is dissolved in the distilled water in a 500-ml flask.
2. Autoclave at 121°C for 15 min.
3. Cool to about 50°C.
4. Add 15 ml of aseptically collected defibrinated rabbit blood.
5. Dispense 4 ml into sterile screw-cap culture tubes (16 by 125 mm).
6. Place the tubes at a 10° angle (shallow slant position) until the agar sets.

APPENDIX 9.9.5-1 (continued)

7. Immediately transfer the tubes into test tube stands, and let stand in an upright position at 4°C so that the bottom portion of the slants is covered with the water of condensation. Rapid cooling increases the water of condensation.
8. Label as Offutt's medium with the preparation date and an expiration date of 3 weeks from the date of preparation.
9. Store at 4°C.

C. Overlay solution (to be used with NNN or NNN modified medium)

sodium chloride (NaCl)4.5 g
double-distilled water500.0 ml

1. Autoclave at 121°C.
2. Dispense 4 ml aseptically into sterile culture tubes (16 by 125 mm).
3. Label as 0.9% NaCl with the preparation date and an expiration date 3 weeks from the date of preparation.
4. Store at 4°C.

D. Evan's modified Tobie's medium (leishmaniasis or Chagas' disease)

beef extract (Oxoid Lab-Lemco L29)0.3 g
bacteriological peptone (Oxoid L37)0.5 g
sodium chloride (NaCl)0.8 g
agar (Oxoid purified)2.0 g
double-distilled water100.0 ml

1. Mix all the ingredients in the distilled water in a large beaker by using a magnetic stirrer.
2. Heat the mixture until the agar melts.
3. Dispense 5 ml into screw-cap culture tubes (16 by 125 mm).
4. Autoclave at 121°C for 15 min.
5. Cool to about 50°C.
6. Add 1.2 ml of aseptically collected defibrinated horse blood.
7. Hold the tubes in an upright position in the palms of your hands, and roll the tubes gently to mix the blood and agar well.
8. Place the tubes at a 10° angle (shallow slant position) until the agar sets.
9. Immediately transfer the tubes into test tube stands, and let stand in an upright position at 4°C so that the bottom portion of the slants will be covered with the water of condensation. Rapid cooling increases the water of condensation.
10. Label as Evan's modified Tobie's medium with the preparation date and an expiration date 3 weeks from the date of preparation.
11. Store at 4°C.

E. Overlay solution (to be used with Tobie's medium)

potassium chloride (KCl)0.4 g
sodium phosphate, dibasic
(Na₂HPO₄ · 12H₂O) 0.06 g
potassium phosphate, monobasic
(KH₂PO₄) 0.06 g
calcium chloride (CaCl₂ · 2H₂O)0.185 g
magnesium sulfate (MgSO₄ · 7H₂O)0.1 g
magnesium chloride (MgCl₂ · 6H₂O)0.1 g
sodium chloride (NaCl)8.0 g
L-proline1.0 g
phenol red0.5 ml
double-distilled water1,000.0 ml

1. Place 750 ml of distilled water in a 1-liter beaker, and add the above ingredients one at a time in the order given until dissolved. Use a magnetic stirrer.
2. Adjust the pH to 7.2 by adding slowly, while stirring, solid Tris.
3. Bring the volume to 1,000 ml with distilled water.
4. Dispense 100 ml into a number of screw-cap flasks or bottles.
5. Autoclave at 121°C for 15 min.

APPENDIX 9.9.5–1 (continued)

6. Label as overlay solution with the preparation date and an expiration date of 1 month.
7. Store at 4°C.

F. Yaeger's liver infusion tryptose (LIT) medium (for Chagas' disease)

liver infusion (Difco)	35.0 g
tryptose (Difco)	5.0 g
sodium chloride (NaCl)	4.0 g
potassium chloride (KCl)	0.4 g
sodium phosphate, dibasic (Na ₂ HPO ₄ · 12H ₂ O)	8.0 g
glucose	2.0 g
hemin (stock solution)	4.0 ml
double-distilled water to	1,000.0 ml

1. Add all the ingredients to the distilled water, and mix well by using a magnetic stirrer until dissolved. Heat if necessary to dissolve all the ingredients.
2. Using a Whatman no. 42 filter paper in a Büchner funnel, filter with suction. Do this filtration once more, using new filter paper.
3. Adjust pH to 7.2 with 1 N NaOH or 1 N HCl.
4. Sterilize by filtration using a 0.22- μ m-pore-size membrane filter.
5. Dispense 4.5 ml into each tube.
6. Label as LIT medium with the date of preparation and an expiration date of 1 month.

G. Hemin stock solution

hemin	100.0 mg
triethanolamine	10.0 ml
sterile double-distilled water	10.0 ml

1. Mix triethanolamine with water, add the mixture to tube containing hemin, shake well, and let dissolve.
2. Complete medium
Just before inoculation, add 0.5 ml of inactivated fetal bovine serum and 0.25 ml of antibiotic solution. Final concentrations of the antibiotics are 100 U of penicillin, 100 μ g of streptomycin, and 0.2 μ g of amphotericin B per ml.

H. Schneider's *Drosophila* medium (leishmaniasis)

This medium was originally designed for cultivation of insect tissue culture cells. Hendricks used this medium containing 30% inactivated fetal bovine serum to isolate and grow etiologic agents of cutaneous leishmaniasis. This medium can be purchased from GIBCO, New York, N.Y.

I. Stock antibiotic solution (to be used with all media)

sodium penicillin G	1,000,000 U
streptomycin sulfate	1,000,000 μ g
amphotericin B	2,000 μ g
sterile double-distilled water	50.0 ml

1. Mix the above thoroughly. Concentrations of stock solution are

penicillin	20,000 U/ml
streptomycin	20,000 μ g/ml
amphotericin B	40 μ g/ml
2. Dispense 1 ml of the antibiotic mixture into sterile screw-cap vials or sterile cryovials.
3. Label as antibiotic solution with the date of preparation and an expiration date of 1 year.
4. Store at -20°C in cryoboxes.

9.10.1

Appendix 9.10.1–1—Identification Aids: Artifacts

I. PRINCIPLE

Laboratorians must differentiate extraneous materials present in a specimen from actual parasites.

II. STOOL ARTIFACTS**A. Sources**

Gross and microscopic examination of stool may be complicated by the presence of artifacts resembling parasitic trophozoites, cysts, eggs, larvae, and adult worms (Table 9.10.1–A1). Many such artifacts arise from the large array of vegetable and meat products ingested every day by humans. Cells of human enteric origin may also mimic pathogenic or commensal protozoa in their appearance. Spurious infections with human or nonhuman parasites are known to occur following ingestion of contaminated or infected meats. The use of improper collection techniques offers another mechanism by which specimens are contaminated with extraneous organisms (3, 4).

B. Protozoa**1. Amebae**

Improper collection and preservation of feces may result in contamination with free-living amebae from soil or water. Most species have large cytoplasmic contractile vacuoles, thick cyst walls, and nuclei with large karyosomes. Inflammatory cells are often present in a variety of infectious and noninfectious enteric syndromes and include PMNs, eosinophils, lymphocytes, and macrophages. Careful evaluation should be made to prevent these cells being mistaken as intestinal parasites, especially *Entamoeba histolytica* or the *E. histolytica/E. dispar* group. Report any occurrence of inflammatory cells, and make a quantitative assessment. Amebae also must be differentiated from intestinal epithelial cells (squamous or columnar), yeasts, plant cells, and another protozoan, *Blastocystis hominis*.

2. Flagellates

Free-living aquatic flagellates may be recovered from feces contaminated with water or saline and are difficult to differentiate from enteric flagellates. Stool samples contaminated with urine may also contain *Trichomonas vaginalis* and urine samples contaminated with stool may contain *Pentatrichomonas hominis*.

3. Ciliates

As with amebae and flagellates, free-living ciliates are also commonly found in standing water and may contaminate improperly collected stool specimens. Some species appear similar to *Balantidium coli* and may require differentiation by an expert.

Table 9.10.1–A1 Clinical specimens: summary of artifacts resembling parasites

Source and type of artifact	Resemblance
Stool	
Cells of host origin	
PMNs	<i>Entamoeba histolytica</i> / <i>E. dispar</i> cysts
Macrophages	<i>E. histolytica</i> / <i>E. dispar</i> trophozoites
Columnar epithelial cells	Amebic trophozoites
Squamous epithelial cells	Amebic trophozoites
Coprozoic (free-living protozoa)	
Amebae	Amebic trophozoites or cysts
Flagellates	Any of the intestinal flagellates
Ciliates	<i>Balantidium coli</i> trophozoites
Yeasts	Protozoan cysts (particularly <i>Endolimax nana</i>)
Fungal conidia	Helminth eggs
Plant cells	Protozoan cysts, helminth eggs
Plant hairs	Nematode larvae
Pollen grains	Helminth eggs (particularly <i>Ascaris</i> or <i>Taenia</i> eggs)
Diatoms	Helminth eggs
Starch granules, fat globules, air bubbles, mucus	Protozoan cysts
Ingested mite eggs	Helminth eggs
Ingested plant nematode eggs, larvae	Helminth eggs, nematode larvae
Blood	
Platelets	Malaria, <i>Babesia</i> spp.
Stain precipitate	Malaria, <i>Babesia</i> spp.
Stain contaminants	
Yeasts	Fungemia, parasitemia
Bacteria	Bacteremia
Plant fibers	Microfilariae
Body fluid	
Detached ciliary tufts	Ciliate or flagellate protozoa

II. STOOL ARTIFACTS

(continued)

4. Coccidia

The identification of *Cryptosporidium* spp. poses significant challenges because of the smallness of the organism and the lack of specificity of the commonly used acid-fast stains (*certain other organisms, including some yeasts, may stain positive*). Use of an immunofluorescence method increases specificity significantly and may be used as either a primary or confirmatory method. Certain pollen grains are known to mimic *Isospora belli* or *Sarcocystis* sp. oocysts and should be differentiated on the basis of size.

5. Microsporidia

The identification of microsporidia also presents challenges because of the small size of the spores and the lack of specificity of the commonly used modified trichrome stains (other organisms, including bacteria and small yeasts, often stain pink/reddish pink, as do the microsporidial spores). Optical brightening agents (calcofluor white) are helpful but also nonspecific; microsporidial spores, as well as small yeasts, will fluoresce. Unfortunately, no specific immunoassay reagents are commercially available for the identification of the microsporidia.

II. STOOL ARTIFACTS

(continued)

C. Helminths

1. Adult worms

Many types of partially digested vegetable or fruit fibers are similar in appearance to adult nematodes or tapeworm proglottids. This is especially common with individuals whose enteric transit time has been decreased following administration of a cathartic. Adult free-living nematodes may be recovered from stool specimens contaminated with soil or water. Specimens in question should be preserved in formalin and forwarded for identification.

2. Helminth eggs

A large variety of plant cells, algae, pollen grains, and fungal conidia are routinely seen in feces and may resemble *Ascaris lumbricoides*, *Taenia* spp., *Clonorchis sinensis*, and other helminth eggs. Vegetables contaminated with mites or infected with plant nematodes are a ready source of eggs similar in size and shape to pathogenic forms. With the ingestion of meat products from mammals, fish, birds, or other hosts, coincidental ingestion of a wide variety of helminths and their eggs may occur and result in spurious infections. Organisms with which such infections have been reported have included *Fasciola hepatica*, *Dicrocoelium dendriticum*, and *Capillaria hepatica*, among others (1). True infections may be ruled out with subsequent stool examinations.

3. Helminth larvae

Many kinds of plant or root hairs show a superficial resemblance in size and shape to nematode larvae. However, most appear as clear, refractile structures that lack both symmetry and identifiable internal organs. Unlike plant hairs, true larvae retain iodine when stained.

III. BLOOD ARTIFACTS

Artifacts present in thick and thin blood films may be mistaken for parasites and result in inappropriate or unnecessary treatment of the patient. These artifacts are usually of two types: (i) normal cellular elements, such as platelets, which may mimic malarial parasites when superimposed on erythrocytes, and (ii) contaminants from the staining process, such as yeast cells, bacteria, stain precipitate, or cellulose fibers, which may mimic true fungemia, bacteremia, or parasitemia with malaria or microfilariae.

IV. BODY FLUID ARTIFACTS

The appearance of detached ciliary tufts (ciliocytophthoria) in a variety of body fluids (especially peritoneal and amniotic fluids) has been recognized for many years. Such tufts are the luminal remnants of ciliated epithelium that occur as part of the normal cellular turnover in a variety of organs (respiratory tract and sinuses, ventricles of the brain, central canal of the spinal cord, and epithelia of the male and female reproductive tracts). In wet preparations, these ciliated tufts are 10 to 15 μm in diameter, exhibit rhythmic motion, and may easily be confused with ciliated or flagellated protozoa, including *Trichomonas*, *B. coli*, *Giardia lamblia*, and *Chilomastix mesnili*. However, on close examination of direct wet or permanent stained preparations, there is little internal structure reminiscent of such organisms (2).

V. CORRECTIVE ACTION

Misidentification of artifacts as parasites may be minimized by providing appropriate training of the parasitologist, performing preservation and staining procedures according to established protocols, stressing the importance of correct collection procedures to patients or staff, and strictly adhering to established morphologic criteria when performing the microscopic examinations.

Appendix 9.10.2–1—Information Tables

Table 9.10.2–A1 Body sites and specimen collection

Site	Specimen option	Collection method ^a
Blood	Smears of whole blood	Fresh thick and thin films (1st choice)
	Anticoagulated blood	Anticoagulant (2nd choice) EDTA (1st choice) Heparin (2nd choice)
Bone marrow	Aspirate	Sterile
Central nervous system	Spinal fluid	Sterile
Cutaneous ulcers	Aspirates from below surface	Sterile plus air-dried smears
	Biopsy specimen	Sterile, nonsterile to histopathology (formalin acceptable)
Eye	Biopsy specimen	Sterile (in saline)
	Scrapings	Sterile (in saline)
	Contact lens	Sterile (in saline)
	Lens solution	Sterile
Intestinal tract	Fresh stool	0.5-pt (ca. 0.237-liter) waxed container
	Preserved stool	5 or 10% formalin, MIF, SAF, Schaudinn's, PVA
	Sigmoidoscopy material	Fresh, PVA or Schaudinn's smears
	Duodenal contents	Entero-Test or aspirates
	Anal impression smear	Cellulose tape (pinworm examination)
	Adult worm or worm segments	Saline, 70% alcohol
Liver, spleen	Aspirates	Sterile, collected in four separate aliquots (liver)
	Biopsy specimen	Sterile, nonsterile to histopathology (formalin acceptable)

(continued)

Table 9.10.2–A1 Body sites and specimen collection (*continued*)

Site	Specimen option	Collection method ^a
Lung	Sputum	True sputum (not saliva)
	Induced sputum	No preservative (10% formalin if time delay)
	Bronchoalveolar lavage fluid	Sterile
	Transbronchial aspirate	Air-dried smears
	Tracheobronchial aspirate	Air-dried smears
	Brush biopsy specimen	Air-dried smears
	Open lung biopsy specimen	Air-dried smears
Muscle	Aspirate	Sterile
	Biopsy specimen	Fresh, squash preparation Nonsterile to histopathology (formalin acceptable)
Skin	Scrapings	Aseptic, smear or vial
	Skin snip	No preservative
	Biopsy specimen	Sterile (in saline) Nonsterile to histopathology
Urogenital system	Vaginal discharge	Saline swab, transport swab (no charcoal), culture medium Air-dried smear for FA
	Urethral discharge	Air-dried smear for FA
	Prostatic secretions	Air-dried smear for FA
	Urine	Unpreserved spot specimen or 24-h unpreserved specimen Midday urine

^a MIF, merthiolate-iodine-formalin; SAF, sodium acetate-acetic acid-formalin; PVA, polyvinyl alcohol; FA, fluorescent-antibody assay.

		Urogenital system	<i>Trichomonas vaginalis</i> <i>Schistosoma</i> spp. Microsporidia ^b

^a This table does not include every possible parasite that could be found in a particular body site. Only the most likely organisms are listed. Diagnostic stages include trophozoites, cysts, oocysts, spores, adults, larvae, eggs, amastigotes, trypomastigotes.

^b Disseminated in severely immunocompromised individuals.

Table 9.10.2–A3 Body site, specimen, and recommended stain(s)^a

Body site	Specimen(s)	Recommended stain for suspect organism	Comments
Blood	Whole or anticoagulated blood	Giemsa for all blood parasites Hematoxylin-based stain for microfilariae (sheathed)	Most drawings and organism descriptions of blood parasites were originally based on Giemsa-stained blood films. Although Wright's stain (or Wright-Giemsa combination stain) will work, stippling in malaria will normally not be visible and organism colors will not match descriptions. However, if other stains (those listed above) are used in addition to some of the "quick" blood stains, organisms should be visible on blood films.
Bone marrow	Aspirate	Giemsa for all blood parasites	See comments for blood
Central nervous system	Spinal fluid, brain biopsy specimen	Giemsa for trypanosomes, <i>Toxoplasma gondii</i> Giemsa, trichrome, or calcofluor for amebae (<i>Naegleria</i> , <i>Acanthamoeba</i> , and <i>Balamuthia</i> spp.) (cysts only) Giemsa, acid-fast PAS, modified trichrome, calcofluor, and silver methenamine for microsporidia Hematoxylin and eosin (routine histology) for larval cestodes	If CSF is received (with no suspect organism suggested), Giemsa is the best choice, but calcofluor is recommended as a second stain. If brain biopsy material is received (particularly from an immunocompromised patient), EM studies may be required to identify microsporidia to the genus or species level.
Cutaneous ulcer	Aspirate, biopsy specimen	Giemsa for leishmaniae Hematoxylin and eosin (routine histology) for <i>Acanthamoeba</i> spp., <i>Entamoeba histolytica</i>	Most likely causative agents would be leishmaniae, all of which would stain with Giemsa. Hematoxylin and eosin (routine histology) could also be used to identify these organisms.
Eye	Biopsy specimen, scrapings, contact lens, lens solution	Calcofluor for amebae (<i>Acanthamoeba</i> spp.) (cysts only) Giemsa for amebae (trophozoites, cysts) Hematoxylin and eosin (routine histology) for cysticerci, <i>Loa loa</i> , <i>Toxoplasma gondii</i> Silver methenamine, PAS, acid-fast stains, calcofluor, and EM studies for microsporidia	Some free-living amebae (most commonly <i>Acanthamoeba</i> spp.) have been implicated as a cause of keratitis. Although calcofluor will stain cyst walls, it will not stain trophozoites. Therefore, in suspected cases of amebic keratitis, use both stains. Hematoxylin and eosin (routine histology) can be used to detect and confirm cysticercosis. Adult <i>Loa loa</i> worm, when removed from the eye, can be stained with hematoxylin-based stain (Delafield's) or can be stained and examined via routine histology. <i>Toxoplasma</i> infection could be diagnosed by using routine histology and/or serology results. Confirmation of microsporidia to the genus and species levels may require EM studies.
Intestinal tract	Stool, sigmoidoscopy material, duodenal contents	Trichrome or iron hematoxylin for intestinal protozoa Modified trichrome and calcofluor for microsporidia Modified acid-fast stain for <i>Cryptosporidium parvum</i> and <i>Cyclospora cayentanensis</i> Immunoassay reagents (EIA, FA, cartridge format) for <i>Entamoeba histolytica</i> / <i>E. dispar</i> , <i>Entamoeba histolytica</i> , <i>Giardia lamblia</i> , <i>Cryptosporidium parvum</i> , and microsporidia (experimental)	Although trichrome or iron hematoxylin stains can be used on almost all specimens from the intestinal tract, actual worm segments (tapeworm proglottids) can be stained with special stains. However, after routine dehydration with alcohols and xylenes (or xylene substitutes), the branched uterine structure will be visible, allowing identification of proglottids to the species level. Immunoassay detection kits are also available for the identification of <i>Giardia lamblia</i> , <i>Entamoeba histolytica</i> / <i>E. dispar</i> , <i>Entamoeba histolytica</i> , and <i>Cryptosporidium parvum</i> . Confirmation of microsporidia to the genus or species level may require EM studies.

Table 9.10.2–A3 (continued)

Body site	Specimen(s)	Recommended stain for suspect organism	Comments
Intestinal tract (continued)	Anal impression smear	No stain, cellulose tape, or egg collection device	Four to six consecutive negative tapes are required to rule out infection
	Adult worm or worm segments	Carmine stains (rarely used)	Proglottids can usually be identified to the species level without using tissue stains
	Biopsy specimen	Hematoxylin and eosin (routine histology) for <i>Entamoeba histolytica</i> (also PAS), <i>Cryptosporidium parvum</i> , <i>Cyclospora cayetanensis</i> , <i>Isospora belli</i> , <i>Giardia lamblia</i> , and microsporidia	Special stains may be helpful in the identification of microsporidia: tissue Gram stains, silver stains, PAS, and Giemsa stain
Liver, spleen	Aspirates	Giemsa for leishmaniae	Aspirates and/or touch preparations from biopsy material can be routinely stained with Giemsa stain. This will allow identification of leishmaniae. Definite risks are associated with spleen aspirates and/or biopsy material. Other parasites, such as larval cestodes, trematodes, amebae, or microsporidia can be seen and identified by routine histological staining.
	Biopsy specimen	Hematoxylin and eosin (routine histology)	
Lung	Sputum, induced sputum, bronchoalveolar lavage fluid, transbronchial aspirate, tracheobronchial aspirate, brush biopsy specimen, open lung biopsy specimen	Silver methenamine stain, calcofluor for <i>Pneumocystis carinii</i> (cysts only) Giemsa for <i>Pneumocystis carinii</i> (trophozoites only) Modified acid-fast stains for <i>Cryptosporidium parvum</i> Hematoxylin and eosin (routine histology) for <i>Strongyloides stercoralis</i> , <i>Paragonimus</i> spp., amebae Silver methenamine stain, PAS, acid-fast, modified trichrome, tissue Gram stains, and EM studies for microsporidia	<i>Pneumocystis carinii</i> is the most common parasite recovered from the lung and identified by using silver or Giemsa stains or monoclonal reagents (FA). Monoclonal reagents (FA) for the diagnosis of pulmonary cryptosporidiosis are also available. Routine histology procedures would allow identification of any helminths or helminth eggs in the lung.
Muscle	Biopsy specimen	Hematoxylin and eosin (routine histology) for <i>Trichinella spiralis</i> , cysticerci Silver methenamine, PAS, acid-fast and tissue Gram stains and EM studies for microsporidia	If <i>Trypanosoma cruzi</i> is present in the striated muscle, it can be identified from routine histological preparations. Confirmation of microsporidia to the genus or species level may require EM studies.
Skin	Aspirates Skin snip, scrapings, biopsy specimen	See Cutaneous Ulcer above. Hematoxylin and eosin (routine histology) for <i>Onchocerca volvulus</i> , <i>Dipetalonema streptocerca</i>	Any of these parasites can be identified by using routine histological procedures and stains.
Urogenital system	Vaginal discharge Urethral discharge, prostatic secretions Urine Biopsy specimen	Giemsa Immunoassay reagents (FA) for <i>Trichomonas vaginalis</i> Delafield's hematoxylin for microfilariae Hematoxylin and eosin (routine histology) for <i>Schistosoma haematobium</i> , microfilariae Silver methenamine stain, PAS, acid-fast, modified trichrome, tissue Gram stains, and EM studies for microsporidia	Although <i>Trichomonas vaginalis</i> is probably the most common parasite identified, there are others to consider, the most recently implicated organisms being in the microsporidia. Microfilariae can also be recovered and stained.

^a PAS, periodic acid-Schiff; EM, electron microscopy; FA, fluorescent antibody.

Table 9.10.2–A4 Examination of tissues and body fluids

Suspect causative agent(s)	Disease(s)	Appropriate test(s)	Positive result
Protozoa			
<i>Naegleria fowleri</i>	Primary amebic meningoencephalitis	1. Wet examination of CSF (not in counting chamber) 2. Stained preparation of CSF sediment	Trophozoites present and identified
<i>Acanthamoeba</i> spp.	Amebic keratitis, chronic meningoencephalitis	1. Culture or stained smears 2. Calcofluor (cysts only) 3. Biopsy or routine histology	Trophozoites and/or cysts present and identified
<i>Balamuthia mandrillaris</i>	Chronic meningoencephalitis (granulomatous amebic encephalitis)	1. Calcofluor (cysts only) 2. Biopsy for routine histology	Trophozoites and/or cysts present and identified
<i>Entamoeba histolytica</i>	Amebiasis	Biopsy or routine histology	Trophozoites present and identified
<i>Giardia lamblia</i>	Giardiasis	1. Duodenal aspirate 2. Duodenal biopsy or routine histology 3. Entero-Test capsule 4. Immunoassays	Trophozoites and/or cysts present and identified
<i>Leishmania</i> spp. (cutaneous lesions)	Cutaneous leishmaniasis	1. Material from under bed of ulcer a. Smear b. Culture c. Animal inoculation 2. Punch biopsy a. Routine histology b. Squash preparation c. Culture d. Animal inoculation	Amastigotes recovered in macrophages of skin or from animal inoculation; other stages recovered in culture
<i>Leishmania</i> spp. (mucocutaneous lesions)	Mucocutaneous leishmaniasis	As for cutaneous leishmaniasis	Amastigotes recovered in macrophages of skin and mucous membranes or from animal inoculation; other stages recovered in culture
<i>Leishmania</i> spp. (visceral)	Visceral leishmaniasis (kala-azar)	1. Buffy coat a. Stain b. Culture c. Animal inoculation 2. Bone marrow a. Stain b. Culture c. Animal inoculation 3. Liver or spleen biopsy with routine histology a. Stain b. Culture c. Animal inoculation	Amastigotes recovered in cells of reticuloendothelial system
<i>Pneumocystis carinii</i> ^a	Pneumocystosis	1. Open lung biopsy for histology 2. Lung needle aspirate 3. Bronchial brush 4. Transtracheal aspirate 5. Bronchoalveolar lavage 6. Induced sputum (AIDS patients) 7. Calcofluor 8. Immunoassays	Trophozoites or cysts present and identified Trophozoite- and cyst-specific stains available Monoclonal antibody fluorescent detection of cysts and trophozoites Cysts present and identified
<i>Toxoplasma gondii</i>	Toxoplasmosis	1. Lymph node biopsy a. Routine histology b. Tissue culture isolation c. Animal inoculation 2. Serology	Identification of organisms plus appropriate serological test results

Table 9.10.2–A4 (continued)

Suspect causative agent(s)	Disease(s)	Appropriate test(s)	Positive result
Protozoa (continued)			
<i>Cryptosporidium parvum</i>	Cryptosporidiosis	<ol style="list-style-type: none"> 1. Duodenal scraping 2. Duodenal biopsy <ol style="list-style-type: none"> a. Stain b. Routine histology 3. Punch biopsy <ol style="list-style-type: none"> a. Routine histology b. Squash preparation 4. Sputum 5. Immunoassays 	Identification of organisms in microvillus border or other tissues (lung and gall bladder have also been involved); routine stains or monoclonal antibody reagents to identify oocysts in stool
Microsporidia <i>Nosema</i> spp. <i>Encephalitozoon</i> spp. <i>Enterocytozoon</i> spp. <i>Septata</i> sp. <i>Pleistophora</i> spp. <i>Trachipleistophora</i> spp. <i>Brachiola</i> sp. <i>Microsporidium</i> spp. <i>Vittaforma corneae</i>	Microsporidiosis	Routine histology; modified trichrome, tissue Gram stains, silver, periodic acid-Schiff, and Giemsa stains recommended (spores); animal inoculation not recommended/latent infections Electron microscopy may be necessary for confirmation.	These organisms (spores) have been found as insect or other animal parasites; route of infection is probably ingestion. Human cases involve muscle, CSF (AIDS); other body sites have also been documented.
Helminths			
Larvae (<i>Ascaris</i> and <i>Strongyloides</i> spp.)	“Pneumonia”	Sputum, wet preparation	This is an incidental finding but has been reported in severe infections.
Eggs (<i>Paragonimus</i> spp.)	Paragonimiasis	Sputum, wet preparation	Eggs will be coughed up and appear as “iron filings”; eggs could also be found in stool.
Hooklets (<i>Echinococcus</i> spp.)	Hydatid disease	Sputum, wet preparation	Rare finding, but hooklets can be found when the hydatid cyst is in the lung.
<i>Onchocerca volvulus</i>	Onchocerciasis	Skin	Skin snips examined in saline; microfilariae may be present.
<i>Mansonella streptocerca</i>	Schistosomiasis	<ol style="list-style-type: none"> 1. Rectal valve biopsy 2. Bladder biopsy 	Eggs present and identified
<i>Schistosoma</i> spp.			

^a Now classified with the fungi.

Table 9.10.2–A5 Protozoa of the intestinal tract and urogenital system: key characteristics^a

Organism	Trophozoite or tissue stage	Cyst or other stage in specimen	Comments
Amebae			
<i>Entamoeba histolytica</i> (pathogenic)	Cytoplasm clean; presence of RBCs is diagnostic, but cytoplasm may also contain some ingested bacteria; peripheral nuclear chromatin evenly distributed, with central, compact karyosome	Mature cyst contains four nuclei; chromatoidal bars have smooth, rounded ends; immature cyst usually contains one enlarged nucleus (precyst)	Considered pathogenic; report to Public Health; trophozoites can be confused with macrophages and cysts can be confused with WBCs in the stool
<i>Entamoeba dispar</i> (nonpathogenic)	Morphology identical to that of <i>E. histolytica</i> (confirmed by presence of RBCs in cytoplasm). If no RBCs, zymodeme analysis ^b or immunoassay is necessary to confirm species designation.	Mature cyst has morphology identical to that of <i>E. histolytica</i> .	Nonpathogenic; morphology resembles that of <i>E. histolytica</i> ; these organisms will continue to be signed out as <i>E. histolytica/E. dispar</i> and reported to Public Health. Immunoassay reagents are now available to differentiate pathogenic <i>E. histolytica</i> and nonpathogenic <i>E. dispar</i> ; some laboratories may decide to use these reagents on a routine basis, depending on positivity rate and cost.
<i>Entamoeba histolytica/E. dispar</i>			Correct way to report, unless immunoassay is used to identify <i>E. histolytica</i> or trophozoites are seen with ingested RBCs (<i>E. histolytica</i>)
<i>Entamoeba hartmanni</i> (nonpathogenic)	Looks identical to <i>E. histolytica</i> but smaller (<12 μm); RBCs will not be ingested	Mature cyst contains four nuclei but often stops at two; chromatoidal bars often present and look like those in <i>E. histolytica</i> (size, <10 μm); immature cyst (precyst) may mimic <i>E. histolytica</i> but will be <10 μm	Shrinkage occurs on permanent stain (especially in cyst form). <i>E. histolytica</i> may actually be below the 12- and 10-μm cutoff limits; it could be as much as 1.5 μm below the limits quoted for wet preparation measurements. Entire space (including shrinkage) must be measured.
<i>Entamoeba coli</i> (nonpathogenic)	Cytoplasm dirty, may contain ingested bacteria or debris; peripheral nuclear chromatin unevenly distributed, with a large, eccentric karyosome	Mature cyst contains eight nuclei, may see more; chromatoidal bars (if present) tend to have sharp, pointed ends	If a smear is too thick or thin and if stain is too dark or light, then <i>E. histolytica/E. dispar</i> and <i>E. coli</i> are often confused; much overlap in morphology. Assess smear thickness before identifying organisms to the species level.
<i>Endolimax nana</i> (nonpathogenic)	Cytoplasm clean, not diagnostic, great deal of nuclear variation, may even be some peripheral nuclear chromatin. Normally, only karyosomes are visible.	Cyst is round to oval, with four nuclear karyosomes visible	More nuclear variation in this ameba than in any others; can be confused with <i>Dientamoeba fragilis</i> and/or <i>E. hartmanni</i>
<i>Iodamoeba bütschlii</i> (nonpathogenic)	Cytoplasm contains much debris; organisms usually larger than <i>E. nana</i> but may look similar; large karyosome	Cyst contains single nucleus (may be “basket nucleus”) with bits of nuclear chromatin arranged on nuclear membrane (karyosome is the basket, bits of chromatin are the handle); large glycogen vacuole	Glycogen vacuole stains brown with addition of iodine in wet preparation; “basket nucleus” more common in cyst but can be seen in trophozoite; vacuole may be so large that the cyst collapses on itself

Table 9.10.2–A5 (continued)

Organism	Trophozoite or tissue stage	Cyst or other stage in specimen	Comments
<i>Amebae (continued)</i>			
<i>Giardia lamblia</i> (pathogenic)	Trophozoites teardrop shaped from front, like a curved spoon from side; contain nuclei, linear axonemes, and curved median bodies	Cyst is round to oval; contains multiple nuclei, axonemes, and median bodies	Organisms live in duodenum, and multiple stools may be negative; may have to use additional techniques (immunoassay, aspirate, Enterotest). Organism numbers may have little relevance to presence of symptoms.
<i>Chilomastix mesnili</i> (nonpathogenic)	Trophozoites teardrop shaped; cytostome must be visible for identification	Cyst is lemon shaped, with one nucleus and curved fibril called shepherd's crook	Cyst can be identified much easier than trophozoite form. Trophozoite will look like other small flagellates.
<i>Dientamoeba fragilis</i> (pathogenic)	Cytoplasm contains debris; may contain one or two nuclei (chromatin often fragmented into four dots)	No known cyst form	Tremendous size and shape range on a single smear; trophozoites with one nucleus can resemble <i>E. nana</i>
<i>Trichomonas vaginalis</i> (pathogenic)	Supporting rod (axostyle) present; undulating membrane comes halfway down the organism; small dots may be seen in cytoplasm along axostyle	No known cyst form	Recovered from genitourinary system; often diagnosed at bedside with wet preparation (motility)
<i>Pentatrichomonas hominis</i> (nonpathogenic)	Supporting rod (axostyle) present; undulating membrane comes all the way down the organism; small dots may be seen in cytoplasm along axostyle	No known cyst form	Recovered in stool; trophozoites may resemble other small flagellate trophozoites
<i>Ciliate</i>			
<i>Balantidium coli</i> (pathogenic)	Very large trophozoites (50–100 μm long) covered with cilia; large bean-shaped nucleus	Morphology not significant except for large, bean-shaped nucleus	Rarely seen in United States; causes severe diarrhea with large fluid loss; will be seen in proficiency testing specimens
<i>Coccidia</i>			
<i>Cryptosporidium parvum</i> (pathogenic)	Seen in intestinal mucosa (edge of brush border), gall bladder, and lung biopsy specimens	Oocysts seen in stool and/or sputum; organisms acid fast, 4–6 μm long; hard to find if few in number	Chronic infection in compromised host (internal autoinfective cycle), self-cure in immunocompetent host; numbers of oocysts correlate with stool consistency; can cause severe, watery diarrhea; oocysts immediately infective when passed
<i>Cyclospora cayentanensis</i> (pathogenic)	Experience with this organism is not extensive; organism may be difficult to identify in tissue; since patients are immunocompetent, biopsy specimens will probably rarely be required or requested	Oocysts seen in stool; approximately 8–10 μm in size; are unsporulated and thus difficult to recognize as coccidia; will mimic <i>C. parvum</i> (4–6 μm) on modified acid-fast-stained smears.	Oocysts have been seen in stool but were not recognized as coccidia until recently. To date, most infections are associated with immunocompetent individuals, but they may also be seen in immunosuppressed patients; organism may be associated with traveler's diarrhea and has been linked to the ingestion of imported food (raspberries, mesclun, basil)

(continued)

Table 9.10.2–A5 Protozoa of the intestinal tract and urogenital system: key characteristics^a (continued)

Organism	Trophozoite or tissue stage	Cyst or other stage in specimen	Comments
Coccidia (continued) <i>Isospora belli</i> (pathogenic)	Seen in intestinal mucosal cells and in biopsy specimens; less common than <i>C. parvum</i>	Oocysts seen in stool; organisms acid fast; best technique is concentration, not permanent stained smear	Thought to be the only <i>Isospora</i> sp. that infects humans; oocysts not immediately infective when passed; oocysts will be missed if PVA-preserved specimens are concentrated
Microsporidia <i>Nosema</i> spp. <i>Encephalitozoon</i> spp. <i>Septata</i> sp. <i>Pleistophora</i> spp. <i>Trachipleistophora</i> spp. <i>Brachiola</i> sp. <i>Enterocytozoon</i> spp. "Microsporidium" spp. <i>Vittaforma comeae</i>	Developing stages sometimes difficult to identify; spores can be identified by size, shape, and presence of polar tubules	Depending on the genus involved, spores could be identified in stool or urine using the modified trichrome stain, calcofluor, or immunoassay reagents (experimental).	Spores are generally quite small (1–2.0 µm for <i>Enterocytozoon</i> spp.) and can easily be confused with other organisms or artifacts (particularly in stool). Infections tend to be present in immunosuppressed patients. It is unclear whether all genera listed here can disseminate to all parts of the body (gastrointestinal tract, urogenital system); however, the list is complete in terms of all body sites.

^a PVA, polyvinyl alcohol; EM, electron microscopy.^b Zymodeme analysis is based on the identification of various isoenzymes found in cultured isolates of *Entamoeba histolytica*/*E. dispar*. These zymodemes (given separate numbers) tend to separate into two groups: those from symptomatic patients, some of whom have extraintestinal amebiasis, tend to group with the zymodeme isolates characteristic of the pathogen *E. histolytica*, while those from asymptomatic carriers tend to group with the zymodeme isolates characteristic of the nonpathogen, *E. dispar*.

Table 9.10.2-A6 Tissue protozoa: characteristics

Species	Shape and size	Other features ^a
<i>Toxoplasma gondii</i>		
Trophozoites (tachyzoites)	Crescent shaped; 4–6 μm long by 2–3 μm wide	Found in peritoneal fluid of experimentally infected mice; intracellular forms somewhat smaller and not usually seen in humans. May be isolated in tissue culture, particularly from CSF. Diagnosis is most frequently based on clinical history and serological evidence (acute- and convalescent-phase sera).
Cysts (bradyzoites)	Generally spherical; 200 μm to 1 mm in diam	Occur in many body tissues (approx 30–50% of the U.S. population have these organisms in tissues, indicating past infection). Many infections are asymptomatic. Infections in the compromised host are very serious and involve the CNS. In these patients, particularly those with AIDS, diagnostic serological titers may be very difficult to demonstrate. <i>Note:</i> Organisms identified in histological preparations or isolated in animal or tissue culture systems may or may not be causative agents of symptoms.
<i>Pneumocystis carinii</i>		
Trophozoites	Ameboid in shape; about 5 μm ; nucleus visible with Giemsa or hematoxylin stain	AIDS patients may have longer incubation period (avg, approx 40 days, but can be up to 1 yr). As many as 28% of these patients show normal chest X rays and no or ill-defined physical signs in chest. Rales may or may not be detected. Serological studies indicate that by age 4 yr, approx 80% of those tested are positive. Diagnosis is based on actual demonstration of the organism.
Cysts	Usually round; when mature, contain eight trophozoites; often measure 5 μm and contain very small trophozoites (1 μm)	Before AIDS epidemic, procedure of choice was open lung biopsy. Currently, BAL, transbronchial biopsy, and collection of induced sputum specimens are more widely used. No commercial reagents are available for serological diagnosis. Monoclonal reagents for direct organism detection are commercially available. <i>Note:</i> Disseminated infections with <i>P. carinii</i> in other body sites have been reported for AIDS patients. <i>P. carinii</i> has been reclassified with the fungi.
<i>Cryptosporidium parvum</i>	Oocyst usually round, 4–6 μm , each mature oocyst containing sporozoites (infective on passage)	Oocyst usually diagnostic stage in stool, sputum, and possibly other body specimens. Various other stages in life cycle can be seen in biopsy specimens taken from GI tract (brush border of epithelial cell-intestinal tract) and other tissues (lung, gall bladder). Several modified acid-fast stains have been used successfully. Direct detection methods using immunoassay reagents are also available. <i>Note:</i> Infection in the immunocompetent host is self-limiting; however, in immunodeficient patients (AIDS), infection is chronic because of an autoinfective capability in the life cycle. The number of oocysts usually correlates with symptoms (watery diarrhea = many oocysts in specimen). The more normal the stool, the more difficult it is to find oocysts. Risk groups include animal handlers, travelers, immunocompromised individuals, children in day care centers, and those who come in contact with these individuals. Since oocysts are immediately infective, nosocomial transmission has been documented.
<i>Cyclospora cayetanensis</i>	Oocyst usually round, 8–10 μm ; each oocyst is immature on passage; no internal morphology visible; oocysts appear as “wrinkled” cellophane	Oocyst is the diagnostic stage in stool. Various other stages in the life cycle can be seen in biopsy specimens taken from the GI tract (within epithelial cells and intestinal tract). The morphology is similar to that of <i>Isospora belli</i> . A number of modified acid-fast stains have been used successfully to demonstrate the oocysts (quite acid-fast variable). Detection methods involving immunoassay reagents are under development.

(continued)

Table 9.10.2–A6 Tissue protozoa: characteristics (*continued*)

Species	Shape and size	Other features ^a
<i>Isospora belli</i>	Ellipsoidal oocyst; usual range, 20–30 µm long by 10–19 µm wide; sporocysts rarely seen broken out of oocysts but measure 9–11 µm	Mature oocyst contains two sporocysts with four sporozoites each; usual diagnostic stage in feces is immature oocyst containing spherical mass of protoplasm (diarrhetic stool). Developing stages can be recovered from intestinal biopsy specimens. Oocysts are also acid fast and can be detected during acid-fast staining of stool for <i>Cryptosporidium</i> spp. Oocysts are often detected in concentration sediment (wet preparation).
Microsporidia <i>Nosema</i> spp. <i>Encephalitozoon</i> spp. <i>Septata</i> sp. <i>Pleistophora</i> spp. <i>Trachipleistophora</i> spp. <i>Brachiola</i> sp. <i>Enterocytozoon</i> spp. "Microsporidium" spp. <i>Vittaforma corneae</i>	Spores are extremely small and have been recovered from all body sites, including the eye.	These organisms have been found as insect or other animal parasites; the route of infection may be ingestion, inhalation, or direct inoculation (eye). Histology results vary (spores are acid fast); PAS, silver, tissue Gram, and Giemsa stains are recommended for spores. Animal inoculation is not recommended; laboratory animals may carry occult infection; electron microscopy may be necessary for confirmation and identification to the genus and species levels. Although difficult to diagnose, infections have been found in a large number of AIDS patients (<i>Enterocytozoon bienewisi</i> , <i>Encephalitozoon</i> [Septata] <i>intestinalis</i> in the intestinal tract, <i>Pleistophora</i> spp. in muscle, and various other microsporidia in other tissues, including the CNS). To date, it is still somewhat difficult to diagnose this infection by examining stool specimens prepared with optical brightening agents (calcofluor) or routine stains (modified trichrome, acid-fast trichrome stains). Diagnostic immunoassay reagents are under development but are not yet commercially available.
<i>Sarcocystis hominis</i> , <i>S. suihominis</i> , <i>S. bovis</i>	Thin-walled oocyst contains two mature sporocysts, each containing four sporozoites; frequently thin oocyst wall ruptures; ovoidal sporocysts are 9–16 µm long by 7.5–12 µm wide	Thin-walled oocyst or ovoidal sporocysts occur in stool. Compromised host may show fever, severe diarrhea, abdominal pain, and weight loss, although the number of patients has been small. Infections occur from ingestion of uncooked pork or beef. Life cycle occurs within intestinal cells, with eventual production of sporocysts in stool.
<i>Sarcocystis "lindemanni"</i>	Shapes and sizes of skeletal and cardiac muscle sarcocysts vary considerably.	When humans accidentally ingest oocysts from other animal stool sources, sarcocysts that develop in human muscle apparently do little if any harm. These can be identified by routine histological methods.

^a CNS, central nervous system; BAL, bronchoalveolar lavage; GI, gastrointestinal; FA, fluorescent antibody; PAS, periodic acid-Schiff.

Table 9.10.2-A7 Helminths: key characteristics^a

Helminth	Diagnostic stage	Comments
Nematodes (roundworms)		
<i>Ascaris lumbricoides</i> (pathogenic)	Egg: both fertilized (oval to round with thick, mammillated-tuberculated shell) and unfertilized (tends to be more oval-elongate, with bumpy shell exaggerated) can be found in stool. Adult worms: 10–12 in., found in stool. Rarely (in severe infections), migrating larvae can be found in sputum.	Unfertilized eggs will not float in flotation concentration method; adult worms tend to migrate when irritated (anesthesia, high fever), so check patients from areas of endemicity for infection prior to elective surgery.
<i>Trichuris trichiura</i> (whipworm) (pathogenic)	Egg: barrel shaped, with two clear, polar plugs; adult worm rarely seen; quantitative eggs (rare, few, etc.), since light infections may not be treated.	Dual infections with <i>Ascaris</i> may be seen (both infections acquired from egg ingestion in contaminated soil); in severe infections, rectal prolapse may occur in children or bloody diarrhea can be mistaken for amebiasis (bloody diarrhea usually not seen in United States).
<i>Enterobius vermicularis</i> (pinworm)	Egg: football shaped, with one flattened side Adult worm: about 3/8 in. long, white with pointed tail; female migrates from anus and deposits eggs on perianal skin.	May cause symptoms (itching) in some patients; test of choice is tape preparation; six consecutive tapes necessary to rule out infection; symptomatic patient often treated without actual confirmation of infection; eggs become infective within a few hours.
<i>Ancylostoma duodenale</i> (Old World hookworm), <i>Necator americanus</i> (New World hookworm) (pathogenic)	Egg: eggs of both identical; oval, with broadly rounded ends, thin shell, clear space between shell and developing embryo (8–16 ball stage) Adult worms: rarely seen in clinical specimens	May cause symptoms in some patients (blood loss anemia on differential smear in heavy infections). If stool remains unpreserved for several hours or days, eggs may continue to develop and hatch; rhabditiform larvae may resemble those of <i>Strongyloides stercoralis</i> .
<i>Strongyloides stercoralis</i> (pathogenic)	Rhabditiform larvae (noninfective) usually found in stool (short buccal cavity or capsule with large, genital primordial packet of cells [“short and sexy”]); in very heavy infections, larvae occasionally found in sputum and/or filariform (infective) larvae found in stool (slit in tail)	May see unexplained eosinophilia, abdominal pain, unexplained episodes of sepsis and/or meningitis, pneumonia (migrating larvae) in compromised patient. Potential for internal autoinfection can maintain low-level infections for many years (patient will be asymptomatic, with elevated eosinophilia); hyperinfection can occur in compromised patient (leading to disseminated strongyloidiasis and death); agar plate culture is the most sensitive diagnostic method; many infections are low level, and larvae are difficult to recover.
<i>Ancylostoma braziliensis</i> (dog-cat hookworm) (pathogenic)	Humans are accidental hosts; larvae wander through outer layer of skin, creating tracks (severe itching, eosinophilia); no practical microbiological diagnostic tests	Cause of cutaneous larva migrans; typical setup for infection: dogs and cats defecate in sandbox, and hookworm eggs hatch and penetrate human skin in contact with infected sand or soil (children playing in sandbox).
<i>Toxocara cati</i> or <i>Toxocara caninum</i> (dog-cat ascarid) (pathogenic)	Humans are accidental hosts; ingestion of dog or cat ascarid eggs from contaminated soil; larvae wander through deep tissues (including eye); can be mistaken for cancer of the eye; serology helpful for confirmation; eosinophilia	Cause of visceral larva migrans and ocular larva migrans; requests for laboratory services often originate in ophthalmology clinic.
Cestodes (tapeworms)		
<i>Taenia saginata</i> (beef tapeworm)	Scolex (four suckers, no hooklets), gravid proglottids (>12 branches on single side) are diagnostic; eggs indicate <i>Taenia</i> spp. only (thick, striated shell containing six-hooked embryo or oncosphere); worm usually approx 12 ft long	Adult worm can cause symptoms in some individuals; acquired from ingestion of raw or poorly cooked beef; usually only single worm/patient; individual proglottids may crawl from anus; proglottids can be injected with India ink to show uterine branches for identification.

(continued)

Table 9.10.2–A7 Helminths: key characteristics^a (continued)

Helminth	Diagnostic stage	Comments
Cestodes (tapeworms) (continued)		
<i>Taenia solium</i> (pork tapeworm)	Scolex (four suckers with hooklets), gravid proglottids (<12 branches on single side) are diagnostic; eggs indicate <i>Taenia</i> spp. only (thick, striated shell, containing six-hooked embryo or oncosphere), worm usually approx 12 ft long	Adult worm can cause GI complaints in some individuals; cysticercosis (accidental ingestion of eggs) can cause severe symptoms in the CNS; acquired from ingestion of raw or poorly cooked pork; usually only single worm/patient; occasionally two to three proglottids (hooked together) are passed; proglottids can be injected with India ink to show uterine branches for identification; cysticerci are normally small and contained within enclosing membrane; occasionally they may develop as racemose type, where worm tissue grows in the body like a metastatic cancer.
<i>Diphyllobothrium latum</i> (broad fish tapeworm)	Scolex (lateral sucking grooves), gravid proglottid (wider than long, reproductive structures in center “rosette”); eggs operculated	Can cause GI complaints in some individuals; acquired from ingestion of raw or poorly cooked freshwater fish; life cycle has two intermediate hosts (copepod, fish); worm may be 30 ft long; associated with vitamin B ₁₂ deficiency in genetically susceptible groups (Scandinavians)
<i>Hymenolepis nana</i> (dwarf tapeworm)	Adult worm not normally seen; egg round to oval, thin shell, containing six-hooked embryo or oncosphere with polar filaments lying between embryo and egg shell	Can cause GI complaints in some individuals; acquired from ingestion of eggs (only life cycle where the intermediate host, the grain beetle, can be bypassed); life cycle of egg to larval form to adult can be completed in human; most common tapeworm in the world
<i>Hymenolepis diminuta</i> (rat tapeworm)	Adult worm not normally seen; egg round to oval, thin shell, containing six-hooked embryo or oncosphere with no polar filaments lying between embryo and egg shell	Uncommon; egg can be confused with that of <i>H. nana</i> ; eggs will be submitted in proficiency testing specimens and must be differentiated from those of <i>H. nana</i> .
<i>Echinococcus granulosus</i> (pathogenic)	Adult worm found only in the carnivore (dog); hydatid cysts develop (primarily in liver) when humans accidentally ingest eggs from dog tapeworms; cyst contains daughter cysts and many scolices; examine fluid aspirated from cyst at surgery.	Humans are accidental intermediate hosts; normal life cycle is in sheep and dog, with hydatid cysts developing in liver, lung, etc., of sheep. Human may be unaware of infection unless fluid leaks from cyst (can trigger an anaphylactic reaction) or pain is felt from cyst location.
<i>Echinococcus multilocularis</i> (pathogenic)	Adult worm found only in the carnivore (fox, wolf); hydatid cysts develop (primarily in liver) when humans accidentally ingest eggs from carnivore tapeworms; cyst grows like a metastatic cancer with no limiting membrane.	Humans are accidental intermediate hosts; prognosis poor; surgical removal of tapeworm tissue very difficult; found in Canada, Alaska, and, less frequently, in the northern United States, although it is becoming more common in the United States, where the geographic range is moving further south
Trematodes (flukes)		
<i>Fasciolopsis buski</i> (giant intestinal fluke)	Eggs found in stool; very large and operculated (morphology like that of <i>Fasciola hepatica</i> eggs)	Symptoms depend on worm burden; acquired from ingestion of plant material (water chestnuts) on which metacercariae have encysted; worms hermaphroditic
<i>Fasciola hepatica</i> (sheep liver fluke)	Eggs found in stool; cannot be differentiated from those of <i>F. buski</i>	Symptoms depend on worm burden; acquired from ingestion of plant material (watercress) on which metacercariae have encysted; worms hermaphroditic
<i>Opisthorchis (Clonorchis) sinensis</i> (Chinese liver fluke)	Eggs found in stool; very small (<35 μm); operculated, with shoulders into which operculum fits	Symptoms depend on worm burden; acquired from ingestion of raw fish; eggs can be missed unless 400× power is used for examination; eggs can resemble those of <i>Metagonimus yokogawai</i> and <i>Heterophyes heterophyes</i> (small intestinal flukes); worms hermaphroditic
<i>Paragonimus westermani</i> <i>Paragonimus</i> spp. (lung flukes)	Eggs coughed up in sputum (brownish “iron filings” = egg packets); can be recovered in sputum or stool (if swallowed); operculated, with shoulders into which operculum fits	Symptoms depend on worm burden and egg deposition; acquired from ingestion of raw crabs; eggs can be confused with those of <i>D. latum</i> ; infections seen in Orient; infections with <i>Paragonimus mexicanus</i> found in Central and South America; worms hermaphroditic but often cross-fertilize with another worm if present

Table 9.10.2–A7 (continued)

Helminth	Diagnostic stage	Comments
Trematodes (flukes)		
<i>(continued)</i>		
<i>Schistosoma mansoni</i> (blood fluke) (pathogenic)	Eggs recovered in stool (large lateral spine); collect specimens with no preservatives (to indicate egg viability); worms in veins of large intestine	Acquired from skin penetration of single cercariae from freshwater snail; pathology caused by body's immune response to eggs in tissues; adult worms in veins cause no problems; adult worms are separate sexes.
<i>Schistosoma haematobium</i> (blood fluke) (pathogenic)	Eggs recovered in urine (large terminal spine); collect specimens with no preservatives (to indicate egg viability); worms in veins of bladder	Acquired from skin penetration of single cercariae from freshwater snail; pathology as with <i>S. mansoni</i> ; collect 24-h and spot urine samples; chronic infection associated bladder cancer; adult worms are separate sexes.
<i>Schistosoma japonicum</i> (blood fluke) (pathogenic)	Eggs recovered in stool (very small lateral spine); collect specimens with no preservatives (to indicate egg viability); worms in veins of small intestine	Acquired from skin penetration of multiple cercariae from freshwater snail; pathology as with <i>S. mansoni</i> ; infection usually most severe of the three because of original-loading infective dose of cercariae from freshwater snail (multiple cercariae stick together); pathology associated with egg production, which is greatest in <i>S. japonicum</i> infections

^a GI, gastrointestinal; CNS, central nervous system.

Table 9.10.2–A8 Parasites found in blood: characteristics^a

Protozoa	Diagnostic stage	Comments
Malaria		
<i>Plasmodium vivax</i> (benign tertian malaria)	Ameboid rings; Schüffner's dots, beginning in older rings (appear later than those in <i>P. ovale</i>); all stages seen in peripheral blood; mature schizont contains 16–18 merozoites.	Infects young cells; 48-h cycle; large geographic range; tends to have true relapse from residual liver stages, enlarged RBCs
<i>Plasmodium ovale</i> (ovale malaria)	Nonameboid rings; Schüffner's dots, beginning in young rings (appear earlier than those in <i>P. vivax</i>); all stages seen in peripheral blood; mature schizont contains 8–10 merozoites; RBCs may be oval and have fimbriated edges.	Infects young cells; 48-h cycle; narrow geographic range; tends to have true relapse from residual liver stages, enlarged RBCs
<i>Plasmodium malariae</i> (quartan malaria)	Thick rings; no stippling; all stages seen in peripheral blood; "band forms" and "rosette"-shaped mature schizont; lots of malarial pigment	Infects old cells; 72-h cycle; narrow geographic range; associated with recrudescence and nephrotic syndrome, no true relapse, normal or small RBCs
<i>Plasmodium falciparum</i> (malignant tertian malaria)	Multiple rings; appliqué-accolé forms; no stippling (rare Mauer's clefts); rings and crescent-shaped gametocytes seen in peripheral blood (no other developing stages; rare exception, mature schizont)	Infects all cells, 36- to 48-h cycle; large geographic range; no true relapse; most pathogenic of four species; plugged capillaries can cause severe symptoms and sequelae (cerebral malaria, RBC lysis, etc).
<i>Babesia</i> spp.	Ring forms only (resemble <i>P. falciparum</i> rings); seen in splenectomized patients; endemic in United States (no travel history necessary); if present, "Maltese cross" configuration diagnostic, but it is not always seen	Tick-borne infection associated with Nantucket Island; infection mimics malaria; ring forms more pleomorphic than those in malaria; more rings/cell (usually) than in malaria; endemic in several areas within the United States; organisms occasionally seen outside RBCs (unlike malaria merozoites)
Trypanosomes		
<i>Trypanosoma brucei gambiense</i> (West African sleeping sickness)	Trypomastigotes long and slender, with typical undulating membrane; lymph nodes and blood can be sampled; microhematocrit tube concentration helpful; examine spinal fluid in later stages of infection.	Tsetse fly vector; tends to be chronic infection, exhibiting real symptoms of sleeping sickness
<i>Trypanosoma brucei rhodesiense</i> (East African sleeping sickness)	Trypomastigotes long and slender, with typical undulating membrane; lymph nodes or blood can be sampled; microhematocrit tube concentration helpful; examine spinal fluid in later stages of infection.	Tsetse fly vector; tends to be more severe, short-lived infection (particularly in children); patient may expire before progressive symptoms of sleeping sickness appear.
<i>Trypanosoma cruzi</i> (Chagas' disease; American trypanosomiasis)	Trypomastigotes short, stumpy, often curved in C shape; sample blood early in infection; trypomastigotes enter striated muscle (heart, GI tract) and transform into amastigote form.	Reduviid bug ("kissing bug") vector; chronic in adults, severe in young children; great morbidity associated with cardiac failure and loss of muscle contractility in heart and GI tract
<i>Leishmania</i> spp. (cutaneous) (not actually a blood parasite but presented for comparison with <i>L. donovani</i>)	Amastigotes found in skin macrophages; intracellular forms containing nucleus and kinetoplast are diagnostic.	Not actually blood parasite but presented for comparison with <i>Leishmania donovani</i> ; sand fly vector; organisms recovered from site of lesion only; stain specimens or culture in NNN and/or Schneider's medium; animal inoculation (hamster) rarely used
<i>Leishmania braziliensis</i> (mucocutaneous) (not actually a blood parasite but presented for comparison with <i>L. donovani</i>)	Amastigotes found in macrophages of skin and mucous membranes; intracellular forms containing nucleus and kinetoplast are diagnostic.	Not actually blood parasite but presented for comparison with <i>L. donovani</i> ; sand fly vector; organisms recovered from site of lesion only; stain specimens or culture in NNN and/or Schneider's medium; animal inoculation (hamster) rarely used

Table 9.10.2–A8 (continued)

Protozoa	Diagnostic stage	Comments
Trypanosomes (continued)		
<i>Leishmania donovani</i> (visceral)	Amastigotes found throughout reticuloendothelial system; spleen, liver, bone marrow, etc.; intracellular forms containing nucleus and kinetoplast are diagnostic.	Sand fly vector; organisms recovered from buffy coat (rarely found), bone marrow aspirate, spleen or liver puncture (rarely performed); stain specimens or culture in NNN and/or Schneider's medium; animal inoculation (hamster) rarely used; cause of kala-azar
Helminths		
<i>Wuchereria bancrofti</i>	Microfilaria sheathed, clear space at end of tail; nocturnal periodicity; elephantiasis seen in chronic infections	Pathogenicity due to adult worms; mosquito vector; microfilariae recovered in blood (membrane filtration, Knott concentrate, thick films); hematoxylin stains sheath; sheath does not stain well with Giemsa, but the Innenkörper (inner body) stains a pink color
<i>Brugia malayi</i>	Microfilaria sheathed, subterminal and terminal nuclei at end of tail; nocturnal periodicity; elephantiasis seen in chronic infections	Pathogenicity due to adult worms; mosquito vector; microfilariae recovered in blood (membrane filtration, Knott concentrate, thick films); hematoxylin stains sheath; sheath tends to stain pink with Giemsa
<i>Loa loa</i> (African eye worm)	Microfilaria sheathed, nuclei continuous to tip of tail; diurnal periodicity; adult worm may cross conjunctiva of the eye.	Pathogenicity due to adult worms; mango fly vector; history of Calabar swellings, worms in the eye; microfilariae difficult to recover from blood; hematoxylin stains sheath
<i>Mansonella</i> spp.	Microfilaria unsheathed, nuclei may or may not extend to tip of tail (depending on species); nonperiodic; symptoms usually absent or mild	Pathogenicity mild and due to adult worms; midge or blackfly vector; microfilariae recovered in blood (membrane filtration, Knott concentrate, thick films)
<i>Mansonella streptocerca</i>	Microfilaria unsheathed, nuclei extend to tip of tail; when immobile, curved like shepherd's crook; adults in dermal tissues	Pathogenicity mild and due to adult worms and/or microfilariae; midge vector; microfilariae found in skin snips; microfilarial tails split rather than blunt
<i>Onchocerca volvulus</i>	Microfilaria unsheathed, nuclei do not extend to tip of tail; adults in nodules	Pathogenicity due to microfilariae; blackfly vector; microfilariae found in skin snips; microfilariae migrate to optic nerve; cause of river blindness

^a GI, gastrointestinal.

Table 9.10.2–A9 Parasitic infections: clinical findings in healthy and compromised hosts

Organism(s)	Clinical findings in:	
	Healthy host	Compromised host ^a
<i>Entamoeba histolytica</i>	Asymptomatic to chronic-acute colitis; extraintestinal disease may occur (primary site: right upper lobe of liver).	Diminished immune capacity may lead to extraintestinal disease.
Free-living amebae	Patients tend to have eye infections with <i>Acanthamoeba</i> spp.; linked to poor eye care	Primary amebic meningoencephalitis caused by <i>Naegleria fowleri</i> , granulomatous amebic encephalitis caused by <i>Acanthamoeba</i> spp. and <i>Balamuthia</i> sp.; severe cutaneous infections in compromised patients (<i>Acanthamoeba</i> spp.)
<i>Giardia lamblia</i>	Asymptomatic to malabsorption syndrome	Certain immunodeficiencies tend to predispose an individual to infection.
<i>Blastocystis hominis</i>	Asymptomatic to symptomatic, often depending on number of organisms present	Not enough information to tell whether actual differences occur in compromised patients; infections may be more difficult to eradicate in AIDS patients
<i>Toxoplasma gondii</i>	Approximately 50% of individuals have antibody and organisms in tissue but are asymptomatic.	Disease in compromised host tends to involve CNS, with various neurological symptoms.
<i>Pneumocystis carinii</i>	Most individuals are probably carriers but asymptomatic.	Disease state develops as pneumonia.
<i>Cryptosporidium parvum</i>	Self-limiting infection with diarrhea and abdominal pain	Due to autoinfective nature of life cycle, will not be self-limiting, may produce fluid loss of over 10 liters/day, and may show multisystem involvement; no known totally effective therapy
<i>Cyclospora cayatanensis</i>	Self-limiting infection with diarrhea (3–4 days), with relapses common	Diarrhea may persist for 12 wk or more; biliary disease has also been reported for this group, particularly for those with AIDS.
<i>Isospora belli</i>	Self-limiting infection with mild diarrhea or no symptoms	May lead to severe diarrhea, abdominal pain, and possible death (rare case reports); diagnosis may occasionally be missed due to nonrecognition of oocyst stage; will not be seen when concentrated from PVA fixative
<i>Sarcocystis</i> spp.	Self-limiting infection with diarrhea or mild symptoms	Symptoms may be more severe and last longer.
Microsporidia (<i>Nosema</i> , <i>Bra-chioli</i> , <i>Vittaforma</i> , <i>Encephali-tozoon</i> , <i>Septata</i> , <i>Enterocyto-zoon</i> , <i>Pleistophora</i> , <i>Trachipleistophora</i> , “ <i>Microspo-ridium</i> ” spp.)	Less known about these infections in the healthy host; serologic evidence suggests that infections may be more common than recognized.	Can infect various parts of the body; diagnosis often depends on histologic examination of tissues; routine examination of clinical specimens (stool, urine, etc.) is becoming more common; organisms can cause death.
<i>Leishmania</i> spp.	Asymptomatic to mild disease	More serious manifestations of visceral leishmaniasis; some cutaneous species will manifest visceral disease; difficult to treat and manage; definite coinfection with AIDS

Table 9.10.2-A9 (continued)

Organism(s)	Clinical findings in:	
	Healthy host	Compromised host ^a
<i>Strongyloides stercoralis</i>	Asymptomatic to mild abdominal complaints; can remain latent for many years due to low-level infection maintained by internal autoinfective life cycle	Can result in disseminated disease (hyperinfection syndrome due to autoinfective nature of life cycle); abdominal pain, pneumonitis, sepsis-meningitis with gram-negative bacilli, eosinophilia
Crusted (Norwegian) scabies (<i>Sarcoptes scabiei</i>)	Infections can range from asymptomatic to causing moderate itching.	Severe infection with reduced itching response; hundreds of thousands of mites on body; infection very easily transferred to others; secondary infection very common

^a CNS, central nervous system; PVA, polyvinyl alcohol; EM, electron microscopy.

Appendix 9.10.3–1—Common Problems in Organism Identification

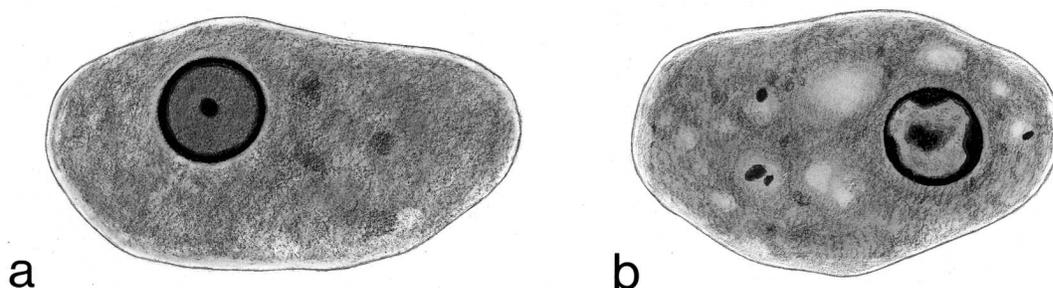

Figure 9.10.3–A1 (a) *Entamoeba histolytica*/*E. dispar* trophozoite. Note the evenly arranged nuclear chromatin, central compact karyosome, and relatively “clean” cytoplasm. (b) *Entamoeba coli* trophozoite. Note the unevenly arranged nuclear chromatin, eccentric karyosome, and “messy” cytoplasm. These characteristics are very representative of the two organisms. (Illustration by Sharon Belkin.)

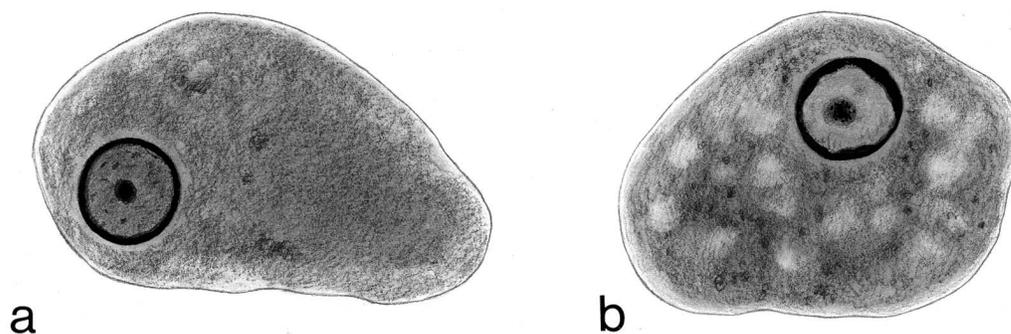

Figure 9.10.3–A2 (a) *Entamoeba histolytica*/*E. dispar* trophozoite. Note the evenly arranged nuclear chromatin, central compact karyosome and “clean” cytoplasm. (b) *Entamoeba coli* trophozoite. Note that the nuclear chromatin appears to be evenly arranged, the karyosome is central (but more diffuse), and the cytoplasm is “messy,” with numerous vacuoles and ingested debris. The nuclei of these two organisms tend to resemble one another (very common finding in routine clinical specimens). (Illustration by Sharon Belkin.)

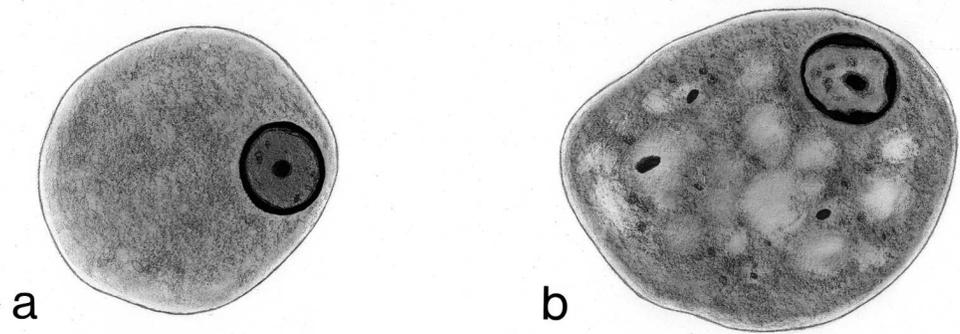

Figure 9.10.3-A3 (a) *Entamoeba histolytica*/*E. dispar* trophozoite. Again, note the typical morphology (evenly arranged nuclear chromatin, central compact karyosome, and relatively “clean” cytoplasm). (b) *Entamoeba coli* trophozoite. Although the nuclear chromatin is eccentric, note that the karyosome seems to be compact and central. However, note the various vacuoles containing ingested debris. These organisms show some characteristics that are very similar (very typical in clinical specimens). (Illustration by Sharon Belkin.)

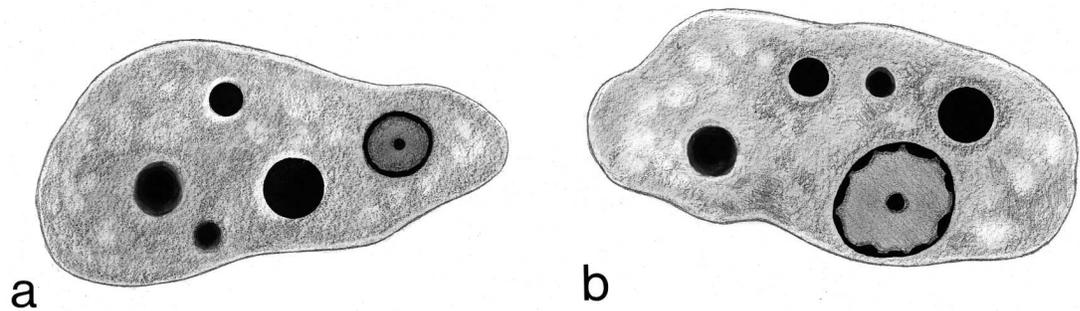

Figure 9.10.3-A4 (a) *Entamoeba histolytica* trophozoite. Note the evenly arranged nuclear chromatin, central compact karyosome, and RBCs in the cytoplasm. (b) Human macrophage. The key difference between the macrophage nucleus and that of *E. histolytica* is the size. Usually, the ratio of nucleus to cytoplasm in a macrophage is approximately 1:6 or 1:8, while the true organism has a nucleus/cytoplasm ratio of approximately 1:10 or 1:12. The macrophage also contains ingested RBCs. In cases of diarrhea or dysentery, trophozoites of *E. histolytica* and macrophages can often be confused, occasionally leading to a false-positive diagnosis of amebiasis when no parasites are present. Both the actual trophozoite and the macrophage may also be seen without ingested RBCs, and they can mimic one another. (Illustration by Sharon Belkin.)

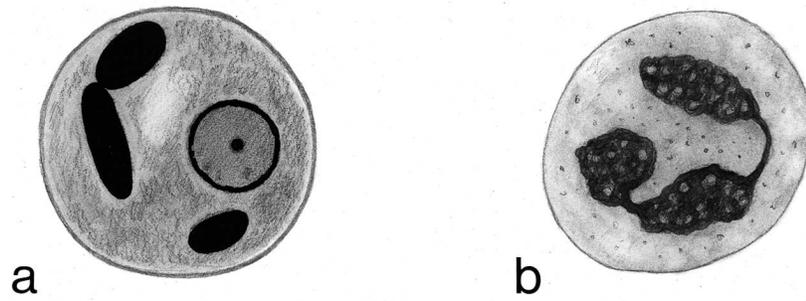

Figure 9.10.3–A5 (a) *Entamoeba histolytica*/*E. dispar* precyst. Note the enlarged nucleus (prior to division) with evenly arranged nuclear chromatin and central compact karyosome. Chromatoidal bars (rounded ends, with smooth edges) are also present in the cytoplasm. (b) PMN. The nucleus is somewhat lobed (normal morphology) and represents a PMN that has not been in the gut very long. Occasionally, the positioning of the chromatoidal bars and the lobed nucleus of the PMN can mimic one another. The chromatoidal bars will stain more intensely, but shapes can overlap, as seen here. (Illustration by Sharon Belkin.)

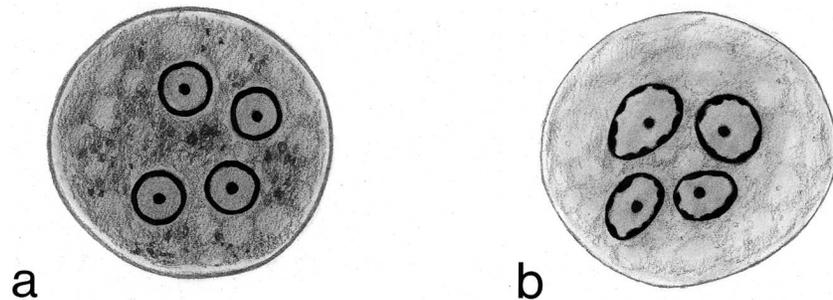

Figure 9.10.3–A6 (a) *Entamoeba histolytica*/*E. dispar* cyst. Note that the four nuclei are very consistent in size and shape. (b) PMN. Note that the normal lobed nucleus has now broken into four fragments, which mimic four nuclei with peripheral chromatin and central karyosomes. When PMNs have been in the gut for some time and have begun to disintegrate, the nuclear morphology can mimic that seen in an *E. histolytica*/*E. dispar* cyst. However, human cells are often seen in the stool in cases of diarrhea; with rapid passage of the gastrointestinal tract contents, there will not be time for amebic cysts to form. Therefore, in cases of diarrhea and/or dysentery, if “organisms” are seen that resemble the cell in panel b, think first of PMNs, not *E. histolytica*/*E. dispar* cysts. (Illustration by Sharon Belkin.)

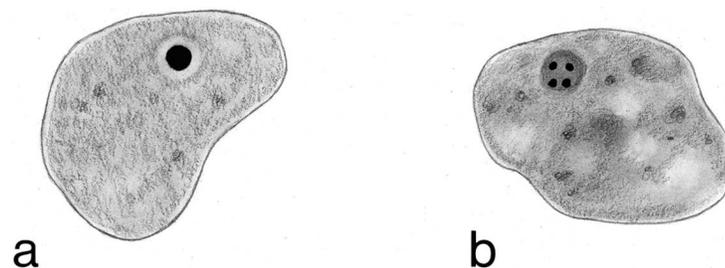

Figure 9.10.3–A7 (a) *Endolimax nana* trophozoite. This organism is characterized by a large karyosome with no peripheral chromatin, although there are normally many nuclear variations seen in any positive specimen. (b) *Dientamoeba fragilis* trophozoite. Normally, the nuclear chromatin is fragmented into several dots (often a “tetrad” arrangement). The cytoplasm is normally more “junky” than that seen in *E. nana*. If the morphology is typical, as in these two illustrations, then differentiating between these two organisms is not that difficult. However, the morphologies of the two will often be very similar. (Illustration by Sharon Belkin.)

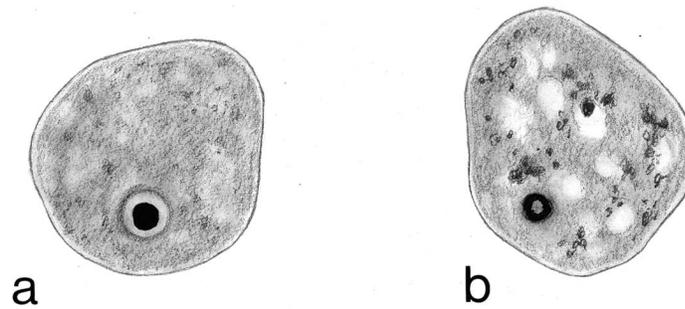

Figure 9.10.3-A8 (a) *Endolimax nana* trophozoite. Notice that the karyosome is large and surrounded by a “halo,” with very little, if any, chromatin on the nuclear membrane. (b) *Dientamoeba fragilis* trophozoite. In this organism, the karyosome is beginning to fragment, and there is a slight clearing in the center of the nuclear chromatin. If the nuclear chromatin has not become fragmented, *D. fragilis* trophozoites can very easily mimic *E. nana* trophozoites. This could lead to a report indicating that no pathogens were present, when, in fact, *D. fragilis* is considered a definite cause of symptoms. (Illustration by Sharon Belkin.)

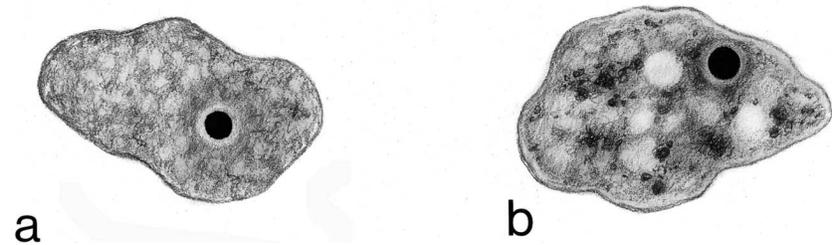

Figure 9.10.3-A9 (a) *Endolimax nana* trophozoite. Note the large karyosome surrounded by a clear space. The cytoplasm is relatively “clean.” (b) *Iodamoeba bütschlii*. Although the karyosome is similar to that of *E. nana*, note that the cytoplasm in *I. bütschlii* is much more heavily vacuolated and contains ingested debris. Often, these two trophozoites cannot be differentiated. However, the differences in the cytoplasm are often helpful. There will be a definite size overlap between the two genera. (Illustration by Sharon Belkin.)

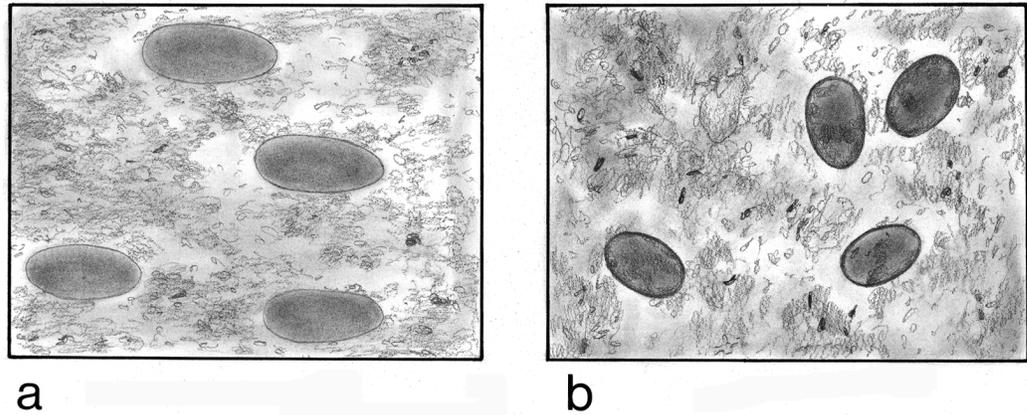

Figure 9.10.3-A10 (a) RBCs on a stained fecal smear. Note that the cells are very pleomorphic but tend to be positioned in the direction the stool was spread onto the slide. (b) Yeast cells on a stained fecal smear. These cells tend to remain oval and are not aligned in any particular way on the smear. These differences are important when the differential identification is between *Entamoeba histolytica* containing RBCs and *Entamoeba coli* containing ingested yeast cells. If RBCs or yeast cells are identified in the cytoplasm of an organism, they must also be visible in the background of the stained fecal smear. (Illustration by Sharon Belkin.)

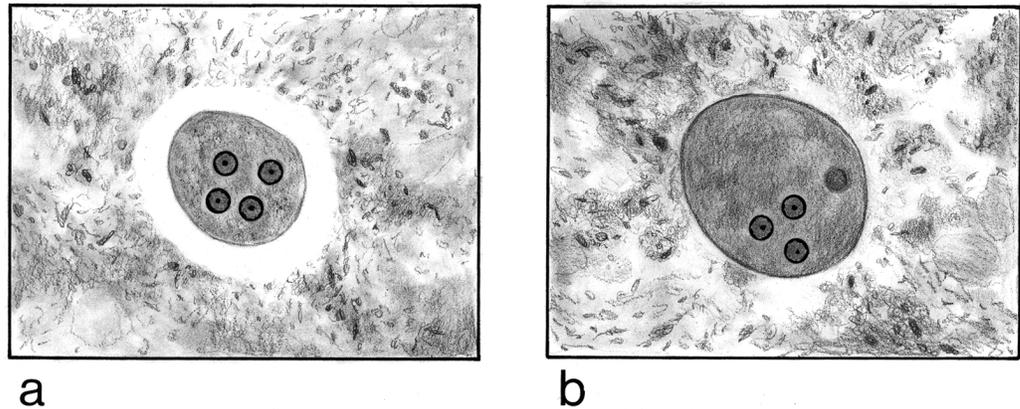

Figure 9.10.3-A11 (a) *Entamoeba histolytica*/*E. dispar* cyst. Note the shrinkage due to dehydrating agents in the staining process. (b) *E. histolytica*/*E. dispar* cyst. In this case, the cyst exhibits no shrinkage. Only three of the four nuclei are in focus. Normally, this type of shrinkage is seen with protozoan cysts and is particularly important when a species is measured and identified as either *E. histolytica*/*E. dispar* or *Entamoeba hartmanni*. The whole area, including the halo, must be measured prior to species identification. If just the cyst is measured, the organism would be identified as *E. hartmanni* (nonpathogenic) rather than *E. histolytica*/*E. dispar* (possibly pathogenic). (Illustration by Sharon Belkin.)

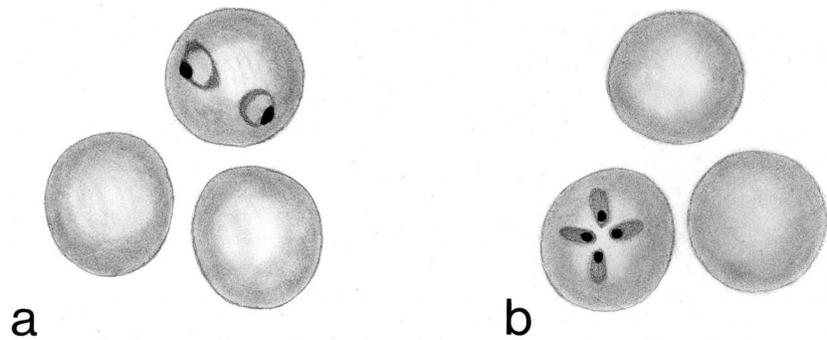

Figure 9.10.3-A12 (a) *Plasmodium falciparum* rings. Note the two rings in the RBC. Multiple rings per cell are more typical of *P. falciparum* than of the other species of human malaria. (b) *Babesia* rings. In one of the RBCs are four small *Babesia* rings. This particular arrangement is called the Maltese cross and is diagnostic for *Babesia* spp. However, the Maltese cross configuration is not always present. *Babesia* infections can be confused with cases of *P. falciparum* malaria, primarily because multiple rings can be seen in the RBCs. Another difference involves ring morphology. *Babesia* rings are often of various sizes and tend to be very pleomorphic, while those of *P. falciparum* tend to be more consistent in size and shape. (Illustration by Sharon Belkin.)

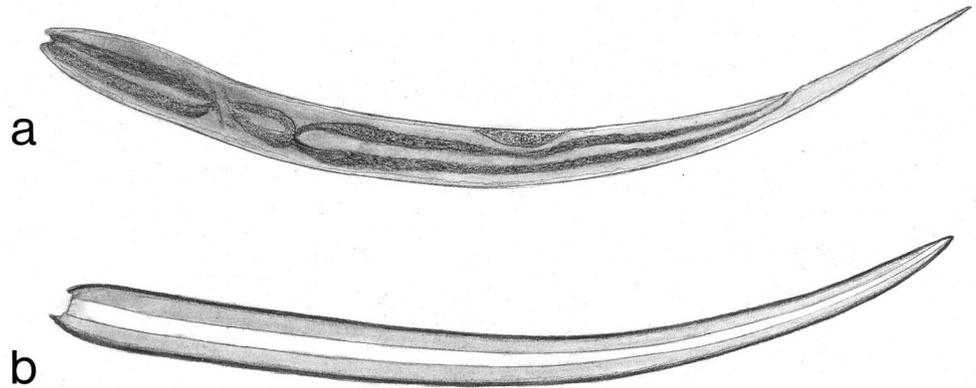

Figure 9.10.3-A13 (a) *Strongyloides stercoralis* rhabditiform larva. Note the short buccal capsule (mouth opening) and the internal structure, including the genital primordial packet of cells. (b) Root hair (plant material). Note that there is no specific internal structure and the end is ragged (where it was broken off from the main plant). Often plant material mimics some of the human parasites. This comparison is one of the best examples. These artifacts are occasionally submitted as proficiency testing specimens. (Illustration by Sharon Belkin.)

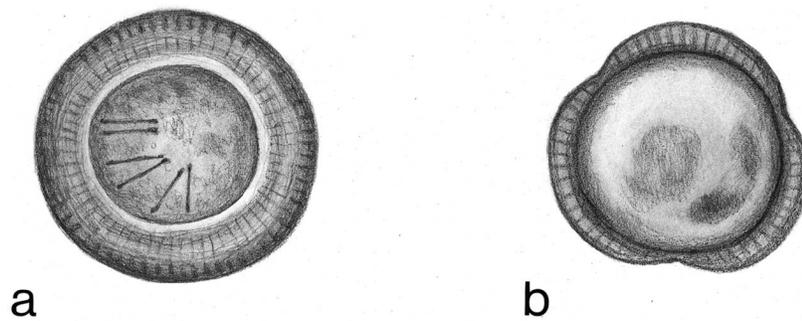

Figure 9.10.3–A14 (a) *Taenia* egg. This egg has been described as having a thick, radially striated shell containing a six-hooked embryo (oncosphere). (b) Pollen grain. Note that this trilobed pollen grain has a similar type of “shell” and, if turned the right way, could resemble a *Taenia* egg. This represents another confusion between a helminth egg and a plant material artifact. When examining fecal specimens in a wet preparation, tap on the coverslip to get objects to move around. As they move, you can see more morphological detail. (Illustration by Sharon Belkin.)

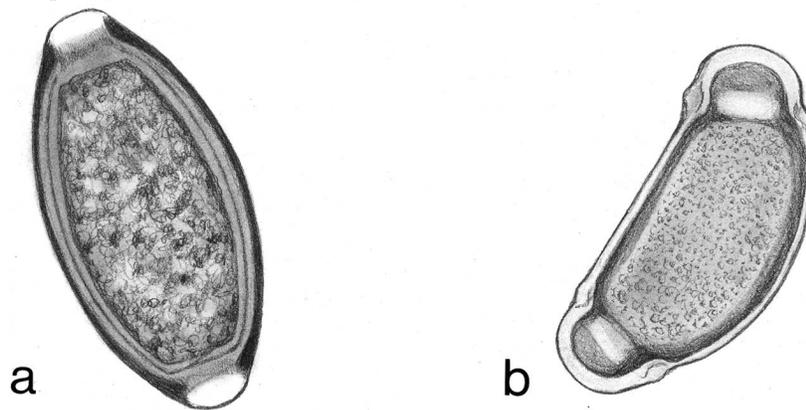

Figure 9.10.3–A15 (a) *Trichuris trichiura* egg. This egg is typical and is characterized by the barrel shape with thick shell and two polar plugs. (b) Bee pollen. This artifact certainly mimics the actual *T. trichiura* egg. However, note that the actual shape is somewhat distorted. This is an excellent example of a parasite “look-alike” and could be confusing. (Illustration by Sharon Belkin.)

9.10.4

Appendix 9.10.4–1—Quality Control Recording Sheets

Forms on pages 9.10.4.2 to 9.10.4.5 are for use in QC testing of cultures and reagents.

DIAGNOSTIC PARASITOLOGY QC (REAGENTS)—EXAMPLE

1. Reagent Name: _____

2. QC Requirements (frequency): _____

3. Acceptable Criteria: _____

Negative Control: _____

Positive Control: _____

Date	Lot No.	Exp. Date	QC Organism	Tech	Results (A/NA) ¹	Comments Corrective Action

Comments: _____

Date	Lot No.	Exp. Date	QC Organism	Tech	Results (A/NA)	Comments Corrective Action

Comments: _____

Date	Lot No.	Exp. Date	QC Organism	Tech	Results (A/NA)	Comments Corrective Action

Comments: _____

Date	Lot No.	Exp. Date	QC Organism	Tech	Results (A/NA)	Comments Corrective Action

Comments: _____

¹A = Acceptable, NA = Not Acceptable

**DIAGNOSTIC PARASITOLOGY QC (CULTURE)
EXAMPLE OF A WORKSHEET**

DIAGNOSTIC PARASITOLOGY QC (CULTURE)
EXAMPLE OF A WORKSHEET

1. Patient's Name/Organism trying to isolate: _____

2. Medium Number 1: _____

Medium Number 2: _____

3. ATCC Control Strain (Indicate Organism Name and ATCC Number): _____

4: Frequency: QC strain must be set up every time patient specimen is cultured (there are no exceptions to this requirement):

Medium 1: _____

Date	Medium Lot No.	Exp. Date	Tech	A ¹	NA ²	Date Read	Comments ³ Corrective Action

Comments: _____

Medium 2: _____

Date	Medium Lot No.	Exp. Date	Tech	A ¹	NA ²	Date Read	Comments ³ Corrective Action

Comments: _____

¹Acceptable: QC organism growth or motile trophozoites can be detected microscopically in sample of QC medium (inoculated with ATCC strain).

²Not Acceptable: QC organism growth or motile trophozoites cannot be detected microscopically in sample of QC medium (inoculated with ATCC strain).

³Follow-up: in the event the QC culture is negative, the control strain should be resubbed to fresh media.

EQUIPMENT MAINTENANCE

Equipment Description: _____
 (Include Inventory Number)

Serial Number: _____ Model Number: _____ Purchase Date: _____

Equipment Location: _____

Maintenance Requirements and Time Frames:
 (List specific requirements, time frames below - use table for recording actual maintenance.)

1. _____
2. _____
3. _____
4. _____

Date and Initials	Maintenance (List # of Maintenance Requirements)	Comments/Corrective Action

Remember to attach all relevant paperwork to this sheet (repair invoices, replacement part invoices, etc.).

9.10.5

Appendix 9.10.5–1—Flowcharts for Diagnostic Procedures

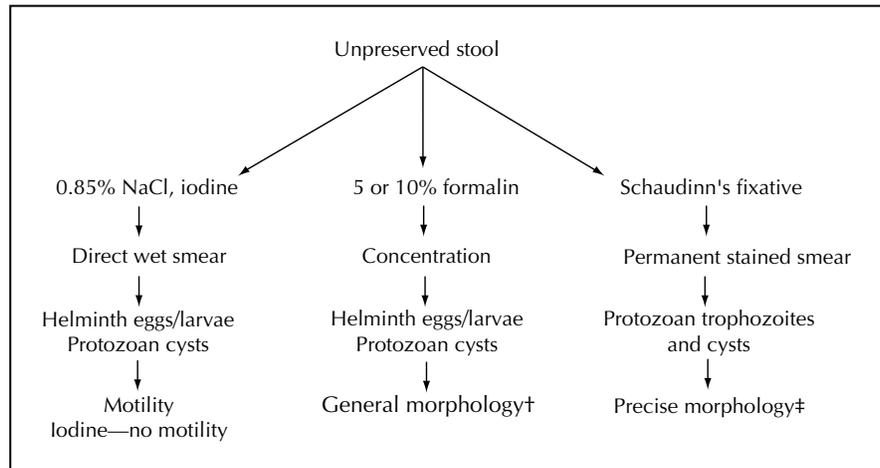

Figure 9.10.5–A1 Procedure for processing fresh stool for the ova and parasite examination. Special stains will be necessary for *Cryptosporidium* and *Cyclospora* (modified acid-fast) and the microsporidia (modified trichrome, calcofluor). Immunoassay kits are now available for some of these organisms. If the permanent staining method (iron hematoxylin) contains a carbol fuchsin step, the coccidia will stain pink. Symbols: †, some protozoa may not be identified using the wet examination only; ‡, protozoa (primarily trophozoites) can be identified and cysts can be confirmed.

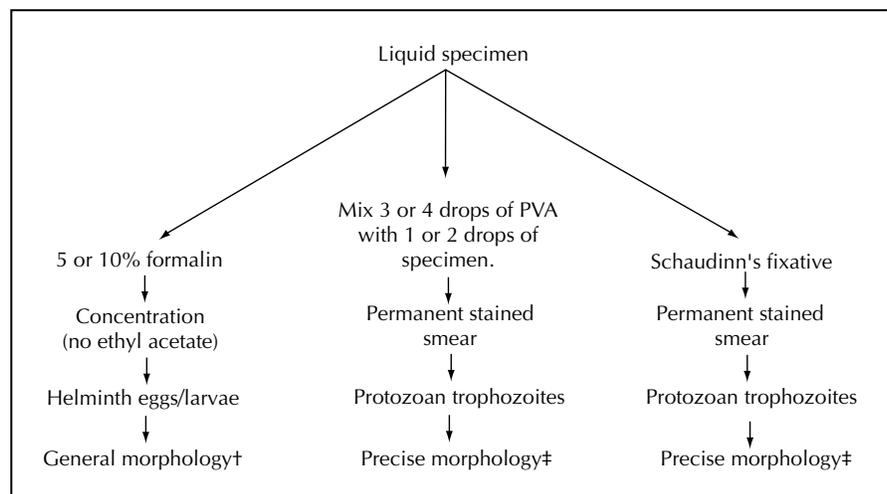

Figure 9.10.5–A2 Procedure for processing liquid specimens for the ova and parasite examination. Polyvinyl alcohol (PVA) and specimen will be mixed together on the slide, allowed to air dry, and then stained (fixation is sufficient for liquid specimen but not for formed stool). Symbols: †, some protozoa may not be identified from the concentration procedure; ‡, protozoa (trophozoites can be identified).

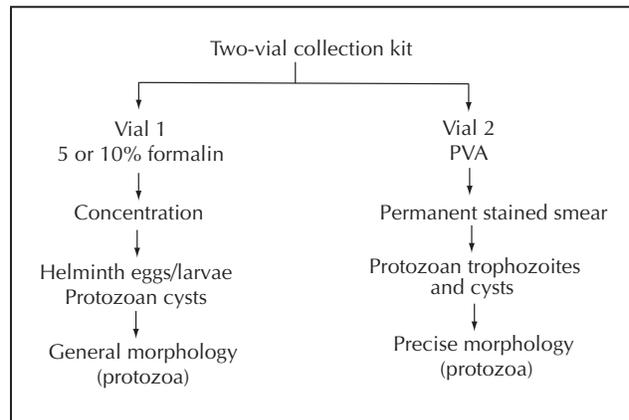

Figure 9.10.5-A3 Procedure for processing preserved stool for the ova and parasite examination. Fixatives and effects: mercuric chloride, best polyvinyl alcohol (PVA) (trichrome, iron hematoxylin); zinc, current best substitute (trichrome, hematoxylin probably okay); copper sulfate, fair substitute (trichrome, iron hematoxylin: both fair to poor); sodium acetate-acetic acid-formalin, good substitute for PVA fixative (iron hematoxylin is best, and trichrome is okay).

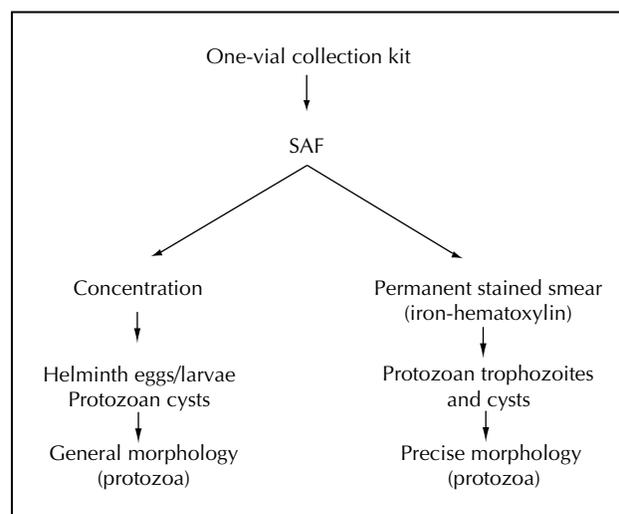

Figure 9.10.5-A4 Procedure for processing sodium acetate-acetic acid-formalin (SAF)-preserved stool for the ova and parasite examination. SAF can also be used with EIA, fluorescent-antibody, and cartridge immunoassay kits and the modified trichrome stain for microsporidia.

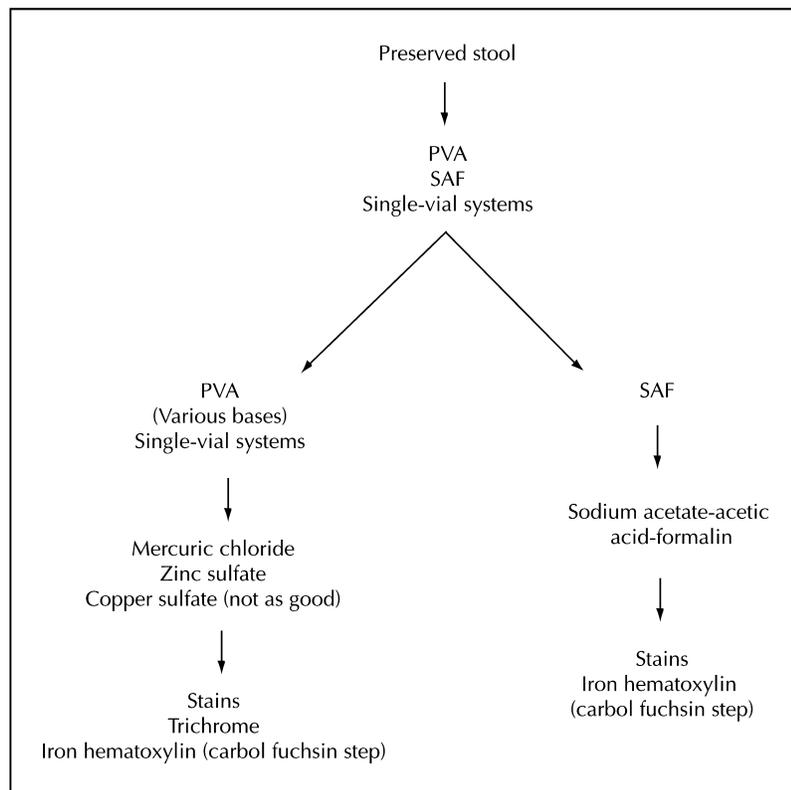

Figure 9.10.5–A5 Use of various fixatives and their recommended stains. PVA, polyvinyl alcohol; SAF, sodium acetate-acetic acid-formalin. Five or 10% formalin, SAF, and *some* of the single-vial systems can also be used with immunoassay kits and the modified trichrome stains for microsporidia.

9.10.6

Appendix 9.10.6–1—Commercial Supplies and Suppliers

See Tables 9.10.6–A1 to 9.10.6–A7 on the following pages. (Company names may not reflect recent mergers and subsequent name changes.)

^a Any procedure for the *Entamoeba histolytica/E. dispar* group or *E. histolytica* requires the use of fresh or fresh, frozen stools. All other tests (with the exception of direct fluorescent antibody [DFA] for the *Cryptosporidium-Giardia* combination) can be used with fresh, frozen, or preserved stools (formalized base, not PVA [some single-vial systems without PVA may be acceptable; consult the manufacturer]). Since the combination *Cryptosporidium-Giardia* tests (DFA) are based on visual recognition of the fluorescing oocysts and/or cysts, the specimens must not be frozen if fresh stools are used for testing.

Appendix 9.10.7–1—Current OSHA Regulations on the Use of Formaldehyde

OSHA requires all workers to be protected from dangerous levels of vapors and dust. Formaldehyde vapor is the air contaminant most likely to exceed the regulatory threshold in the clinical laboratory. Current OSHA regulations require vapor levels not to exceed 0.75 ppm (measured as a time-weighted average [TWA]) and 2.0 ppm (measured as a 15-min [short-term] exposure). *OSHA requires monitoring for formaldehyde vapor wherever formaldehyde is used in the workplace. The laboratory must have evidence at the time of inspection that formaldehyde vapor levels have been measured, and both 8-h and 15-min exposures must have been documented (1, 3, 4).*

If each measurement is below the permissible exposure limit and the 8-h measurement is below 0.5 ppm, no further monitoring is required providing the laboratory procedures remain constant. Changes in the laboratory that would require repeat monitoring include the following: large increase in the overall number of specimens processed each day (for example, from 20 to >100), change in location of reagents from inside a fume hood to outside the fume hood (on the open laboratory bench), or introduction of new procedures that require the use of forma-

lin. If either the 0.5-ppm 8-h TWA or the 2.0-ppm 15-min level is exceeded, monitoring must be repeated every 6 months. If either the 0.75-ppm 8-h TWA or the 2.0-ppm 15-min level is exceeded (unlikely in a clinical laboratory setting), employees are required to wear respirators. Accidental skin contact with aqueous formaldehyde must be prevented by the use of proper clothing and equipment (gloves, laboratory coats).

The amendments of 1992 add medical removal protection provisions to supplement the existing medical surveillance requirements for employees suffering significant eye, nose, or throat irritation and for those experiencing dermal irritation or sensitization from occupational exposure to formaldehyde. In addition, these amendments establish specific hazard labeling requirements for all forms of formaldehyde, including mixtures and solutions composed of at least 0.1% formaldehyde in excess of 0.1 ppm. Additional hazard labeling, including a warning label that formaldehyde presents a potential cancer hazard, is required where formaldehyde levels, under reasonably foreseeable conditions of use, may exceed 0.5 ppm. The final amendments also provide for annual training of all employees

exposed to formaldehyde at levels of 0.1 ppm or higher.

■ **NOTE:** Monitoring badges are not sensitive enough to correctly measure the 15-min exposure level. Contact the occupational health and safety office within your institution for monitoring options. Usually, the accepted method involves monitoring airflow in the specific area(s) within the laboratory where formaldehyde vapors are found.

Chemical Hygiene Plan

OSHA also requires each laboratory to develop a comprehensive, written chemical hygiene plan (CHP). Regardless of type of risk, volume, or concentration, every hazardous chemical in the laboratory must be included in the CHP. The plan should include storage requirements, handling procedures, location of OSHA-approved material, safety data sheets, and the medical procedures that are to be followed should exposure occur. The CHP must specify the clinical signs and symptoms of the environmental conditions (such as a spill) that would give the employer reason to believe exposure had occurred. When such conditions exist, the CHP should indicate the appropriate medical attention required (2).

9.10.8

Appendix 9.10.8–1—CPT Codes (Parasitology)

Current Procedural Terminology (CPT) comprises a list of descriptive terms and identifying codes for reporting medical services and procedures performed by physicians/laboratorians. The CPT list is published by the American Medical Association (AMA) (website, www.ama-assn.org/cpt). The most recent version is CPT 2003. The purposes of the CPT codes are to (i) provide a uniform language that will accurately describe medical, surgical, and diagnostic services and (ii) provide an effective means for reli-

able nationwide communication among physicians, patients, and third parties. The CPT list is the most widely accepted nomenclature for the reporting of physician/laboratory procedures and services under government and private health insurance programs.

CPT comparisons are used for claims processing and the development of guidelines for medical care review. They also provide a useful basis for local, regional, and national utilization comparisons. The CPT code format is a five-digit

code; one of the six sections is Pathology and Laboratory Medicine.

The following information should allow you to code the diagnostic parasitology procedures correctly for billing purposes. In addition, if a procedure requires the use of multiple codes, you should have this information in written form within your protocol manuals, preferably the appendix or another separate section so changes can be easily made without requiring changes in every individual protocol.

CPT codes for diagnostic parasitology

Procedure name	New CPT ^a	Comments
Agar plate culture (<i>Strongyloides</i>)	87081 + 87210	Includes culture and wet mount examination
Baermann concentration (plus examination)	87015 + 87210	Includes concentration and wet mount examination
<i>Cyclospora</i> examination (modified AFB ^b)	87207	Modified acid-fast stain
<i>Cryptosporidium</i> examination (modified AFB)	87207	Modified acid-fast stain
<i>Cryptosporidium</i> examination (FA)	87272	Immunoassay
<i>Cryptosporidium</i> examination (EIA)	87328	Immunoassay
<i>Cryptosporidium</i> / <i>Giardia</i> examination (FA)	87272	Immunoassay
<i>Cryptosporidium</i> / <i>Giardia</i> examination (EIA)	87328 (negative) 87328 (positive) + 2 more (87328)	Screen that detects both <i>Giardia</i> and <i>Cryptosporidium</i> but does not differentiate between the two. If positive (and individual antigens are subsequently tested), then a total of 3 87328 procedures is appropriate; if negative, then a single 87328.
<i>Cryptosporidium</i> / <i>Giardia</i> examination (cartridge)	87328	Possibility of two answers, but only one test (limit billing to once); immunoassay (immunochromatographic format)
<i>Cryptosporidium</i> / <i>Giardia</i> / <i>Entamoeba histolytica</i> - <i>E. dispar</i> group examination (cartridge)	87328	Possibility of three answers, but only one test (limit billing to once); immunoassay (EIA immunoassay format)
Ectoparasite identification (macroscopic) (arthropod)	87168	Macroscopic exam
Ectoparasite identification (wet mount) (arthropod)	87210	Wet mount examination
Ectoparasite identification (skin, scabies)	87220	
Fat, stool (qualitative)	82705	
<i>Giardia</i> examination (FA)	87272	Immunoassay
<i>Giardia</i> examination (EIA)	87328	Immunoassay

9.10.8.1

CPT codes for diagnostic parasitology (continued)

Procedure name	New CPT ^a	Comments
Harada-Mori concentration (plus examination)	87015 + 87210	Includes concentration and wet mount examination
Helminth egg hatching (concentration, wet mounts)	87177	Includes concentration and wet mount examination
<i>Isospora</i> examination (modified AFB only)	87207	Without concentration. 87015 + 87207 would be an option if this is an orderable test, which includes concentration and modified AFB stain.
Microsporidia, special stain (modified trichrome)	87015 + 87207	Modified trichrome on concentration sediment; includes concentration and modified trichrome stain
Microsporidia, fluorescent stain (calcofluor) (on concentration sediment)	87015 + 87206	Includes concentration and fluorescent stain (optical brightening agent) on sediment
Occult blood, stool	82270	
Occult blood, gastric	82273	
Ova and parasite examination	87177	Includes direct wet mount, concentration, and concentrate wet mount examinations. This <i>does not</i> include the permanent stain.
Ova and parasite examination (permanent stain) (example: trichrome)	88313	Permanent stain only
Ova and parasite examination (routine ova and parasite exam) (performed on <i>fresh stool</i> , includes direct wet mount)	87177 + 88313	Includes direct wet mount, concentration, concentrate wet mount, and permanent stained smear examinations (<i>Note:</i> There is an error in the code book under 87177 where 88312 is specified for trichrome—it should read 88313); CPT 2003 now states that 88313 should be used.
Ova and parasite examination (routine ova and parasite exam) (performed on <i>preserved stool</i> , no direct wet mount)	87015, 87210, 88313	Includes concentration, concentrate wet mount, and permanent stained smear examinations
Parasite concentration, iodine prep (wet prep only)	87015 + 87210	Includes concentration and wet mount examination (iodine mount)
Parasite concentration, saline prep 1 (wet prep only)	87015 + 87210	Includes concentration and wet mount examination (saline mount)
Saline prep 2 (wet prep only)	87210	Multiple wet mounts may have to be examined in certain circumstances: duodenal aspirates, string test mucus, urine concentrations, etc.
Saline prep 3 (wet prep only)	87210	
Saline prep 4 (wet prep only)	87210	
Saline prep 5 (wet prep only)	87210	
Parasite examination, wet prep only	87210	Wet mount examination
Parasite examination, duodenum (concentration, wet mounts)	87177	Includes direct wet mount, concentration, and concentrate wet mount examinations. This <i>does not</i> include any type of permanent stain.
Parasite examination, duodenum (permanent stain)	88313	Trichrome stain
Parasite examination, Entero-Test (wet mounts only)	87210	Entero-Test (string test, “fishing” test, capsule test): sampling of duodenal contents
Parasite examination, Entero-Test (permanent stain only)	88313	Trichrome
Parasite examination, urine (random) (concentration, wet mounts)	87015 + 87210	Includes concentration and wet mount examination; may include multiple wet mounts prepared/examined—use additional 87210 with modifier
Parasite examination, 24-h urine (concentration, wet mounts)	87015 + 87210	May be multiple wet mounts prepared/examined—use additional 87210 with modifier
Parasite concentration, blood (concentration, wet mounts)	87015 + 87210	May be multiple wet mounts prepared/examined—use additional 87210 with modifier (will include Knott and membrane concentrations using Nuclepore filters)
Parasite, calcofluor stain (direct material, no concentration)	87206	Optical brightening agent; fluorescence
Parasite concentration (miscellaneous)	87015	Concentration only
Giemsa stain, thin blood film	87207	Giemsa stain
Giemsa stain, thick blood film	87015 + 87207	Includes concentration and Giemsa stain

(continued)

CPT codes for diagnostic parasitology (continued)

Procedure name	New CPT ^a	Comments
Parasite culture (intestinal and blood protozoa)	87081 + 87015 + 87210 + 87207 (Giemsa) or 88313 (trichrome)	Includes culture, concentration, wet mount, permanent stain of culture sediment (intestinal and blood protozoa)
Parasite culture, presumptive, screening only (<i>Trichomonas</i>)	87081	(Pouch) (screen) (microscope exam through plastic pouch)
Parasite culture, presumptive, screening only (<i>Acanthamoeba</i>)	87081 + 87210 + 87205 (Giemsa)	Includes culture (agar plates/bacterial overlay), wet mount, permanent stain (for the trichrome stain, use 88313, not 87205)
Parasite detection (<i>E. histolytica</i> / <i>E. dispar</i> group EIA)	87336	Immunoassay for the <i>E. histolytica</i> / <i>E. dispar</i> group; does not differentiate the true pathogen, <i>E. histolytica</i> ; immunoassay
Parasite detection (<i>E. histolytica</i> EIA)	87337	Should read <i>E. histolytica</i> ; specific for the true pathogen, <i>E. histolytica</i> ; immunoassay
Parasite detection (<i>Cryptosporidium</i> / <i>Giardia</i> EIA)	87328 (negative) 87328 (positive) + 2 more (87328)	Immunoassay that detects both <i>Giardia</i> and <i>Cryptosporidium</i> , but does not differentiate between the two. If positive, then a total of 387328 procedures is appropriate; if negative, then a single 87328.
Parasite detection, EIA (<i>Cryptosporidium</i> only)	87328	Immunoassay
Parasite detection, EIA (<i>Giardia</i> only)	87328	Immunoassay
Parasite examination, blood (thin film)	87207	Giemsa stain
Parasite examination, blood (thick film)	87015 + 87207	Includes concentration and Giemsa stain
Parasite referral in (stool for ova and parasite exam)	87177 + 88313	Includes direct wet mount, concentration, concentrate sediment, and permanent stained smear examinations
Petri dish culture/concentration (plus examination)	87015 + 87210	Includes concentration and wet mount examination
pH, stool	83986	pH, body fluid, except blood (probably the best option), previously approved by consultants
Pinworm examination	87172	Single cellophane tape/paddle/other device examination
Reducing substances, stool (pH)	83986	
Tissue homogenization for culture	87176	Since this may not have been specifically ordered by physician, may not be billable unless part of written routine algorithm approved by medical staff and pathology for handling tissues
Trypsin activity, stool	84488	
Worm identification (macroscopic)	87169	Example: <i>Ascaris</i> adult worm
Worm identification (wet mount)	87210	Example: <i>Enterobius</i> adult worm; small structures that resemble worms

^a Each time a procedure requires multiple codes for billing, this information should be included in your protocol manuals, possibly in a separate section within the appendix (specifying that the procedure includes multiple coded procedures, thus the need for multiple codes; define procedure and each code required [could be in table format]). This information is similar to that required for the use of laboratory algorithm testing, in which multiple steps/procedures are required to complete a more comprehensive test or series of tests.

^b AFB, acid-fast bacilli.

10.1

Laboratory Diagnosis of Viral Infections: Introduction

The virology laboratory uses several diagnostic modalities, including culture, antigen and nucleic acid detection assays, cytohistopathology, and serologic methods, to aid the physician in the diagnosis of viral infections. The method of choice is influenced by several variables, including the nature of the suspected virus, the availability of test reagents, and the intended purpose of the assay (e.g., detecting active infection, assessing response to therapy). Since no single test modality can satisfy all needs, the laboratory scientist must carefully assess factors such as the patient population and setting as well as

the needs and resources of the facility. Furthermore, knowledge of the natural history and pathogenesis of viral infections is essential for the optimal implementation of assays and the interpretation of results.

Maintaining active communication with other laboratories serves to enhance identification of cell culture and reagent problems and is useful in identifying sources of reference materials and training opportunities. In some cases, arrangements may be made whereby laboratories may perform the initial steps of viral culture and forward isolates to other labora-

tories, including state health departments, for identification. This is useful in that specimens are not compromised by storage and transport prior to inoculation and culture can be provided in settings where it remains useful but in which resources are limited.

Information provided in this section is useful not only for a full-service virology laboratory but also for those sites offering a limited test menu or dispatching specimens to off-site or reference laboratories. Human viral infections are summarized in Table 10.1–1, while zoonotic viral infections are summarized in Table 10.1–2.

Table 10.1-1 Clinical manifestations of human viral diseases^a

Viral agent	Respiratory	CNS and neuromuscular	Genitourinary tract	Mucocutaneous	Gastrointestinal	Ocular	Other
Adenoviruses (51 types)	URI (common cold, pharyngitis, tonsillitis), pertussis syndrome, acute respiratory disease, bronchitis, pneumonia	Rare: meningitis, encephalomyelitis	Acute hemorrhagic cystitis	Exanthems	Gastroenteritis (types 40 and 41), hepatitis	Conjunctivitis, pharyngoconjunctival fever, follicular conjunctivitis, epidemic keratoconjunctivitis, acute hemorrhagic conjunctivitis	Immunocompromised patients (10); pneumonia, gastroenteritis, meningoencephalitis, disseminated disease
Coronaviruses	Common cold, pneumonia				Gastroenteritis		
Enteroviruses							
Coxsackie group A (types 1-22, 24)	Common cold, pharyngitis, pneumonia in infants	Aseptic meningitis, acute rhabdomyolysis, paralysis (uncommon)		Herpangina; lymphonodular pharyngitis; gingivostomatitis; hand, foot, and mouth disease; exanthems (vesicular, petechial, maculopapular)	Infantile diarrhea, hepatitis	Acute hemorrhagic conjunctivitis	Undifferentiated febrile illness; severe disease in neonates and in individuals with agammaglobulinemia
Coxsackie group B ^b (types 1-6)	URI, pneumonia	Meningoencephalitis (infants), paralysis (uncommon)		Exanthems (maculopapular, vesicular, and petechial)	Hepatitis		Undifferentiated febrile illness, myocarditis, pericarditis, pleurodynia; severe disease in neonates and in individuals with agammaglobulinemia
Echoviruses (types 1-7, 9, 11-21, 24-27, and 29-33)	URI	Aseptic meningitis, encephalitis, paralysis, acute rhabdomyolysis		Exanthems (maculopapular, vesicular, petechial, hemangioma-like)			Undifferentiated febrile illness, diabetes/pancreatitis, orchitis; severe disease in neonates and in individuals with agammaglobulinemia
Enterovirus type 68	Pneumonia, bronchiolitis	Paralytic myelitis					
Enterovirus type 70		Aseptic meningitis, meningoencephalitis, paralysis		Hand, foot, and mouth disease			
Enterovirus type 71		Aseptic meningitis, poliomyelitis, paralysis				Acute hemorrhagic conjunctivitis	
Polioviruses (3 types)							
Gastroenteritis viruses (1) (e.g., Noroviruses)					Common-source outbreaks of gastroenteritis		Associated with contaminated drinking water and shellfish

Hepatitis viruses (A–G)				Hepatitis	HBV and HCV associated with hepatocellular carcinoma
Herpesviruses CMV	Neonatal pneumonitis				Heterophile-negative mononucleosis; congenital CMV syndrome; immunocompromised individuals; pneumonia, hepatitis, retinitis, encephalitis, myelitis, polyradiculopathy, gastrointestinal disease (esophagitis, gastritis, colitis, papillary stenosis, cholangitis, hepatitis, proctitis), adrenalitis, bone marrow graft suppression
Epstein-Barr virus	Pharyngitis, tonsillitis			Hepatitis	Infectious mononucleosis (complications include splenic rupture, chronic mononucleosis syndrome); associated with Burkitt's lymphoma, nasopharyngeal carcinoma; AIDS-associated CNS lymphoma
Herpes simplex (2 types)	Pharyngitis	Meningoencephalitis, encephalitis, Mollaret's meningitis (recurrent aseptic meningitis)	Anogenital vesicular/ulcerative mucocutaneous lesions, cervicitis	Proctitis	Infection may be severe in neonates; CNS and disseminated disease can occur in the absence of mucocutaneous lesions; immunocompromised patients: severe/persistent mucocutaneous lesions, proctitis, esophagitis, encephalitis, hepatitis, pneumonitis
HHV-6		Meningitis, meningoencephalitis in young children (12, 15)			Febrile illness; opportunistic infection in immunocompromised individuals, particularly bone marrow and organ transplant recipients (8, 18) and HIV-infected individuals (17)
HHV-7					
HHV-8					
Varicella-zoster virus	Pneumonia	Rare: cerebellar ataxia	Chickenpox, shingles	Hepatitis	Associated with Kaposi's sarcoma (7, 11, 16), multicentric Castleman's disease (19), and body cavity-based lymphomas (6)
			Exanthem subitum (22)		Neonatal disease may be severe; congenital disease is rare; immunocompromised patients: zoster, visceral disease, retinitis, encephalitis, myelitis

(continued)

Table 10.1-1 Clinical manifestations of human viral diseases^a (continued)

Viral agent	Respiratory	CNS and neuromuscular	Genitourinary tract	Mucocutaneous	Gastrointestinal	Ocular	Other
Human papillomaviruses (>100 types)	Laryngeal papillomatosis		Condylomata, anogenital intraepithelial neoplasia (14)	Common warts, plantar warts, epidermodysplasia verruciformis			Immunocompromised patients: disease generally more severe or progressive, e.g., AIDS patients; associated with cervical carcinoma (20)
Influenza virus types A, B, and C	Influenza, pneumonia (particularly in elderly and debilitated), otitis media, sinusitis						Severely immunocompromised adults may be at risk for pneumonia
Paramyxoviruses Mumps		Meningoencephalitis, aseptic meningitis, encephalomyelitis Rare: meningitis					Orchitis, oophoritis, pancreatitis
Parainfluenza viruses (4 types)	Laryngotracheobronchitis (croup), bronchiolitis, tracheobronchitis, pneumonia						Severely immunocompromised adults may be at risk for pneumonia
Respiratory syncytial virus	URI, bronchiolitis, pneumonia, croup						Most important cause of severe respiratory disease in children; in adults, severe disease occurs in elderly or immunocompromised patients (e.g., bone marrow transplant recipients) and those with underlying cardiopulmonary disease (9) Immunocompromised patients: giant cell pneumonia
Measles virus (rubeola)		Encephalitis, SSPE		Measles			
Parvovirus B 19		Arthralgia		Erythema infectiosum (fifth disease)			Aplastic crisis in sickle cell patients; immunocompromised patients; chronic anemia; congenital disease (fetal hydrops)

Polyomaviruses (BK and JC viruses)	JC virus is associated with progressive multifocal leukoencephalopathy in immunocompromised patients.	BK virus is associated with interstitial nephritis and hemorrhagic cystitis in renal transplant recipients.
Poxviruses Molluscum contagiosum Vaccinia virus		Pearly nodular exanthem with caseous exudate Mucocutaneous vesicles
Reoviruses	URI, pharyngitis	Maculopapular rashes Gastroenteritis
Retroviruses HIV-1 HIV-2 HTLV-1	Encephalomyopathy and dementia HTLV-associated myelopathy, tropical spastic paraparesis	Association with disease is not well documented; rarely isolated from clinical samples AIDS AIDS Associated with adult T-cell leukemia
Rhinoviruses (> 100 types)	Common cold; lower respiratory tract disease may occur with predisposing conditions	
Rotaviruses		Gastroenteritis, primarily among infants Infection may be chronic in immunocompromised patients
Rubella virus (German measles)	Arthralgia, polyarthritis (these occur primarily in females)	Maculopapular rash Congenital rubella syndrome

^a Abbreviations: CNS, central nervous system; URI, upper respiratory infection; HBV, hepatitis B virus; HCV, hepatitis C virus; CMV, cytomegalovirus; HHV, human herpesvirus; KS, Kaposi's sarcoma; HIV, human immunodeficiency virus; HTLV, human T-cell leukemia virus; SSPE, subacute sclerosing panencephalitis.

^b Coxsackievirus A23 shown to be echovirus type 9; echovirus type 10 reclassified as a reovirus; echovirus type 28 reclassified as rhinovirus type 1; echovirus type 34 is related to coxsackievirus A24 as a prime strain; disease association has not been demonstrated for enterovirus type 69.

Table 10.1-2 Zoonotic viral infections associated with human disease^a

Virus	Respiratory	Central nervous system and neuromuscular	Mucocutaneous	Gastrointestinal	Other	Lab diagnosis	Comments
Arboviruses (3) Arthropod-borne viruses; include viruses belonging to several major families, including <i>Togaviridae</i> , <i>Flaviviridae</i> , <i>Bunyaviridae</i> , <i>Bunyaviridae</i> , and <i>Reoviridae</i> , and <i>Rhabdoviridae</i>		Encephalitis (e.g., EEE, WEE, VEE, SLE, Everglades, California LaCrosse, Jamestown Canyon, and Powassan viruses); myalgia, arthralgia (e.g., Colorado tick fever, dengue)	Maculopapular rashes (several, including dengue)	Hepatitis (e.g., yellow fever)	Undifferentiated febrile illness (several, including Colorado tick fever); hemorrhagic fever (e.g., Rift Valley fever, dengue, yellow fever)	Serology: IgM testing on serum, plasma, and CSF; follow-up with convalescent-phase serum samples to demonstrate diagnostic titer increases and/or confirmation with other assays (e.g., neutralization) RT-PCR, isolation, antigen: blood (viremia usually brief); CSF; autopsy tissues (brain, spleen, lung, liver)	Humans are incidental hosts, with transmission by hematophagous arthropod vectors (primarily mosquitoes but also ticks or flies); BSL 2, BSL 3, or BSL 4 level required, with agents causing encephalitis or hemorrhagic fever requiring the higher biosafety levels.
Arenaviruses Lassa fever virus and other viruses causing hemorrhagic fevers					Lassa fever, hemorrhagic fever	Serology: LCMV testing more widely available than other agents RT-PCR, isolation, antigen, etc.: blood, nasopharyngeal washing, CSF (LCMV), autopsy tissues	Maintained in nature in rodent hosts. Transmission is usually via an aerosol route from human to human or following exposure to infected rodent excreta. Except for LCMV, these viruses are geographically restricted to tropical Africa and South America and require BSL-4 containment practices. LCMV is widely distributed, with the house mouse (<i>Mus musculus</i>) being its natural host. Infected mice and hamsters are important sources to laboratory workers and pet owners.
LCMV (2)	Flu-like illness	Aseptic meningitis, meningoencephalitis			Undifferentiated febrile illness	See above	See above

Filoviruses Ebola, Marburg virus		Same as for arenaviruses	Same as for arenaviruses
Hantaviruses <i>Bunyaviridae</i>	HPS: sin nom- bre virus (13)	Hemorrhagic fever with renal syndrome (e.g., Korean hemorrhagic fever virus)	Mice (e.g., deer mouse [<i>Peromyscus maniculatus</i>]) are the natural hosts. Transmission is by the aerosol route after exposure to infected rodent excreta; person-to-person transmission does not appear to occur.
Paramyxoviruses (21)	Newcastle disease virus	Conjunctivitis	Transmission is by the aerosol route from infected fowl to humans in the poultry industry. Transmission by bats to livestock, with transmission to humans handling infected animals
	Hendra, Nipah	Isolation in cell culture	
	Flu-like illness		
	Flu-like illness		
Poxviruses (para- and orthopoxviruses)			
	Milker's nodule (pseudocowpox), orf (pustular dermatitis; sheep and goats), monkeypox	Serology: acute- and convalescent-phase serum samples Cytohistopathology: detection of typical eosinophilic cytoplasmic inclusion bodies (Guarnieri bodies) PCR, isolation, antigen: lesion scrapings	Occurs in individuals exposed to infected animals; limited testing available through public health laboratories or the CDC

(continued)

Table 10.1-2 Zoonotic viral infections associated with human disease^a (continued)

Virus	Respiratory	Central nervous system and neuro-muscular	Mucocutaneous	Gastrointestinal	Other	Lab diagnosis	Comments
Rabies		Encephalitis				<p>Postmortem (human and animal): immunofluorescence (brain); confirmation by culture (e.g., mouse neuroblastoma cultures).</p> <p>Antemortem (human only): RT-PCR (saliva), immunofluorescence (skin biopsy with several [~10] hair follicles from the posterior region of the neck just above the hairline, corneal impression); neutralization test (serum, CSF); viral culture (saliva)</p>	<p>Humans are accidental hosts after exposure to infected animals. In North America, rabies virus cycles in bats, foxes, skunks, raccoons, and coyotes, with spillover to many other wild and domestic species. Contact the local or state public health laboratory, or the CDC, for information regarding handling and shipping of animals and specimens for testing and for postexposure prophylaxis guidelines, including following known or possible bat contact. BSL 2 practices are adequate for routine diagnostic activities; individuals preparing animals for shipment should wear heavy rubber gloves and protective clothing, including a face shield. BSL 3 facilities are necessary for research and vaccine production activities.</p>

<p>Simian B virus (<i>Herpesviridae</i>)</p>	<p>Encephalitis</p>	<p>Vesicular lesions</p>	<p>Isolation: lesion specimen (vesicular fluid, lesion swab or scraping). Although isolation is possible in cells routinely available in the diagnostic laboratory (e.g., PMK), testing should be referred to a specialized laboratory. Serology: EIA, Western blot</p>	<p>Simian B virus (herpesvirus simiae) is indigenous to Old World monkeys such as rhesus (<i>Macaca mulatta</i>), cynomolgus (<i>Macaca fascicularis</i>), and other Asiatic monkeys of the genus <i>Macaca</i>. Infection in primates is asymptomatic or manifested by dermal, oral, ocular, or genital lesions. Transmission to humans occurs primarily by bites or by direct contact (5) with saliva or infected tissues, although human-to-human transmission has been reported (4). Testing available through the B Virus Research and Reference Laboratory at Georgia State University, (404) 651-0808. BSL 2 is recommended for activities involving the use or manipulation of tissues, body fluids, and primary tissue culture material from macaques, with BSL 3 recommended for activities involving the use or manipulation of any materials known to contain this virus.</p>
--	---------------------	--------------------------	---	---

^a Abbreviations: EEE, eastern equine encephalitis; WEE, western equine encephalitis; VEE, Venezuelan equine encephalitis; SLE, St. Louis encephalitis; LCMV, lymphocytic choriomeningitis virus; IgM, immunoglobulin M; RT-PCR, reverse transcription-PCR; HPS, hantavirus pulmonary syndrome.

10.2

Selection, Maintenance, and Observation of Uninoculated Monolayer Cell Cultures

I. PRINCIPLE

Viruses are obligate intracellular parasites requiring metabolically active cells to support their replication. While many viruses of diagnostic interest can be cultured in readily available monolayer cell cultures (Table 10.2–1), there are several agents that can be isolated only using specialized systems (Table 10.2–2) such as organ culture (e.g., coronaviruses), leukocyte culture (e.g., the human immunodeficiency viruses and Epstein-Barr virus), or animals (e.g., rabies, virus, several coxsackie A vi-

ruses, and arboviruses). In addition, there are several important viral agents for which an *in vitro* system has not been identified (e.g., hepatitis B and C viruses, human papillomaviruses, Norwalk virus, and parvovirus B19).

Cell cultures routinely used in the diagnostic laboratory are available commercially (Appendix 10.2–1) and consist of single layers (monolayers) of metabolically active cells which are adherent to the surface of a tube or to a coverslip con-

tained in a flat-bottomed shell vial. Viruses exhibit a selective pattern of replication in cell cultures. The number of different cell culture types utilized should be consistent with the anticipated spectrum of isolates. This procedure provides information necessary for laboratories using commercially supplied cell cultures. For on-site preparation of cell cultures, refer to procedure 10.3.

II. MATERIALS

A. Cell culture monolayers (received or prepared at least weekly)

Viral culture laboratories generally utilize a combination of tube and shell vial cultures. Shell vials are particularly valuable for performing cytomegalovirus (CMV) (7, 15) and varicella-zoster virus (VZV) (6, 17, 24) cultures but have been applied to the rapid detection of several other viruses, including herpes simplex virus (HSV) (8), respiratory viruses (3–5, 9, 12, 14, 19, 23), and measles virus (13). Although the shell vial technique is rapid and provides good sensitivity in many cases, some laboratories have experienced lower rates of recovery of CMV from blood (10, 15) and of adenoviruses from respiratory samples (14) with shell vial cultures. See Appendix 10.2–1 for commercial cell culture sources.

B. Culture medium

Eagle's minimum essential medium in either Earle's or Hanks' balanced salt solution (EBSS or HBSS, respectively) and containing 2% heat-inactivated fetal bovine serum (FBS) is a medium suitable for the maintenance of rou-

tinely used, uninoculated and inoculated monolayer cell cultures (*see* Appendix 10.2–2).

C. Supplies

1. Racks designed to hold culture tubes in a horizontal position, with the tube necks slightly raised, or shell vials in the upright position
2. Sterile individually wrapped pipettes (5 and 10 ml) and safety pipetting devices
3. PPE
4. 1:10 Dilution of household bleach
5. Autoclavable containers

D. Equipment

1. Microscope ($\times 100$)

Shell vials can be examined by using an inverted microscope with a glass microscope slide used to support the vial. Tube cultures can be examined with a standard or inverted microscope; tubes can be held in place with a holder consisting of two parallel tracks glued to the stage.

☑ **NOTE:** One end of the holder should be slightly higher so that the culture medium does not flow into the caps during observation.

Table 10.2–1 Cell cultures used for viral culture^a

Virus ^a	Cell cultures (references) ^b	Comments (references) ^c
Adenovirus types 1–39, 42, and higher	HNK, A-549	Primary or low-passage human kidney cells are preferred to continuous cell lines; isolation in PMK is variable.
Adenovirus types 40–41 (enteric)	Graham-293 (1, 21), A-549	
BK virus	MRC-5, WI-38, HF, HNK	CPE may require several weeks to develop; can use shell vial cultures. Antibody to simian virus 40 T antigen cross-reacts with human polyomaviruses.
CMV	MRC-5, WI-38, HF, ML (shell vials)	
Enteroviruses (poliovirus types 1–3; echovirus types 1–7, 9, 11–21, 24–27, 29–33; group A coxsackievirus types 1–22, 24; group B coxsackievirus types 1–6; enterovirus types 68–71)	Maximum recovery achieved with a panel of 4 cell types (primary human and monkey kidney cells, BGMK, H292 RD; diploid human lung cells (e.g., MRC-5) have limited sensitivity.	RD cells support the replication of a number of group A coxsackieviruses that cannot be cultivated in other cell lines (11, 18). However, this cell line monolayer overgrows rapidly and is difficult to interpret.
HSV types 1 and 2	A-549, RK, ML, HNK, MRC-5, WI-38	Isolation in less sensitive cell lines (e.g., MRC-5) may be enhanced by using shell vial cultures. A genetically engineered baby hamster kidney cell line, which contains a reporter transgene for HSV, has been shown to be useful for detecting this virus in shell vials (16, 20).
Influenza virus types A, B, and C	PMK (rhesus), A-549	MDCK cells provide good sensitivity with incorporation of trypsin (1–2 µg/ml) in cell culture medium (5, 22).
Measles virus	PMK, HNK, A-549 shell vials (13)	
Mumps virus	PMK, HNK	
Parainfluenza virus types 1–4	PMK (rhesus) HNK, A-549	
Poxviruses (orthopoxviruses [e.g., vaccinia, monkeypox, cowpox] and parapoxviruses [e.g., orf, milker's nodule])	PMK, MRC-5, WI-38, HNK	
Respiratory syncytial virus	HEp-2, H292, A-549	PMK and MRC-5 are also useful (2) but do not develop characteristic CPE.
Reovirus types 1–3	PMK, PHK	Not commonly isolated
Rhinoviruses (>100 types)	MRC-5, WI-38, PMK	
Rubella virus	AGMK	
VZV	MRC-5, WI-38, A-549	Shell vials recommended

^a Coxsackie A23 shown to be echovirus type 9; echovirus type 10 reclassified as a reovirus; echovirus type 28 reclassified as rhinovirus type 1; echovirus type 34 is related to coxsackievirus A24 as a prime strain.

^b A-549, human epidermoid lung carcinoma; AGMK, primary African green monkey kidney; BGMK, Buffalo green monkey kidney; Graham-293, adenovirus-transformed human kidney; H292, human pulmonary epidermoid carcinoma; HLF, MRC-5, and WI-38, diploid human lung fibroblasts; HNK, human neonatal kidney; MDCK, Madin-Darby canine kidney; ML, mink lung; RD, rhabdomyosarcoma; RK, rabbit kidney; PMK, primary monkey kidney (rhesus, cynomolgous).

^c Some viral agents requiring biosafety levels not generally available in the diagnostic setting may be either isolated (e.g., variola major) or cultivated after adaptation (e.g., selected arboviruses) using some cell culture types included in this table.

Table 10.2–2 Viral culture systems and availability

Culture system	Culture availability	Viruses
Routinely available monolayer cell cultures	Widely available, with a few exceptions (BK, rubella, vaccinia)	Adenoviruses, group A coxsackieviruses (not all types), group B coxsackieviruses, CMV, echoviruses, enterovirus types 68–71, HSV, influenza viruses, measles virus (rubeola), mumps virus, parainfluenza viruses, polioviruses, polyomavirus (BK), reoviruses, respiratory syncytial virus, rhinoviruses, rubella virus, vaccinia virus, VZV
Leukocyte cultures	Not typically available in the diagnostic setting	Human herpesvirus type 6 ^a ; human immunodeficiency virus type 1, Epstein-Barr virus
Specialized cell cultures or techniques (e.g., organ cultures)	Research settings	Coronaviruses, hepatitis type A virus (enterovirus type 72), hepatitis type E virus, para- and yatapoxviruses, rotaviruses
Animal hosts (suckling mice)	Not available in the diagnostic setting Specialized reference labs, state laboratories, CDC	Several types of group A coxsackieviruses Rabies, ^b arboviruses, ^b arenaviruses, ^b filoviruses ^b
Noncultivable		Papillomaviruses, molluscum contagiosum, parvovirus B19, hepatitis viruses (other than types A and E), Noroviruses

^a Has been cultivated in human lung fibroblast shell vial monolayer cultures.

^b Replicate in some cell lines (e.g., Vero, LLC-MK₂). Several require BSL 3 or BSL 4 containment; clinical presentation and travel and/or exposure history should alert the laboratorian to the possibility of these agents and the need to use appropriate precautions. Contact a local public health laboratory or the Special Pathogens Branch, CDC, regarding information and testing.

II. MATERIALS (continued)

2. Class II biological safety cabinet

It is highly recommended that separate cabinets be used for uninoculated and inoculated monolayers. If a single cabinet is used, uninoculated cell culture work should precede work with specimens or stock viruses, with decontamination in between. Before and after each use, wipe down all surfaces with 70% ethanol or a high-level disinfectant such as 2% alkaline glutaraldehyde. While 0.5% sodium hypochlorite is good for routine decontamination, it may corrode the stainless steel

surfaces. Do not impede the airflow within the unit by blocking airflow vents. Avoid disrupting the air curtain at the front of the hood; minimize movements into and out of the hood, and avoid outside air turbulence such as that created by air conditioning units or open doors or windows. Do not use the unit for storage; remove all supplies at the completion of work.

3. Refrigerator at 2 to 8°C

4. Incubator (35 to 37°C)

☑ **NOTE:** CO₂ atmosphere is not necessary for closed containers.

III. ASSESSMENT, MAINTENANCE, AND QUALITY CONTROL OF UNINOCULATED CELL CULTURES

A. Assessment

Cell cultures may exhibit extensive lot-to-lot variation in appearance and quality. Assess each lot upon receipt by visually and microscopically observing the monolayers as described in Fig. 10.2–1 and Table 10.2–3.

B. Maintenance (refeeding)

Since cell cultures are used within 5 to 7 days of receipt, refeeding with fresh medium is generally not necessary until the time of inoculation. One indication for interim refeeding is a low pH (see Table 10.2–3).

1. Discard the medium (decant, aspirate, or pipette).

☑ **NOTE:** Be careful not to scrape the monolayer with the pipette.

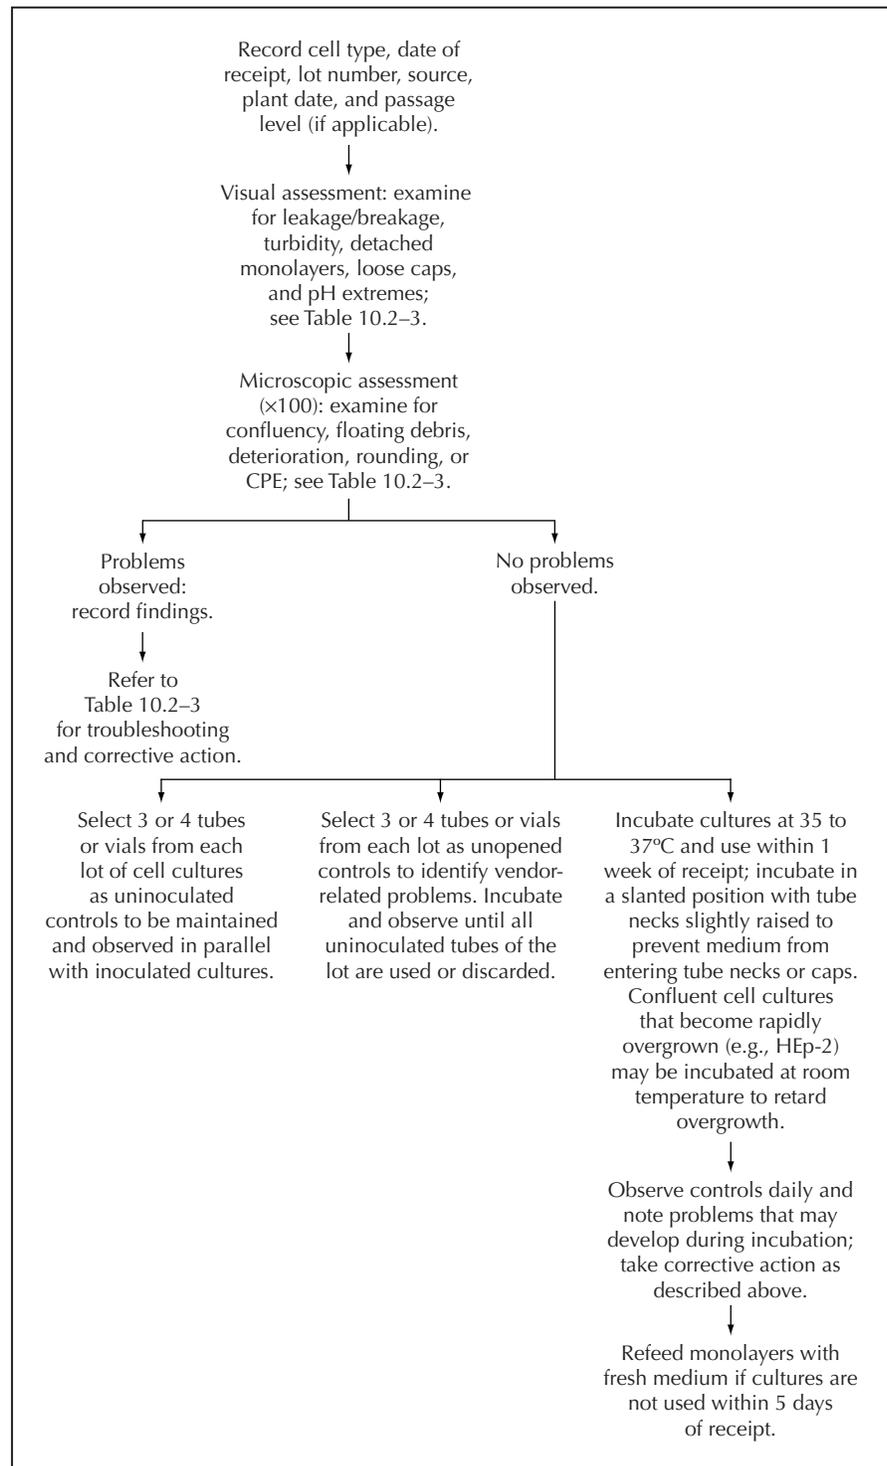

Figure 10.2-1 Assessment, incubation, and maintenance of uninoculated cell cultures.

Table 10.2-3 Assessment of monolayered cell cultures and troubleshooting

Component	Appearance	Possible cause(s)	Corrective action
Medium ^a	Clear yellow (low pH)	CO ₂ accumulation	Examine microscopically for evidence of microbial contamination. If none, refeed with fresh maintenance medium and incubate. Reevaluate after 18–24 h. Retain approximately four to six tubes without medium change for observation.
	Clear purple (high pH)	Loose caps Shipping trauma, chilling Poor cell quality, metabolically inactive cells; sparse monolayer	Tighten caps; incubate. Notify vendor. Incubate for several hours or overnight and reevaluate. Notify vendor. Incubate; reject if not satisfactory within 24 h.
	Turbid or organisms visible	Bacterial/fungal contamination ^b	Notify vendor; reject. Do not open.
Monolayer ^c	Sparse (less than 60–70%)	Seeded too sparsely, cells failed to divide, medium or glassware problem	Notify vendor. Incubate and reject if not satisfactory within 24–48 h.
	Cells piled/detached	Seeded too heavily, old monolayer or poor cell quality, mycoplasmal contamination ^d , medium or glassware problem, temperature extremes, inverted during shipment	Notify vendor. Reject if extensive.
	Cellular granularity and/or rounding	Shipping trauma, chilling, poor cell quality, bacterial/fungal contamination ^b , mycoplasmal contamination ^d , medium or glassware problem	Incubate for several hours or overnight, and reevaluate. Notify vendor; reject if improvement not observed.
	CPE and/or HAd	Endogenous or contaminating viruses, mycoplasmas	Primary simian cells are frequently contaminated with endogenous viruses. Perform appropriate QC to monitor extent of contamination and effect on sensitivity of cultures. May mimic human viral CPE, cause HAd, or interfere with the recovery of viruses from clinical samples. If a herpeslike CPE is observed, notify the vendor immediately and do not open the tubes because cell cultures may contain simian B virus, which is associated with a high mortality rate in humans. <i>Note:</i> Primary simian cell cultures may be obtained with medium containing antibodies to simian viruses (SV5 and SV40) which may temporarily retard the replication of these viruses.

^a Should be clear and orange-red to cherry pink (pH 6.8 to 7.2).

^b Perform Gram stain of sediment obtained from centrifuged culture supernatant; inoculate broth medium (e.g., THIO, TSB) or agar (e.g., blood, Sabouraud dextrose) with sediment and culture medium, and observe for bacterial or fungal growth for 10 to 14 days.

^c Monolayered cell cultures should consist of a single layer of adherent cells exhibiting normal morphology at or near confluency (100% monolayer). Monolayers that are slightly subconfluent are preferred for viral culture.

^d Mycoplasmal contamination can have a profoundly detrimental effect on viral isolation. Contamination with these organisms frequently does not result in obvious changes of the cell monolayer but may present as a generalized deterioration of the monolayer; occasionally a CPE mimicking viral growth may be observed. Obtain written certification from the vendor that cultures are mycoplasma free.

III. ASSESSMENT, MAINTENANCE, AND QUALITY CONTROL OF UNINOCULATED CELL CULTURES (continued)

2. Add 1 to 2 ml of cell culture maintenance medium to each tube or vial.
 - **NOTE:** Use separate pipettes for each lot of each cell line; change pipettes frequently.

C. QC

1. Select monolayers from each lot to serve as controls as described in Fig. 10.2-1. Incubate and observe these in parallel with viral cultures.
2. Titration of viral reference material is useful for comparing different lots or sources of cell cultures or when there are concerns regarding sensitivity. For this purpose, use archived aliquots of characterized isolates or obtain refer-

III. ASSESSMENT, MAINTENANCE, AND QUALITY CONTROL OF UNINOCULATED CELL CULTURES (*continued*)

ence material from another laboratory or from ATCC, Manassas, Va. To assess relative sensitivities, perform parallel titrations using serial 10-fold dilutions of the virus stock (Appendix 10.5–1). Incubate and observe the titrations by following the procedure routinely employed for isolation of the particular virus.

IV. CELL CULTURE CONTAMINANTS

A. Bacterial and mycotic

Bacterial and fungal contamination may originate from many sources, including contaminated reagents or supplies, room air, work surfaces, or the technologist. A good QC program, rigorous training, and adherence to aseptic techniques are essential.

1. Ensure proper use of a certified and adequately maintained class II biological safety cabinet.
2. Use aseptic technique (Appendix 10.2–3).

B. Mycoplasmal

Mycoplasma contamination of cell cultures may not be obviously apparent by routine macroscopic and microscopic evaluation, but it nonetheless may interfere with the quality and viability of serially propagated cell cultures.

1. Obtain confirmation from commercial suppliers that all cell lines are monitored for mycoplasma contamination.
2. Contamination of continuous cell lines maintained in the laboratory can occur from several sources, including serum and trypsin. Monitor continuous cell lines at least quarterly for mycoplasma contamination (*see* procedure 10.3).

C. Viral

Cell cultures may be contaminated with endogenous viruses, which can interfere with viral isolation, be mistaken for a true isolate, or even present a biohazard. While endogenous viruses are not limited to simian cells, culture contamination in the diagnostic laboratory is associated primarily with these cells. Primary monkey kidney cells are frequently contaminated with endogenous viruses which may produce cytopathic effect (CPE), as with simian virus 40 (SV40), or positive hemadsorption (HAD), as with SV5. Infections in humans caused by simian herpesvirus B are associated with a high mortality rate. While most human infections are associated with direct animal contact, the possibility exists that cell cultures may contain this virus.

Exogenous viral contamination, including cross-contamination of positive cultures, may occur as a consequence of using contaminated reagents or poor technique. The use of culture dishes and multiwell plates increases the risk for all types of contamination, including cross-contamination. Observation of uninoculated controls (Fig. 10.2–1) will facilitate detection of the presence of endogenous viruses.

D. Cellular

Cellular cross-contamination can occur by transferring floating or loosely adherent cells during pipetting processes. The contaminating cells may simply overlay the existing monolayer or actually develop foci of replicating cells (Fig. 10.2–2).

V. TOXICITY

Sources of toxicity include bacterial endotoxins in water and sera; high concentrations of antimicrobial agents; certain rubber, plastic, and cementing products used in cap liners and tubing; photoproducts of riboflavin and tryptophan; and residual detergent or chemicals on labware from washing and/or gas or steam sterilization. Signs of toxicity include a highly alkaline medium, granularity, cell rounding and detachment, and monolayer detachment.

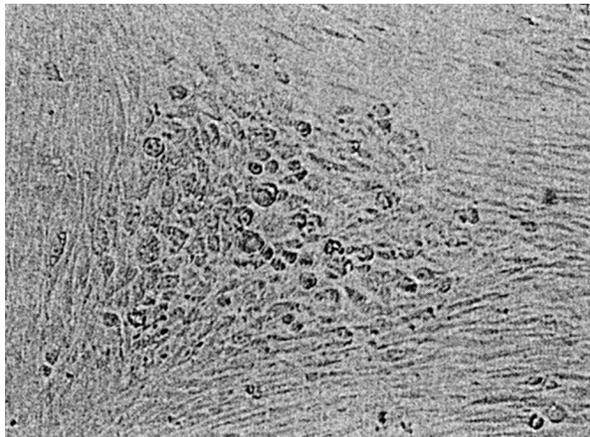

Figure 10.2–2 Focal area of replicating A-549 cells that have inadvertently cross-contaminated an MRC-5 monolayer.

Cell Culture Maintenance Medium

Eagle's minimum essential medium (EMEM) in either HBSS or EBSS with 2 to 5% heat-inactivated FBS is the most widely used cell culture medium for the maintenance of monolayer cell cultures used for routine viral isolation. Serum-free medium is used by many laboratories for influenza and parainfluenza virus cultures. For this purpose, omit FBS in the formulation below; alternatively, specially formulated serum-free medium is commercially available.

Composition of balanced salt solutions and EMEM

Component	Amt (mg/liter) in:		
	EBSS	HBSS	Dulbecco's PBS ^a
Inorganic salts			
CaCl ₂ (anhydrous)	200.00	140.00	
CaCl ₂ · H ₂ O			100.00
KCl	400.00	400.00	200.00
KH ₂ PO ₄		60.00	200.00
MgCl ₂ · 6H ₂ O			100.00
MgSO ₄ · 7H ₂ O	200.00	200.00	
NaCl	6,800.00	8,000.00	8,000.00

APPENDIX 10.2–2 (continued)

A. Viral cell culture maintenance medium

■ **NOTE:** Observe manufacturer's expiration dates and storage recommendations for medium components and use aseptic technique.

EMEM in HBSS with 2% FBS and HEPES buffer

1. To 800 ml of sterile deionized pyrogen-free water, aseptically add the following.

EMEM in HBSS, 10×	
(without L-glutamine or NaHCO ₃)100.0 ml
L-glutamine, 200 mM solution 10.0 ml
HEPES, 1 M solution 20.0 ml
NaHCO ₃ , 7.5% solution 29.3 ml
FBS, heat inactivated (see below) 20.0 ml
gentamicin, 50 mg/ml 0.20 ml
vancomycin, 50 mg/ml2.0 ml
nystatin (Mycostatin), 10,000 U/ml2.5 ml
q.s. to1,000 ml

2. Adjust the pH to between 7.2 and 7.4 if necessary using sterile 1 N NaOH or 1 N HCl.
3. Aseptically dispense the medium into sterile containers and perform a sterility check (see item D below).
4. Store at 4°C; use within 3 months of adding FBS. L-Glutamine is labile; use medium within 3 weeks of adding the glutamine. Add additional glutamine beyond 3 weeks as necessary.

■ **NOTE:** L-Glutamine develops a precipitate when frozen and thawed but is readily resolubilized by warming briefly to 37°C. Avoid repeated freeze-thaw cycles; aliquot stock material into single-use volumes.

B. Medium modifications

1. When using MDCK cells for influenza virus isolation, supplement culture medium with TPCK-trypsin (1-tosylamide-2-phenylethyl chloromethyl ketone) at a final concentration of 1 to 2 µg/ml (1, 2).
2. HBSS is used with tightly capped culture vessels; EBSS is used when caps are loosened and incubation is done in a 5% CO₂ atmosphere.

C. Heat inactivation of FBS

FBS contains heat-labile inhibitors of viral replication. These can be inactivated by heating at 56°C for 30 min.

1. Thaw frozen FBS at room temperature or in a 37°C water bath.
2. Place thawed FBS in a 56°C water bath; the water level should match that of the FBS. *Note:* A thermometer inserted into a bottle containing the same volume of water can be used to assess the time required for the FBS to reach proper temperature.
3. Inactivate the FBS for 30 min, swirling every 10 min to ensure even heating.

■ **NOTE:** Avoid repeated freeze-thaw cycles of FBS.

D. QC

1. FBS

FBS may contain heat-stable inhibitors of viral replication. Since this may vary extensively from lot to lot, it is advisable to assess each new lot prior to use. To facilitate this effort, arrange to obtain samples of reserved lots prior to purchase. These include antibodies or other inhibitors of viral infection, particularly influenza viruses. Before use, assess each lot of FBS with a panel of viruses routinely detected by the laboratory.

2. Medium

- a. Assign a lot number to each batch of medium, and record the lot numbers, sources, and expiration dates of all medium components.
- b. Assess each lot of medium for sterility.
 - (1) Inoculate broth medium (e.g., THIO, BHI, TSB) with 1-ml aliquots of each lot of medium.
 - (2) Incubate and observe for 7 days. Do not use medium until sterility is confirmed.
- c. Assess each lot of medium for cell monolayer toxicity.
 - (1) Feed two or three monolayers of each appropriate cell type with 1 to 2 ml of the medium to be assessed.
 - (2) Incubate the cultures and observe for 10 to 14 days, comparing daily to uninoculated cultures maintained in an acceptable lot of medium. *Note:* Reduce the QC testing burden by purchasing or preparing single lots of media and reagents of the maximum size that can be used within the shelf life.
- d. Label reagents with date of expiration and date opened.

APPENDIX 10.2–2 (continued)

References

1. **Frank, A. L., R. B. Couch, C. A. Griffis, and B. D. Baxter.** 1979. Comparison of different tissue cultures for isolation and quantitation of influenza and parainfluenza viruses. *J. Clin. Microbiol.* **10**:32–36.
2. **Tobita, K., A. Sugiura, C. Enomoto, and M. Furuyama.** 1975. Plaque assay and primary isolation of influenza A viruses in an established line of canine kidney cells (MDCK) in the presence of trypsin. *Med. Microbiol. Immunol.* **162**:9–14.

APPENDIX 10.2–3

Summary of Aseptic Technique

- A. Bacterial and fungal contamination may originate from many sources, including contaminated reagents or supplies, room air, or the technologist's hands. When preparing reagents or handling cell cultures, laboratory personnel must be aware of the need to practice aseptic technique.
- B. Perform all cell culture manipulations in a class II biological safety cabinet and follow good operating practices.
- C. Test all cell culture reagents for sterility before use and handle in a way to maintain sterility throughout their use.
- D. Use only sterile supplies (e.g., pipettes, containers, caps, and stoppers); individually wrapped sterile pipettes are recommended.
- E. Dispense sterile reagents in a manner that maintains sterility; pouring, rather than dispensing with a pipette or other dispenser, increases the risk for contamination.
- F. Avoid touching the exposed necks, caps, or stoppers of opened containers.
- G. Keep the work area and surfaces clean and free of dust.
- H. Arrange materials and equipment within the safety cabinet to provide easy access and to minimize reaching.
- I. Wear clean long-sleeved laboratory gowns or smocks when working with cell cultures and cell culture reagents.
- J. Wipe reagent and medium bottles with 70% ethanol upon removal from storage; flaming bottle, tube, or flask necks is generally not performed when using a biological safety cabinet. Avoid leaving containers uncapped.

10.3

Cell Culture Techniques: Serial Propagation and Maintenance of Monolayer Cell Cultures

I. PRINCIPLE

Monolayer cell cultures are most frequently used in diagnostic virology. They are prepared by treating the tissue or subculture with proteolytic enzymes and/or chelating agents to dissociate the cells and then seeding the cell suspension in a culture vessel. The cells adhere, divide, and form a layer. Adherence to the vessel surface is important for the subsequent survival and growth of the cells.

Monolayer cell cultures may be divided into several types based on certain characteristics of the cells (Table 10.3–1). Primary cell cultures consist of cells ex-

planted from tissues or organs obtained directly from an animal or human source. These cells have the same diploid chromosomes as the tissue of origin and are mainly epithelial. Subcultivation of primary cells is difficult, and in a short time, the cells become senescent and die. Diploid (or semicontinuous) cell lines can sometimes be established from subpassage of primary cells. At least 75% of these cells have two chromosomes that are structurally identical to those of the tissue of origin. These cells maintain their char-

acteristic diploid chromosomal configuration through a number of serial passages but tend to become senescent by the 50th passage. Continuous or heteroploid cell lines are usually derived from tumor cells and possess nuclei that contain numbers of chromosomes other than the diploid number. These cells grow rapidly in culture and can be subpassaged indefinitely. In general, use of one of each type of cell line constitutes a satisfactory combination for the recovery of the major pathogenic viruses.

II. OBTAINING CELLS FOR CULTURE
